EXPERIMENT STATION RECORD.

Vol. XV. September, 1903. No. 1.

The place of the farmers' institute among the agencies for the advancement of agriculture and the assistance of the farmer becomes better defined every year. The results have stamped it as a highly important factor. Experience is demonstrating its proper field and scope and establishing its relations to the other agencies in the system, and its special mission and the means of accomplishing it are becoming clearer.

Like all movements of its kind, it has had to pass through an experimental period, in which it has been alternately a social gathering, a political rally, a lyceum, and a lecture course. It is now in a most important stage of its development, in which it is taking on more definite and logical form and being considered in its relations to other agencies for the moral and material uplifting of farm life.

The meeting of the farmers' institute workers at Toronto this year is a good illustration of the earnestness with which some of the fundamental problems relating to it are being considered, and of the change of sentiment which is taking place in the minds of many of the leaders in this work. Questions involving the future development of the work, of organization, and of providing a corps of trained institute specialists occupied a prominent place in the deliberations. The predominating sentiments and the approval with which they were received show a deeper conception of the purpose and possibilities of this work.

The president of the association, Prof. W. C. Latta, emphasized the high aim and purpose of the institute work in his annual address. He said: "The farmers' institute should be something more than a means of making agriculture more profitable. It should be made the means of uplifting the people morally and socially. To tell how to earn a dollar is a good thing, but to instruct in the wise use of the dollar when earned is better. The institute should be made the means of forever banishing the farmer's low estimate of himself and his calling, and be made the means of ridding farmers of the petty jealousies and suspicions which prevent them from intelligently cooperating with each other for mutual protection and advancement."

In other words, it should strive not only to increase the productiveness and quality of the staple products, but to elevate the ideals of

living. As long as the farmer looks upon his calling as a round of drudgery and is unable to derive stimulation and pleasure from that contact and sympathy with nature which education makes possible, the prospect will be one from which his sons will naturally shrink. Contentment is one of the first requisites to success; and, as Professor Bailey has said, "the compensation in farming is quite as much the pleasure of farming and the joy of being in the country and the satisfaction of being independent, as the mere money that is made."

This is one of the things which secondary agricultural education and the farmers' institute work are seeking to inculcate into the farmer's children especially. Education is the best possible means of elevating agriculture as a calling in the minds of the public and of the farmer himself. And the increased resourcefulness which comes from it will not only bring greater contentment, but will reflect itself in the improvement of farm methods.

A special feature of the institute work in a number of States has to do directly with the farm boys. Special sessions are held for them, and they are encouraged to conduct trials or experiments to add an interest to their work. In Illinois a corn-growing contest is going on this year, which is limited to boys under 18 years of age. Mr. F. H. Rankin, of that State, described his work among the boys and the means he is taking to interest them in farm life and in agricultural education. Every year an excursion is run at a very low rate to bring boys to the agricultural college at Urbana, in order that they may see what is offered there, and have their horizon broadened, their respect for agriculture increased, and their enthusiasm for agricultural education aroused. The results are already apparent.

The need for the farmers' institute springs primarily from the remarkable progress which agriculture has made in the past ten or fifteen years. Much of this is attributable to the work of the experiment stations. There is something new for the farmer to learn every year, which concerns his business as vitally as the latest improvement in labor-saving devices does the manufacturer. He not only should, but must learn these things, if he is to continue to be a good farmer. And this is the mission of his institutes, which bring to him the progress in science as applied to his art, presented in clear and concise form in which he can make use of it.

The success of the undertaking will depend, of course, primarily upon the institute worker, and as he is so important a factor it is not strange that much attention is now being given to the consideration of his qualifications. This matter was freely discussed at the Toronto meeting, and there was a very evident abandoning of some old ideas. "If the work of the institute is confined to telling of what the speakers themselves practice, the institute itself will soon be at an end. What

we must aim at is to teach men to think and reason for themselves." This was the comment of one speaker, and another stated that an institute could be most effectually killed by a semi-oratorical speaker with visionary ideas, or by droning out platitudes.

The standard of requirement has risen very materially, and calls for men of education and training. It is for this reason that experiment station workers and instructors at the agricultural colleges have been much sought as institute workers. They have a message for the farmer, and they have won his confidence by their experimental work and their writings. It is very natural to look to them to explain their work to the farmers verbally; and within bounds this can be defended upon the ground of the mutual benefit which results. But the calls upon the stations should steadily be relatively less, and they should not be expected to bear the brunt of the institute work. It is a distinct and independent line of work from that of the experiment stations, and is in the domain of instruction or university extension. Its aims and its methods of work, as well as its particular field, give it an individuality and distinguish it from all other agencies. The growth of the movement emphasizes the increasing need for the work of the experiment stations. They will furnish the basis for the institute work, as they have shown the need for it. It is well, therefore, to hold to the true conception of the station as being primarily a generator of information rather than a demonstrator and broadcast diffuser. The Office of Experiment Stations is now engaging more largely than formerly in work directly relating to the farmers' institutes, but it is not the intention to abate in any degree our former contention that research is the chief and distinctive business of the experiment station. It will be our effort to secure increased financial support for the institutes with a view to putting them on a more independent basis and relieving station workers from attendance upon the institutes which would in any degree interfere with their work as investigators.

The institute work is now recognized as constituting one of the great factors in the system of agricultural instruction which is being worked out in this country. These factors—nature study and agricultural instruction in the elementary and high schools, agricultural schools and colleges, farmers' institutes, and the experiment stations—are being correlated and their respective fields outlined.

In many States the institute work has been put well on its feet, and is considerably in advance of some of the related agencies. Farmers are believing in it more and more, and the attendance is increasing at a rapid rate. It must develop, as one of the speakers stated, or it will go to seed; and this development will naturally be in the direction of greater individuality and a more effective organization. The connection between it and the stations and colleges will almost necessarily

remain very close, for they are mutually dependent; but it will need eventually to develop a corps of trained institute workers as a nucleus around which to rally the assistance of the college and station workers and others.

This is the present tendency, and there was quite general agreement at the Toronto meeting as to the qualifications which these workers should possess. They should first of all be men well educated in the principles and practice of agriculture, and should keep themselves well informed through reading and contact with the experiment stations and agricultural colleges and with the centers of agricultural activity. They should be specialists in the sense that they devote themselves primarily to some division of the subject of agriculture and aim to keep posted upon that. The day for the all-around worker who is a sort of encyclopedia of universal knowledge has passed in most States. Agriculture is too vast a subject for any one man to cover, and the fund of knowledge is being added to too rapidly. They should, of course, have practical experience and be in thorough sympathy with farm life; and in addition to native ability they must needs be trained for institute work.

Such a class of specialists can not be brought together in a few months. They must be developed gradually, as our agricultural instructors and our station experts have been. Much time will be required, and hence the desirability of working in that direction.

In the meantime much can be done in training the institute forces for the season's campaign. This is already engaging the attention of institute directors, and in several States a beginning has been made. The New York State department of agriculture will hold a normal institute for the technical instruction of institute workers during two weeks of November. One week of the meeting will be held at the College of Agriculture at Cornell University and one week at the agricultural experiment station at Geneva. The plan of bringing the workers together for conference at the agricultural college once a year has been highly commended; and in several States steps have been taken to introduce a normal school plan for training lecturers as a part of their institute system. It is hoped that this Department may be able to contribute, directly and indirectly, toward the better equipment and training of these forces.

The States will not long refuse to appropriate money to place so laudable and popular a work as that of the farmers' institutes on a substantial and independent basis; and the development of interest in agricultural education of different forms will promote this end.

The Mount Hermon School, near Northfield, Mass., founded by the late D. L. Moody, has decided to establish an agricultural department and to offer courses of instruction in that subject. This step on the part of one of the largest secondary schools in the United States will

be a matter of interest to those who are following the progress of secondary agricultural education. It is the more significant from the fact that the institution is not a technical school and that this is the first attempt to establish an industrial course. It is another indication of the hold which this grade of agricultural education is taking.

The school has for some time had a farm of about a thousand acres, which is carried on quite largely with student labor. In consideration of the low rate of tuition and board, pupils are expected to work about fifteen hours a week and many of the boys have put in this time on the farm. As now operated it is said to yield a good profit. Much of the product finds a market at the boys' and girls' departments of the school and the Bible school, which together have and aggregate of about nine hundred students. There is at present a dairy of about two hundred cows, and fruit orchards of considerable proportions, together with a cannery for putting up vegetables, especially tomatoes, peas, and corn.

There has, however, been no theoretical instruction in agriculture or horticulture. Mr. Harry Hayward, a graduate of the school and for several months past assistant chief of the Dairy Division of this Department, has now been called to the school as director of the agricultural department, and entered upon his duties August 1. The department will be organized into divisions for horticulture, dairying, and field work; and courses will be offered in different branches of agriculture, which it is understood will be mainly elective. In other words, only such of the 425 boys in the school as are especially interested in agriculture will be required to take the courses, although others may be required to work on the farm as heretofore.

It is planned to carry the farm on with student labor to even a greater extent than in the past, with practical foremen at the head of the several departments. As the school runs practically the year round, there being three terms of sixteen weeks each, this plan will be feasible.

An effort will be made to make the instruction as practical as experience and the conditions surrounding the school will permit. A considerable number of the pupils come from the farming districts and expect to return to the farm, and the courses will be planned with special reference to their needs. With the equipment already at hand the opportunity would seem to be an unusual one for demonstrating the high value of agricultural courses in secondary schools.

NEW AGRICULTURAL BUILDING AT THE UNIVERSITY OF WISCONSIN.

Agricultural Hall, the new agricultural building of the Wisconsin College of Agriculture, makes provision for the administrative offices of the college and the experiment station, as well as the departments of agronomy, animal husbandry, bacteriology, and chemistry. In it are also located the offices of the superintendent of farmers' institutes.

The structure has a frontage of 200 feet by 64 feet in depth, and is three stories in height over an amply lighted, full-height basement. In the rear is an addition in the form of an octagon (only partly shown in the accompanying plans), two stories in height and 66 feet across. The building is constructed of buff pressed brick, terra cotta, and Indiana buff Bedford limestone. It has a roof of red tile, and all outside metal work, including cornice, is of copper. It is of slow-burning construction throughout.

Heat is supplied by the central heating plant of the agricultural college, the steam pipes being brought from the heating plant to the agricultural building in an ample tunnel. Running under the hallway of the basement is a large tunnel or "plenum," in which one can walk upright without inconvenience. This tunnel has a brick floor, brick sides, and plastered ceiling. Under it runs the sewer pipe. In it run steam, gas, water, and electric-wire pipes, all accessible. From this main tunnel or plenum run branches to vertical air ducts here and there throughout the building. The tunnel system is connected with the fan room. Tempered air is forced by an electric fan into the tunnel, thence into the various branches and upward into the several rooms. Other pipes carry the foul air picked up at the floor out through two large ventilating chimneys in the roof of the building. There are ample steam radiators to warm the building in addition to this indirect system.

The arrangement of the laboratories, lecture rooms, offices, etc., of the various departments accommodated in the building is shown in the accompanying plans. In addition to the usual facilities for these departments, there are five fire-proof vaults, document, museum, and seminary rooms, and an unusual number of closets and storerooms. Space has been reserved for one or two departments not yet organized. The mailing room is located near the east entrance, which has a porte cochere, affording protection from storms in handling mail matter. There is a large room for the storage of extra bulletins and reports; also a room for duplicates from the library.

WISCONSIN UNIVERSITY, AGRICULTURAL BUILDING.

On the basement floor of the octagon at the rear is located the agricultural library, with accommodations for 20,000 volumes, and a large reading room. On the floor above is an auditorium, a gallery communicating with the second floor. This hall has a seating capacity of over 700 and is unobstructed by posts. The octagon form brings the audience as close as possible to the speaker, both on the main floor and in the gallery.

Plate I shows the building in a somewhat incomplete condition. When completed there will be a stone railing around the east portico, and an ornate, wide balustrade stairway of cut Bedford stone will furnish the approach up the sloping incline to the front entrance. It will be ready for occupancy in the early fall.

For this building the legislature of 1901 appropriated $150,000. Architect's fees, grading the grounds, and other initial expenses were not covered by this appropriation. The plans were drawn and the construction supervised by Mr. J. T. W. Jennings, the university architect. The legislature of 1903 made a further appropriation of $25,000 for the necessary furniture and fixtures.

With the completion of this building the agricultural college will occupy a group of four buildings located at the west end of Observatory Hill. These are all devoted strictly to agricultural instruction and experiment station work, the training which agricultural students receive in science, language, mathematics, mechanics, etc., being given in the other departments of the university. The farm barns are located about 60 rods farther west.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Report on progress in agricultural chemistry, F. Mach (*Chem. Ztg., 27 (1903), No. 35, pp. 417–422*).—A brief review with numerous references to literature published during the past year.

The chemistry of plant and animal life, H. Snyder (*Easton, Pa.: Chemical Publishing Co., 1903, pp. XVII+406, pls. 3, figs. 102*).—It is stated in the preface that this book is the outgrowth of instruction in chemistry given in the School of Agriculture of the University of Minnesota since 1891. The opening chapters are devoted to the elements and simpler compounds of plants and animals and the laws governing their combinations, after which the composition of plant and animal bodies, chemistry of plant growth, composition of feeding stuffs, chemistry of digestion and nutrition, rational feeding of animals and men, and other subjects are discussed. Exercises and questions are included.

Ash constituents of cereals, W. P. Gamble (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 48–51*).—Determinations were made of the total ash and the different constituents in the grain and straw of barley, the method used being that of Shuttleworth (E. S. R., 11, p. 304). In the preparation of an ash from a cereal low in silica, as oat straw, the fusion of the ash in the author's experience was not prevented by this method. Lower figures for silica and higher figures for potash than those reported by older methods of analysis were obtained, indicating that previously some of the potash was left in combination with silica. The results of the analyses are given in the following table:

Composition of barley ash.

Constituents.	Grain.	Straw.	Grain.	Straw.	Ratio of constituents in grain and straw.
Material	*Per cent.*	*Per cent.*	*Grains.*	*Grains.*	
Total ash	.....	.....	20.3200	34.1240	.....
SiO_2	2.19	9.70	.4460	3.3370	1 : 7.5
Fe_2O_3	9.60	16.70	.0427	.5674	1 : 13.3
CaO	2.40	1.10	.0107	.0367	1 : 3.4
MgO	4.20	7.60	.0187	.2536	1 : 13.6
P_2O_5	12.00	4.90	.0535	.1635	1 : 3.06
K_2O	30.20	2.10	.1347	.0701	1 : 0.52
Na_2O	26.50	38.50	.1182	1.2847	1 : 10.87
SO_3	23.60	25.20	.0467	.0020	1 : 0.04
Cl	1.40	.45	.0070	.1068	1 : 15.33
	1.56	3.20	.1053	.8409	1 : 8.00

It is estimated that a crop of barley yielding 40 bu. per acre would remove 11.5 lbs. of potash and 13 lbs. of phosphoric acid in the grain and 125 lbs. of potash and 6.5 lbs. of phosphoric acid in the straw. The amount of potash thus removed is greater than usually reported. The desirability of returning the straw to the soil is emphasized.

Ash analyses of some New Mexico plants, A. Goss (*New Mexico Sta. Bul. 44, pp. 14*).—Ash analyses of the following plants are reported: Salt grass (*Distichlis spicata*); bunch grass (*Sporobolus airoides*); sea blite (*Dondia suffrutescens*); cachanilla (*Pluchea sericea*); shadscale (*Atriplex canescens*); creosote bush (*Larrea tridentata*); popotillo (*Ephedra trifurca*); century plant (*Agave aplanata parryi*); sotol, stem and leaves (*Dasylirion wheeleri*); soapweed, stem and leaves (*Yucca radiosa*); Spanish dagger, stem and leaves (*Y. macrocarpa*); ocotillo (*Fouquiera splendens*); prickly pear (*Opuntia camanchica* and *O. macrocentra*); tree cactus (*O. arborescens*); chico bush (*Sarcobatus vermiculatus*), and alfalfa. The different plants are described in connection with a discussion of their composition. Among the general conclusions drawn are the following:

"Plants such as Yuccas, sotol, and prickly pear growing on the arid plains and hill sides where there is very little moisture in the soil, seem as a rule to be very high in ash, although there are exceptions such as ocotillo. In general, all the plants of this region seem to average higher in ash than the plants of the rainfall districts. This is probably due to the more concentrated solutions of mineral matter present in the soils in which they grow.

"In regard to the mineral contents of plants growing on alkali soils, there does not seem to be very much uniformity. Salt grass and bunch grass, for example, while containing something like an average amount of ash, are much lower in soda, potash, lime, magnesia and the other elements usually found in alkali, than many of the plants growing on soils containing much less alkali. The principal portion of the ash of these grasses is silica which does not form a part of alkali at all. On the other hand, the sea blite and chico bush, both alkali loving plants, are very high in soda and some of the other elements found in alkali, and do not contain nearly so much silica as the grasses. Again, in this connection, the prickly pears taken from a limestone hill are very remarkably high in both ash and lime, whereas ocotillo, taken from the same place, is low in both ash and lime. It would seem, therefore, that the species of the plant has perhaps more to do with its mineral composition than the environment under which it grew."

The sea blite is suggested as possibly useful in the removal of alkali from lands. From the average results of analyses of 4 cuttings of alfalfa it is estimated that there is removed in each ton of dry alfalfa 48.8 lbs. of nitrogen, 68.2 lbs. of potash, and 8.2 lbs. of phosphoric acid, estimated at eastern prices at $11.14.

A comparative study was made of the sulphur in ash as determined by the official method of the Association of Official Agricultural Chemists and in the plant as determined by the method of fusion with potash and potassium nitrate. In the latter method large iron crucibles were finally used in place of platinum crucibles, which were seriously injured. Averaging the results for all the samples the sulphur in the ash was 0.29 per cent and in the plant 0.71 per cent. The percentage of sulphur lost in burning varied in different plants and ranged from 34 to 94 per cent. The determination of sulphur in the ash with a view to determining the amount originally present in the plant is therefore considered absolutely worthless.

Detection and determination of ammonia in waters by means of diaminophenol, Manget and Marion (*Ann. Chim. Analyt., 8 (1903), p. 83; abs. in Jour. Chem. Soc. [London], 84 (1903), No. 487, II, p. 390*).—It is stated that diaminophenol (amidol) is superior to Nessler reagent for detecting and determining traces of ammonia in waters. It very distinctly shows 1 part per million or even less.

Investigation of the fat of guinea corn (Andropogon sorghum), N. F. Andreyev (*Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 2, pp. 145–180*).—The seed of guinea corn (*Andropogon sorghum*) is an important cattle feed in Turkestan. Recently the question of its suitability as a fodder for military horses has attracted considerable attention, some empirical trials having given encouraging results. In view of the fact that the favorable effect of oats on horses has been ascribed by some to the high fat content, the author made a study of the fat of

guinea corn. The corn contains over 4 per cent of fat. The constants obtained for the fat were as follows: Specific gravity at 15° C., 0.9282; melting point of fat, 39–40°; melting point of fatty acids, 43–44°; saponification equivalent of fat, 172.1; saponification equivalent of fatty acids, 175.6; saponification equivalent of free acids, 13.86; Hehner's number, 96.1; Reichert-Meissl number, 2.1; iodin number of fat, 98.89; iodin number of fatty acids, 101.63; acetyl number (after Benedict and Ulzer), 9.26, and acetyl number (after Lewkowitsch), 6.85. The ratio of the liquid to the solid acids was as 26.09:72.72. The total content of volatile acids was 0.32 per cent. These proved to be valeric and formic, in the ratio of 2:1.

The fatty acids were converted into ethyl esters, which were subjected to distillation under diminished pressure. The esters in separate fractions were saponified, and from the soaps the respective acids were set free and oxydized with potassium permanganate in alkaline solution.

The conclusions of the author are as follows:

(1) Among the solid acids, which form 96 per cent of the ether extract of the seed of guinea corn, erucic acid predominates and impresses on the fat some of its own characteristics.

(2) The erucic acid is accompanied by small quantities of oleic (ricinoleic) and linoleic acids.

(3) The simultaneous presence of the predominating erucic acid and of oleic acid imparts to the fat a certain likeness to the fat of oats, while the linoleic acid imparts a slight resemblance to the fat of maize.

(4) The presence of a small quantity of linoleic acid accounts for the slow-drying of the fat and for the rapid changeability of guinea-corn flour.

(5) Besides the acids mentioned, volatile fatty acids and oxyacids are present in the fat of guinea corn, valeric acid predominating among the volatile acids, and ricinoleic acid apparently predominating among the oxyacids.—P. FIREMAN.

Action of sulphuric acid on legumen, D. P. PRYANISHNIKOV (*Izv. Moscow Selsk. Khoz. Inst.* [*Ann. Inst. Agron. Moscou*], *8* (*1902*), *No. 4, pp. 375–384*).—The present investigation is an attempt to trace quantitatively, step by step, the process of the decomposition of albumen (legumen) under the influence of weak (4 per cent) sulphuric acid.

The conclusions of the author are as follows:

(1) Four per cent sulphuric acid acts energetically on albumen on the application of heat, causing a rapid decrease of that body and transforming it into compounds not precipitated by cupric oxid.

(2) Among the latter compounds from the very first stages of decomposition appear substances not precipitable by phospho-molybdic acid, increasing rapidly in quantity; toward the end of the experiment two-thirds of the total nitrogen is present in this form. Hence, it is very probable that dilute acid causes the decomposition of albumen to proceed as far as the formation of amido-acids.

(3) The nitrogen of ammonia as well as of organic bases shows a gradual increase, the amount of the former reaching one-tenth toward the end of the experiment and of the latter up to two-tenths of the total nitrogen.

(4) The peptones play the part of an intermediate product, and in accordance with this their amount is large at the beginning of the experiment and, after obtaining a certain maximum, falls off toward the end of the experiment. A more correct estimate of the quantity of peptones and similar compounds can be had when the precipitation with tannin is carried out in the absence of copper compounds.—P. FIREMAN.

A new eudiometer, M. SILBERBERG (*Ztschr. Landw. Versuchsw. Oesterr.*, *6* (*1903*), *No. 6, pp. 591, 592, fig. 1*).

Résumé of the reports of the directors of the government analytical laboratories, 1902 (*Résumé des rapports des directeurs des laboratoires d'analyses de l'état*

pour l'exercice 1902. Brussels: P. Weissenbruch, 1903, pp. 50).—During the year 21,715 samples were analyzed at the 7 government laboratories in Belgium. These included fertilizing materials, feeding stuffs, human foods, and miscellaneous materials. The maximum, minimum, and average results are reported in tabular form and the work at each laboratory is further discussed.

BOTANY.

Economic plants of Porto Rico, O. F. Cook and G. N. Collins (*Smithsn. Inst., U. S. Nat. Mus., Contributions from the U. S. National Herbarium, vol. 8, No. 2, pp. III+57–269, pls. 48, figs. 2*).—A list is given of the economic plants of Porto Rico, the arrangement being an alphabetical one and the scientific and the Spanish and English popular names being given of the different plants, so far as their identification was assured. The authors have compiled this information from a number of sources, including their personal observations in 2 trips to Porto Rico and a study of the available literature relating to the botany of the island. In many instances descriptive notes are given and statements made regarding the economic value of the different plants described. Suggestions are given of a number of species of economic tropical plants which in the estimation of the authors would probably prove valuable if introduced into the country.

Studies of Mexican and Central American plants—No. 3, J. N. Rose (*Smithsn. Inst., U. S. Nat. Mus., Contributions from the U. S. National Herbarium, vol. 8, No. 1, pp. XI+55, pls. 12, figs. 11*).—Descriptions are given of a number of hitherto undescribed species of plants collected by the author and others in various localities in Mexico and Central America. Notes are given on a number of species which appear to have economic value, and living specimens of some of the more interesting forms are now under observation in this Department.

A study of certain Mexican and Guatemalan species of Polypodium, W. R. Maxon (*Smithsn. Inst., U. S. Nat. Mus., Contributions from the U. S. National Herbarium, vol. 8, No. 3, pp. V+271–278, pls. 2*).—Critical notes and descriptions of new species are given of a number of ferns of the genus Polypodium.

Poison ivy, G. E. Stone (*Massachusetts State Bd. Agr. Nature Leaflet 9, pp. 4, figs. 3*).—Popular descriptions are given of the poison ivy (*Rhus toxicodendron*) and some of its related species, and remedies suggested for the poisoning produced by these plants. For this purpose repeated applications of an alcoholic solution of lead acetate are recommended. The author has conducted some experiments on the extermination of this pest and has found that arsenate of soda is quite efficient for its destruction.

Textile plants cultivated in Brazil and Argentina, C. D. Girola (*Bol. Agr. y Ganaderia, 2 (1902), No. 34, pp. 43*).—Descriptions are given of the textile plants which are native or introduced in Brazil and Argentina, and which are more or less exploited for their fibers. The list of fiber plants includes flax, hemp, jute, ramie, China grass, New Zealand hemp, Manila hemp, cotton, etc.

The effect of climate on modifications of the anatomical structure of plants, G. Bonnier (*Compt. Rend. Acad. Sci. Paris, 135 (1902), No. 26, pp. 1285–1289*).—In continuation of the experiments conducted by the author on the effect of climate in modifying the structure of various plants, a report is given showing the modified structure of plants grown in the vicinity of the Mediterranean and at the laboratory of Fontainebleau, France. The plants were selected in the Mediterranean region and one lot planted in pots in that region, the second lot together with soil transferred to the laboratory at Fontainebleau and there grown in the open air. The only difference in conditions are those attributed to the difference in atmospheric phenomena. The climate of the 2 regions is compared, by which it is shown that the growing season of the Mediterranean is 260 days, as compared to 178 days at the other station. The temperature of the 2 regions is compared, from which it is seen

that the available temperature at Toulon on the Mediterranean is about 4600° C. as compared to 2750° for the vicinity of Paris. The most striking difference between the 2 regions is the occurrence of definite wet and dry seasons in the Mediterranean.

The plants experimented upon were trees and shrubs, mostly beeches, mulberries, locusts, linden, ash, lilac, and euonymus. In general the trunks and spring wood were best developed in the Mediterranean region. The vascular system was larger and more abundant in the spring growth in the same species of plant cultivated in the Mediterranean than at Fontainebleau. The parenchyma was more lignified at Toulon and this lignification was affected mostly during the period of drought. The leaves of the arborescent species were thicker at Toulon than at Fontainebleau, the palisade parenchyma in some cases being 2 or 3 times as thick as in the more northern-grown plants.

Among the other adaptations which were attributed to the climatic conditions were those in leaves to reduce transpiration during periods of drought. This was affected most in the plants grown near the Mediterranean. While the stomata were very numerous they were often completely closed and depressed in the surface of the leaf. Annual species of plants whose stems died down during a period of drought did not show any of these modifications which are described for the perennial species.

The upper temperature limits of life, W. A. SETCHELL (*Science, n. ser., 17 (1903), No. 441, pp. 934–937*).—An account is given of investigations of the organisms inhabiting hot springs, in which an attempt was made to ascertain the upper temperature limits of plant life. In the author's investigations it was found that unless considerable care was exercised the accurate temperature of the thermal springs would not be correctly ascertained. Special precautions were taken to determine accurately the temperature of the waters, and the results of the observations are given at considerable length. For the strictly thermal waters, that is, those having temperatures of 43 to 45° C. or above, no animals were found, although careful search was made for them, nor were any living diatoms discovered under such conditions. The only organisms found were groups of plants belonging either to the Schizophyceæ or Schizomycetes. The chlorophyll-bearing members of these groups continued common in temperatures up to 65 or 68° C., and in some cases, although not so abundant, at 75 to 77°. The chlorophylless Schizomycetes are apparently able to endure the highest temperatures of living organisms, as they were found abundant at 70 to 71° C. and remained in considerable quantity at 82 and 89°. The temperature of 89° C. was the highest at which the author was able to find any living organisms.

Living organisms were found at higher temperatures in siliceous waters than in calcareous waters. The limits of life in the siliceous waters were determined by the author's observations to be between 75 and 77° for the chlorophyll-bearing and 89° for the chlorophylless plants. In the calcareous waters the limits of endurance were between 60 and 63° for the chlorophyll-bearing Schizophyta and 70 and 71° for the chlorophylless species. No organisms were found in springs which had a decided acid reaction. A careful study of the species of thermal Schizophyta showed that they were either filamentous or unicellular, but in each case the filaments or cells were inclosed within an abundant mass of jelly.

Chemical stimulation and the evolution of carbon dioxid, E. B. COPELAND (*Bot. Gaz., 35 (1903), Nos. 2, pp. 81–98; 3, pp. 160–183, figs. 2*).—While engaged in a study of the poisonous properties of certain chemicals, the author noted the acceleration of growth in many of the cultures, which led to a series of studies in water cultures to determine the cause of this variation. In considering the growth of the plants the increased respiration was taken as the factor to be considered, and the effect of various substances on the liberation of carbon dioxid was examined. The methods are described in detail. As subjects of the experiments the author used various aquatic plants, such as Cardamine, Callitriche, Ceratophyllum, Potamogeton, Elodea,

as well as tadpoles and some immature fish. The killing point of the different substances for these plants and animals was determined and the death point was used in comparing results.

From a careful review of the results obtained the author claims his method is reliable within a very slight degree of variation. Of a large number of so-called poisonous substances the author found that all acted in certain respects as stimulants. The metallic salts were found to drive the carbon dioxid from the carbonates in the cell sap. This pseudorespiration is in many cases as active as the real respiration of the plant. It was found that carbon dioxid would be given off from the filtered sap of crushed Elodea much more rapidly than from the same plant without injury. The stimulation of potassium salts was found to be greater than that of sodium salts in about the proportion of their relative toxicity. There was no constant difference found between the chlorids and nitrates. The excessive evolution of carbon dioxid under the conditions of the experiment is considered a feature in the death of the plant. Just when the plant begins to die is hard to determine, as the cells in a single leaf do not all die together, and dead cells may become conspicuous, while a large part of the plant is still evidently alive. The evolution of carbon dioxid may continue after the plant, as judged by its physical appearances, would be called dead.

The occurrence of spherulins in plant families, L. Petit (*Compt. Rend. Acad. Sci. Paris, 135 (1902), No. 22, pp. 991, 992*).—The author has given the name spherulin to certain substances which exist in chlorophyll cells of leaves of plants, being present as minute globules which are strongly colored by a tincture of alkanna. He has investigated a large number of families of plants to determine the presence of this substance and arrives at the conclusion that it is of rare occurrence among the families of Apetalæ and monocotyledons.

Experimental studies on inulase, A. L. Dean (*Bot. Gaz., 35 (1903), No. 1, pp. 24–35*).—A study was made of the inulase of Aspergillus and Penicillium to discover whether or not it was identical with the inulase of artichokes reported by Green in 1888. Pure cultures of *Aspergillus niger* and *Penicillium glaucum* were obtained and comparisons made with inulin prepared from Dahlia by alcoholic precipitation. The method of obtaining preparations of inulase is described at length, as well as the influence of various factors on the activity of the enzym. The author was able to confirm the presence of inulase in these molds, and as the enzym of these fungi does not pass into the culture medium it is to be classed as an endoenzym. Inulase acts most vigorously in a medium slightly acid, the enzym being destroyed by 0.01 normal sulphuric acid. Alkalis hinder its activity, 0.0001 normal potassium hydroxid being injurious. The optimum temperature for the action of inulase was found to be about 55° C.

Influence of formaldehyde on the growth of some fresh water algæ, R. Bouilhac (*Compt. Rend. Acad. Sci. Paris, 135 (1902), No. 26, pp. 1369–1371*).—The effect of adding formaldehyde in weak solution to a culture medium in which *Nostoc punctiforme* and *Anabæna* sp. are grown was investigated, from which the author decides that formaldehyde may serve as a nutrient for these algæ and that a certain amount of light is necessary to permit them to polymerize the formaldehyde. The limit of the amount of light required is very nearly that which is necessary for plants to decompose carbon dioxid of the air.

The motility of Rhizobium mutabile, A. Schneider (*Bot. Gaz., 35 (1903), No. 1, pp. 56–58*).—In the previous communications of the author in relation to this root tubercle organism he has stated that it was absolutely nonmotile, but recent events have caused a review of this subject in which the organism was grown on a number of different kinds of media and it was found that it was nonmotile in most neutral media, but was decidedly motile in acid media, whether the media were liquid or solid. The motile forms are much smaller and more uniform in size than the nonmotile ones.

METEOROLOGY—CLIMATOLOGY.

Monthly Weather Review (*Mo. Weather Rev., 31 (1903), Nos. 1, pp. 1-52, figs. 21, charts 11; 2, pp. 53-108, figs. 28, charts 11; 3, pp. 109-164, figs. 13, charts 10*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts for the months of January, February, and March, 1903, recent papers bearing on meteorology, etc., these numbers contain the following articles and notes:

No. 1.—Special contributions on Synchronous Changes in the Solar and Terrestrial Atmospheres (illus.), by F. H. Bigelow; High Winds in Mountain Valleys, by A. D. Elmer; The Southern Limit of a Northwest Gale, by H. H. Ten Broeck; Inductive Studies in Weather Influence, by E. G. Dexter; Elasticity at Low Temperatures (illus.), by J. R. Benton; Violent Wind in South Dakota, by S. W. Glenn; The Vertical Component of the Movement of Clouds Measured by the Nephoscope, by L. Besson; Local Peculiarities of Snowfall, by E. L. Mosely; and The Structure of Cyclones and Anticyclones on the 3,500-foot and 10,000-foot Planes for the United States (illus.), by F. H. Bigelow; and notes on the meteorological reporter to the Government of India, bombarding against hail, horizontal curvilinear movement of clouds, the Scottish Antarctic Expedition, and the climates of geological ages.

No. 2.—Special contributions on The Temperature and Rainfall Departures at Hawaii, as Duplicated in New England Sixty Days Later, by A. D. Elmer; Some High Wind Records on the Pacific Coast (illus.), by A. G. McAdie and W. W. Thomas; Note on the Anemometer Exposure at Point Reyes Light, Cal., by C. F. Marvin; Composite and Other Arrangements of Weather Types (illus.), by H. W. Richardson; Meteorology in the National Agricultural Institute of France, by Miss R. A. Edwards; and The Mechanism of Countercurrents of Different Temperatures in Cyclones and Anticyclones (illus.), by F. H. Bigelow; and notes on James Glaisher, snow from a clear sky, sunshine records at Hamburg, Germany, aerial research in Denmark, courses of instruction in meteorology, Hann's climatology in English, and origin of the word "barometer."

No. 3.—Special contributions on Climatology of the Isthmus of Panama (illus.), by H. L. Abbot; Mean Barometric Pressure at Sea Level on the American Isthmus, by H. L. Abbot; Notes on a Feeble Earthquake Recorded at Washington, D. C. (illus.), by C. F. Marvin; The Districts of the Dominion of Canada (illus.), by R. F. Stupart; The Semidiurnal Tides in the Northern Part of the Indian Ocean (illus.), by R. A. Harris; The Endowment of Research in Meteorology, by T. C. Chamberlin; and March Winds, by B. C. Webber; and notes on second Russian congress on climatology, weather cycles and farmers' almanacs, Chavanne's Temperature and Rainfall in Argentina, the weather in Venezuela, the Cuban meteorological service, student assistants in the United States Weather Bureau, an arctic magnetical and meteorological station, William Kaucher, the first use of the word "barometer," and notes on the barometric pressure at Colon and Alhajuela.

Report on the barometry of the United States, Canada, and the West Indies, F. H. Bigelow (*U. S. Dept. Agr., Weather Bureau Rpt. 1900-1901, II, Chapters 1, 2, 6, 8, pp. 1-117, 423-624, 640-771*).—This report "contains a revision of the meteorological data which have become available since the opening of the Government service in 1871, in order to prepare it on modern scientific principles for the forecasting work of the Bureau. It contains the material necessary for constructing daily weather maps on three planes, the sea level, the 3,500-ft. plane, and the 10,000-ft. plane; also normal values of the pressures, temperatures, and vapor pressures at the stations and on these 3 planes." Of the 4 methods which have previously been used in reduction of barometric data the author adopted that of Ferrel, but "added another for local abnormality, computed the effect of the vapor pressure separately from that of the free air, and discussed thoroughly the tempera-

ture argument, so that these, added to the usual free-air reductions, give the ones required for the plateau districts."

Meteorological records, J. E. Bonebright (*Idaho Sta. Bul. 35, pp. 120–133*).—Daily observations on temperature, pressure, precipitation, and cloudiness at Moscow, Idaho, for each month of 1901 are reported.

Meteorological observations, C. D. Woods (*Maine Sta. Bul. 88, pp. 218–220*).—A summary by months of observations at Orono, Me., during 1902, on pressure, temperature, precipitation, cloudiness, and wind movement.

Meteorological observations at the Michigan Agricultural College for 1901 (*Michigan Sta. Rpt. 1902, pp. 83–107*).—Tabulated daily and monthly summaries of observations during 1901 on temperature, pressure, precipitation, humidity, cloudiness, wind movement, etc. The summary for the year is as follows: Mean temperature, 46.98° F.; humidity, 91.71 per cent; atmospheric pressure (reduced to 32° F.), 29.161; cloudiness, 47.58 per cent; amount of rain or melted snow, 32.23 in.; snowfall, 42.05 in.; number of thunderstorms, 28.

Rainfall and temperature, 1902, J. B. Reynolds (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, p. 13*).—A tabular summary by months of observations at Guelph on temperatures and precipitation averages for 1902 and the two preceding years is given.

Report on the meteorological observations made at the Royal Horticultural Society's gardens at Chiswick in 1902, E. Mawley (*Jour. Roy. Hort. Soc.* [*London*], *27* (*1903*), *No. 4, pp. 1073–1081, figs. 3*).—The temperature, humidity, and precipitation of each month of the year are reported in notes, tables, and diagrams. The air temperature is also compared with soil temperatures at depths of 1, 2, and 4 ft.

Report of the Meteorological Council (*Rpt. Meteor. Council* [*Great Britain*], *1902, pp. 163, pl. 1, fig. 1, maps 5*).—An account of the work of the council during the year ended March 31, 1902, in the lines of ocean meteorology, weather telegraphy and forecasts, climatology, and miscellaneous investigations is given, with statements regarding publications of the council and its library and finances. Information of a miscellaneous character is given in a series of appendixes. The success of 8.30 p. m. forecasts during 1901–2 was, complete 58 per cent, partial 26 per cent, sum of complete and partial 84 per cent. The averages for the preceding 10 years were, complete 55 per cent, partial 27.1 per cent, sum 82.1 per cent.

Weather forecasting according to the phenomena of light in the atmosphere, P. I. Brownov (*Trud. Selsk. Khoz. Meteor., 1902, No. 2; abs. in Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *3* (*1902*), *No. 6, p. 814*).—A summary of literature on observations on the atmospheric light phenomena, with a view to the study of the connection between the optical phenomena and the state of the weather.—P. FIREMAN.

Rainfall and sunspots, W. J. S. Lockyer (*Nature* [*London*], *68* (*1903*) *No. 1749, pp. 8–10; abs. in Science, n. ser., 18* (*1903*), *No. 446, pp. 91, 92*).—In a note in *Science* Professor Ward summarizes the author's conclusions as follows: "Smoothed rainfall curves for the British Isles, Brussels, Madras, Bombay, Cape Town, and the Upper Ohio Valley show a long-period variation at all the stations, and further, the occurrence of the greatest rainfall generally in the years 1815, 1845, and 1878–83, with the minima about the years 1825–30, 1860, and 1893–95. A continuation of the curves, based on the assumption that the apparent law already recognized holds good, indicates that the year 1913 will be at about the middle of the next wet epoch. The sunspot curve shows a close correspondence with the rainfall curves. There appears to be a long-period solar change of thirty-five years, the minimum of sunspots corresponding roughly with the maximum of rainfall. Dr. Lockyer concludes that 'since this long-period rainfall cycle synchronizes so well with the solar changes, the latter may render valuable assistance in determining the epochs of these dry and wet cycles.'" (See also E. S. R., 12, p. 724.)

Application of mathematics in meteorology, F. H. BIGELOW (*Phil. Soc. Washington, Bul. 14 (1903), pp. 215–225*).

Handbook of climatology. I, General climatology, J. HANN, trans. by R. DEC. WARD (*New York and London: The Macmillan Company, 1903, pp. XIV + 437, ill.*).—This is not only a translation but a revision of the most important part of Hann's well-known *Handbuch der Klimatologie*. The matter has been brought down to date and a larger proportion of American examples included. The changes and additions have had the approval of Professor Hann.

"The book is divided into two parts. Part 1 deals with the 'climatic factors,' namely, temperature, moisture, cloudiness, precipitation, winds, pressure, evaporation, composition of the atmosphere, and phenological observations. Part 2 deals with solar or mathematical climate, physical climate, the influence of land and water on the distribution of temperature, the influence of continents upon humidity, cloudiness, precipitation, and winds, the influence of ocean currents upon climate, the influence of forests on climate, the mean temperature of parallels of latitude and of the hemispheres, mountain climate, and finally geologic and periodic changes of climate."

WATER—SOILS.

Normal and polluted waters in Northeastern United States, M. O. LEIGHTON (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 79, pp. 192, figs. 17*).—"This paper is principally a review of the more readily available records, published and unpublished, of examinations made of water supplies derived from streams in the northeastern part of the United States, the principal streams examined being the Merrimac, Connecticut, Housatonic, Delaware, and Ohio rivers, and the various important branches of the latter in the States of Pennsylvania and Ohio. . . . The paper forms one of a series of reports on examinations made as to the character of the natural waters of the United States, and the pecuniary damage to municipal water supply occasioned by city and industrial wastes."

Waters, E. J. RUSSELL and F. T. HOLBROOK (*Jour. Southeast. Agr. Col., Wye, 1903, No. 12, pp. 143–153*).—Analyses of a large number of samples of drinking water are reported, with a brief discussion of the sources of contamination and means of detecting and preventing contamination.

Pollution of well water, K. WITTMAN (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 6, pp. 586–590, fig. 1*).

The water content of the soil on the forage plats of the Poltava experiment field, S. T. TRETYAKOV (*Pochvovedenie [La Pédologie], 4 (1902), Nos. 3, pp. 219–234; 4, pp. 378–392*).—On the basis of numerous observations made at the Poltava field during a number of years, the author arrives at the following conclusions: (1) The moisture of the soil under papilionaceous plants to a depth of 4.66 ft. is lower by 0.32 per cent than under graminaceous plants. The reverse is true of the surface soil to a depth of 2.33 ft., i. e., the grass plats contained 0.44 per cent more water than those bearing papilionaceous plants. These moisture conditions are ascribed to the unequal development of the root system of the 2 families of plants and to the difference in their yields. (2) Separate representatives of the papilionaceous and graminaceous families bear the same relation to the moisture of the soil as mixtures of a number of representatives of each of the 2 families. (3) Alfalfa fields plowed up during the fall, winter, or spring contain more moisture than those remaining under the alfalfa. This increase is noticeable in the crop immediately following and also in the next. (4) The soil under alfalfa dries up 4 times as much as that under the May fallow. (5) Under fallow as well as under cereals (summer and winter wheats) the soil dries up less rapidly than under alfalfa over one year old. (6) The moisture of the soil under alfalfa to a depth of 4.66 ft. is less than under fodder beets. The greater the age of the alfalfa the greater is this difference. (7) The younger the

alfalfa, the more humid the soil occupied by it. (8) The greater the yield of alfalfa, the drier the soil under it. (9) The unequal development of alfalfa and clover on a field depends at least in part on the inequality of the distribution of the soil moisture. (10) An increased water content in the soil occupied by alfalfa or clover furthers a good development and growth of these plants. (11) Deep plowing increases the moisture of the soil. (12) The beneficial effect of the increase of moisture due to deeper plowing is noticeable during 3 years. (13) The use of barnyard manure increases the water content of the soil, especially in its upper layers. (14) The increase of moisture in the soil from manure is noticeable even in the third year after its use. (15) Under beets there is more moisture in the soil than under barley. A like increase of moisture is noticeable in the year following the beet culture. This is one of the causes of the increased yields of alfalfa in the first years of its cultivation after beets.—P. FIREMAN.

Report of the Kherson experiment field for 1899-1900, F. B. YANOVCHIK (*Kherson, 1902, vol. 9, pp. 142; rev. in Pochvovedenie* [*La Pédologie*], *4*, (*1902*), *No. 4, pp. 433, 434*).—The most interesting experiments described in the report are those relating to the evaporation of water by summer wheat as affected by the fertilizing and the different moisture content of the soil. Some of the results are as follows: (1) In the case of a large water content in the soil tillering begins earlier than when the moisture is low, while the other phases of development set in in the converse order; (2) a high moisture content increases the effect of fertilizing; (3) the straw and the root system develop more strongly with the increase of moisture while the head becomes shorter. Regarding the amount of water evaporated per unit of crop, the following data are given: (1) When the moisture content in the soil was small (10 per cent) 500 units of water were required per unit of yield, although the presence of nitrogenous fertilizers lowered this proportion; (2) with a medium moisture content (14 per cent) of the soil the plant evaporate more water; (3) with optimum moisture (18 per cent) of the soil almost no further increase of evaporation took place, in the absence of fertilizer, but the evaporation strongly increased in the presence of nitrogenous fertilizer. The progress of evaporation during the period of vegetation was as follows: (1) In the first period of development (until the middle of May) the daily consumption of water in the vessels without fertilizer (nitrogenous) was greater than in those with fertilizer. (2) About the middle of May the fertilized wheat began to grow rapidly and overtook that without fertilizer and at the same time consumed considerably more water. (3) The maximum consumption of water took place during the last days of May. This was the period of heading and flowering. In the presence of a large store of water and fertilizer in the soil these processes continue for greater lengths of time during which the water consumption continues to be intense. (4) The increase of the consumption of water corresponds not only to the increase of the evaporating surface (corresponding to the larger growth of the plant) but also depends on the fluctuations of the temperature of the air.—P. FIREMAN.

Brack land in relation to irrigation and drainage, P. MACOWAN (*Agr. Jour. Cape Good Hope, 23* (*1903*), *No. 5, pp. 573–581*).—This article discusses the occurrence and causes of the accumulation of alkali salts in South African soils, as well as methods of freeing the soils from alkali. "The investigation of the conditions producing brack in regions like ours, of restricted periodic rainfall, as compared with those of countries with humid climate and greater precipitation, shows with great clearness that the main difficulty is presented by the back-leaching—if it may be so termed—of the limited water supply, that is, its return to the surface under the powerful influence of capillarity kept going by a heated, sun-smitten surface. Whatever perpetuates the downward creeping of the rainfall water, and stops its return upward, cures brackness radically. Toward this end there is one complete remedy, and only one—namely, a system of complete subterranean drainage."

Alkali soils, their influence on plants, and the methods of examining them, P. Kossovich (*Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4* (*1903*), *No. 1, pp. 1-42*).—The author discusses the following questions: (1) What soils are to be designated as alkali soils; (2) the kinds and amounts of salts injurious to individual species of plants; (3) classification of alkali soils on the basis of the composition of the soluble salts; (4) types of alkali lands as determined by the conditions of their origin; (5) laboratory methods for the examination of alkali soils; (6) means of improving alkali soils.

The author considers the American term "alkali soils" more exact than the Russian "saline soils," as it is mainly, if not exclusively, the alkali salts which are responsible for the injurious effects observed in case of such soils.

Experiments on oats, mustard, flax, and the oak grown in pots, each containing 4,765 gm. of dry sandy chernozem soil to which were applied in addition to a basal fertilizer of 0.15 gm. of potash in form of sulphate and 0.25 gm. of phosphoric acid in form of ammonia-sodium phosphate, sodium chlorid, sodium sulphate, and gypsum each at rates of 1.5, 3, 4.5, and 9 gm. per pot. The growth of the plants during the experiments was on the whole quite normal, the oak apparently suffering more than other plants, followed by flax and mustard, and lastly by oats. The most injurious effect on the oaks was produced by sodium chlorid and was most marked in case of the three larger applications. Sodium sulphate exerted a perceptible influence only in the pots containing 4.5 and 9 gm. of the salt. Gypsum was without effect of any kind. With the other plants the most injurious effects were observed in case of sodium chlorid, the greatest injury being observed in case of flax, followed in order by mustard and oats. The yield of oats was increased in case of the smaller applications of sodium chlorid and was injuriously affected only when the proportion of this salt reached 0.194 per cent. Similar results were obtained with mustard, but the yield of flax was decreased by the presence of only 0.032 per cent of sodium chlorid. The influence of sodium sulphate was in general the same as that of sodium chlorid, although less marked. Gypsum did not exert any injurious effect.

Experiments by Loughridge (E. S. R., 13, p. 42) on the tolerance of various plants for alkali are referred to and observations on the germination and growth of wheat, oats, peas, and pine seeds in a large number of alkali soils from Turkestan are reported. As a rule the seeds failed to grow in soils containing 0.125 per cent of chlorin. The pine was able to grow in soils which contained not more than 0.039 per cent of chlorin, although it survived in soils which contained as much as 1 per cent of soluble salts. Wheat and oats grew in soils containing 2 per cent of soluble salts provided the chlorin content was less than 0.125 per cent, showing that the composition of the soluble salts is of more importance than the total quantity. No injurious effects were observed in case of gypsum.—P. FIREMAN.

Reclamation of alkali lands in Egypt as adapted to similar work in the United States, T. H. Means (*U. S. Dept. Agr., Bureau of Soils Bul. 21, pp. 48, pls. 8, figs. 6*).—This report is based on information collected during a visit to Egypt in the summer of 1902. Some of the more important pieces of reclamation work which have been undertaken in Egypt are described in detail and the methods there in use are discussed in their relation to applicability to American conditions. Notes are also given on agricultural development, climate, physiography, geology, and soils of Egypt, and on the drainage area, flow, and composition of water of the Nile.

The methods of reclamation reported to be in use in Egypt are (1) warping (*colmatage*) which affords only temporary relief; (2) flooding with open drains, which is the method in common use and thoroughly effective, but wasteful of lands and inconvenient; (3) flooding with tile drains, which has been recently introduced and is still in an experimental stage, although promising to be the most rapid and effect-

ive method. In the experiments reported the drains were laid 30 inches deep and about 35 feet apart, at a cost of $30 per acre.

The results in Egypt are held to warrant the conclusion that reclamation by drainage is entirely practicable and can be done at so low a cost "that much of the land of the West now lying idle on account of alkali or seepage water can be made to produce crops in from 1 to 3 years, with an expenditure much below the value value of the land when reclaimed." The use of tile drains is considered the most practicable method.

Humus soil, W. P. GAMBLE (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 52, 53*).—The importance of humus as a soil constituent and of methods of determining it are discussed. The following modification of the official method for determining nitrogen in soils is recommended: "In digesting, use only 3 gms. of the soil. Start with a very low flame, and allow the contents of the flask to heat for about 15 minutes. At the end of that time the danger of frothing is over, and the flame may be raised. Just raise it, however, so that the tip will barely touch the flask. Allow it to boil until the liquid is clear, or of a light straw color. Thirty cc. of concentrated sulphuric acid is all the acid needed in this digestion, and should be added to the flask at the beginning. A little pumice stone will reduce the bumping. Take care not to add any water before or during the operation."

The following method for determining moisture in humus soils is described: "Use 10 gms. of the soil. Weigh on a tared porcelain dish or watch glass (6 cm. in diameter). Place for 10 hours in a water oven, and keep it at the temperature of boiling water; also keep a constant stream of carbon dioxid passing through the oven."

Methods of maintaining the productive capacity of soils, C. G. HOPKINS (*Illinois Sta. Circ. 68, pp. 40*).—This is an address delivered before the Illinois State Farmers' Institute at Bloomington, February 25, 1903, in which the following five rules for maintaining the fertility of the soil are given and discussed:

(1) If the soil is acid or sour, apply lime to it to make it sweet; (2) if the soil is poor in nitrogen only, grow clover or some other legume which has the power to secure nitrogen from the air; (3) if the soil is poor in phosphorus only, apply bone meal or some other form of phosphorus; (4) if the soil is poor in potassium only, apply potassium chlorid or some other form of potassium; (5) always save and use all the barnyard manure you have, and also all you can economically obtain from others, and make liberal use of green manures when necessary to maintain the supply of organic matter in the soil.

The rôle of the plant in dissolving the plant food of the soil, P. KOSSOVICH (*Ann. Sci. Agron., 1902–3, I, No. 2, pp. 220–245, figs. 6*).—See E. S. R., 14, p. 427.

Soil temperatures for the year 1901, J. E. BONEBRIGHT (*Idaho Sta. Bul. 35, pp. 134, 135*).—Weekly observations at different depths at Moscow, Idaho, are reported.

Soil temperatures, C. H. MCLEOD (*Proc. and Trans. Roy. Soc. Canada, 2. ser., 7 (1901), III, pp. 13–16, pls. 3*).

Subsoil temperatures, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 11–13, figs. 2*).—Curves show temperatures at depths of 1, 2, and 3 ft. during the growing seasons of 1901 and 1902, accompanied by data for air temperature and rainfall during the same period.

Characterization of the soil according to certain representative species of the animal kingdom, V. P. VRADI (*Selsk. Khoz. i Lyesov, 208 (1903), Mar., pp. 680–690*).—The author reviews the literature of observations which point to the fact that the presence of certain species of animals indicate soils of certain types and properties, and gives a table in which this idea is worked out in detail.—P. FIREMAN.

The new soil science, R. H. WALLACE and W. DYKE (*Jour. Roy. Hort. Soc., 27 (1902), No. 1, pp. 70–85*).—The term "new soil science" is here used "to denote the

biological and more especially the bacteriological point of view in manuring, which to a great extent is to-day supplanting the purely chemical views that have for nearly 60 years held the field." The nature and action of nitrifying and denitrifying organisms, as well as of the organisms which assimilate free nitrogen in symbiosis with leguminous plants, are discussed, and the importance of the biological processes in the soil from a practical standpoint is pointed out.

Historical review of investigations on the fixation of the nitrogen of the atmosphere by soils and plants, L. NAUDIN (*Monit. Sci., 4. ser., 17 (1903), p. 225*).

FERTILIZERS.

Experiments in green manuring, FRUWIRTH (*Mitt. Deut. Landw. Gesell., 18 (1903), Nos. 14, pp. 71–73; 15, pp. 75–77*).—In field experiments on a deep, close loam soil with medium lime content to determine the value of green manuring for hoed crops as a general practice, of different crops for the purpose, and the best means of turning crops under, it was found that the largest mass of green manuring material was furnished by field beans, followed, in declining order, by blue lupines, peas, and crimson clover. In 2 years out of 5 green manuring was followed by bad results on the succeeding crop. Green manuring crops seeded after winter wheat or as late as August 12 to 15 were of doubtful value. Phosphoric acid gave better results when applied to the green manuring crops than with the following hoed crop. Shallow plowing under of the green manures gave better results than deep.

Local deposits of bat guano, H. H. COUSINS (*Bul. Dept. of Agr. Jamaica, 2 (1903), No. 6–7, pp. 144–146*).—Analyses of 35 samples of Jamaica bat guano are reported. The average results are: Moisture, 30.9 per cent; organic matter, 33.4 per cent; nitrogen, 4.5 per cent; phosphoric acid, 5.3 per cent, and potash, 1.3 per cent. The nitrogen varied in the different samples from 0.2 to 10.5 per cent; the phosphoric acid from 0.7 to 13.8 per cent; and the potash from 0.4 to 4.7 per cent.

Hamilton sludge, R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, p. 37*).—Analyses of sludge from the sewage disposal works of Hamilton, Ont., are reported. The material is shown to have about the same amounts of fertilizing constituents as ordinary barnyard manure.

Residue from the purification of sugar-beet juices, S. L. FRANKFURT (*Vyestn. Sakh. Prom., 1902, Nos. 39, pp. 467–471; 40, pp. 511–515; 41, pp. 537–540; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 3 (1902), No. 6, pp. 746–750*).—An analysis of this material is reported which shows it to contain lime 42.70 per cent, magnesia 1.21, phosphoric acid 0.66, nitrogen 0.41, potash 0.30, and carbon dioxid 32.40 per cent.—P. FIREMAN.

Residue from purification of sugar beets as a fertilizer, A. CHEVELY (*Vyesnt. Sakh. Prom., 1902, No. 31, pp. 168–173; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 3 (1902), No. 6, pp. 750, 751*).—The author's experiment indicates that this material is of no importance as a fertilizer on chernozem soils, but increases considerably the yield and only slightly lowers the quality of sugar beets on sandy-clayey soils.—P. FIREMAN.

Experiments with molasses refuse on sugar beets, F. STROHMER (*Oesterr.-Ungar. Ztschr. Zukerind. u. Landw., 32 (1903), No. 2, pp. 1–31; abs. in Chem. Centbl., 1903, I, No. 23, p. 1272*).—Pot experiments are reported which indicate that the nitrogen of this fertilizer is about as effective as that of nitrate of soda and its potash as that of potassium sulphate. No injurious effect on the quality of the beets was observed in any case.

Some local refuse manures, H. H. COUSINS (*Bul. Dept. of Agr. Jamaica, 2 (1903), No. 6–7, pp. 147–150*).—Analyses with reference to fertilizing constituents are given of pond mud, banana trash ash, sheep manure, Kingston city refuse, and of a soil on which bananas had failed to grow. The soil was found to be very low in available potash.

Experiments with the Rippert manure preservative, Gerlach and Vogel (*Fühlings Landw. Ztg., 52 (1903), No. 12, pp. 409–415*).—Experiments with this preservative, the active principles of which are fluorin and sulphuric acid, are reported, from which the conclusion is drawn that manure treated with the preservative was but little more effective than that not so treated.

The action of various phosphatic fertilizers on moor meadows, Bachmann (*Fühling's Landw. Ztg., 52 (1903), No. 9, pp. 315–317*).—Comparative tests of Thomas slag, bone meal, and superphosphate are reported. The order of effectiveness was superphosphate, bone meal, Thomas slag. The superiority of the bone meal over Thomas slag is attributed to the nitrogen content of the bone.

On the value of the phosphoric acid in bone meal as plant food, H. G. Söderbaum (*K. Landt. Akad. Handl. och Tidskr., 42 (1903), No. 1, pp. 42–53*).—A discussion of investigations as to the fertilizer value of the phosphoric acid in bone meal, with accounts of the results of work done in this line by the author at the experiment station at Albano, Sweden. The author summarizes our present knowledge as to the value of bone meal as a phosphatic fertilizer as follows: Bone meal may under certain conditions produce nearly as good results as Thomas phosphate, or even as superphosphate, but its action can easily be reduced to a considerable extent by various factors which have little or no influence on the action of superphosphate or Thomas phosphate. The use of bone meal therefore calls for greater care on the part of the grower than the other phosphates. It can only in exceptional cases be applied to advantage on soils rich in lime. Considering present prices for phosphatic fertilizers, it is still believed, however, that bone meal can be applied economically in preference to expensive and low-grade Thomas phosphate under conditions where it will be apt to produce good results.—F. W. WOLL.

Hoof meal, E. M. Paget (*Amer. Fert., 18 (1903), No. 5, pp. 5–7, fig. 1*).—The method of preparing this material for use as a fertilizer is described.

Upon the utilization of atmospheric nitrogen ("lime nitrogen"), M. Gerlach and P. Wagner (*Deut. Landw. Presse, 30 (1903), No. 42, p. 367*).—In the preparation of acetylene gas from calcium carbid there is formed an impure calcium cyanamid mixed with carbon and caustic lime. This product contains from 15 to 25 per cent of nitrogen, which has been designated "lime nitrogen" and recommended for use as a fertilizer. Pot and field experiments with oats, barley, mustard, and carrots indicate that the nitrogen acts quickly and is almost as effective as nitrate. It was used in large amounts without injurious effect on the crops.

The potash salts, L. A. Groth (*London: Lombard Press, 1902, pp. VI + 291, figs. 62*).—This book reviews the history of the discovery and exploitation of the Stassfurt deposits; explains the formation, geology, and mineralogy of the salts; gives statistics of production and exportation, and discusses their use in industry, agriculture, and horticulture. One important section (106 pages) is devoted to descriptions and discussions of machinery used in mining the salts.

A number of experiments (mostly British) are cited to show the advantage of more liberal use of potash on various field crops and fruits. It is claimed that the amounts of potash now used for fertilizing purposes in Great Britain are not as large in proportion to phosphoric acid and nitrogen as the needs of maximum crops require. In the preface, by S. Rideal, attention is called to the importance of the increased use of potash fertilizers in British agriculture.

Phosphates and other mineral fertilizers, C. W. Hayes and E. C. Eckel (*U. S. Geol. Survey Bul. 213, pp. 418–426*).—The origin and extent of the Tennessee white phosphates are discussed and the white phosphate deposits of Decatur County are described.

Salt and gypsum deposits of southwestern Virginia, E. C. Eckel (*U. S. Geol. Survey Bul. 213, pp. 406–417*).—The location, character, and extent of these deposits are discussed.

Weight per bushel of different fertilizing materials, H. VON FEILITZEN (*Svensk Mosskult. Tidskr., 17 (1903), No. 2, p. 164*).—The following average figures were obtained by actual weighings of ordinary commercial fertilizers found in the Swedish market: Nitrate of soda 100 lbs. per bushel, ammonium sulphate 70 lbs., 20 per cent superphosphate 80 lbs., Thomas phosphate 150 lbs., kainit 100 lbs., 20 per cent potash 80 lbs., 37 per cent potash 80 lbs., muriate 75 lbs., fish guano 40 lbs., steamed bone meal 60 lbs.—F. W. WOLL.

Fertilizer inspection, C. D. WOODS (*Maine Sta. Bul. 90, pp. 25–40*).—This bulletin contains analyses of 158 manufacturers' samples of fertilizers licensed before March 1, 1903, with notes on sources of fertilizing materials, valuation of fertilizers, and the chief provisions of the Maine fertilizer law.

Analyses of commercial fertilizers, M. B. HARDIN (*South Carolina Sta. Bul. 80, pp. 26*).—This bulletin reports analyses and valuations of 177 samples of fertilizers examined during the season of 1902–3, accompanied by information regarding the valuation and composition of fertilizers and the laws and regulations relating to fertilizer control in South Carolina.

Commercial fertilizers, J. L. HILLS and C. H. JONES (*Vermont Sta. Bul. 99, pp. 51–136*).—This bulletin contains, in addition to analyses and valuations of 111 licensed brands of fertilizers representing the output of nine companies, with comments thereon, "a somewhat full discussion of several phases of the general subject of fertilization, including nitrogen, phosphoric acid, potash, lime, salt, meaning of analyses, guaranties, the valuation system, and a review of Vermont's use of fertilizers, as shown by the census returns.

"Ninety-six per cent of the brands examined met their guaranties and none failed to afford a commercial equivalent thereof. The average fertilizer contained 10 per cent more plant food than it was said to contain. The quality of the crude stock used was found to be as a rule above reproach. The average selling price was $28.25, the average valuation, $18.59.

"Vermont uses half a million dollars' worth of commercial fertilizers annually. The 'east side' uses three-fifths of this amount. The fertile Champlain Valley soil and the more intense dairy husbandry of the 'west side' are probably factors in this matter."

Manures, E. J. RUSSELL and F. T. HOLBROOK (*Jour. Southeast. Agr. Col., Wye, 1903, No. 12, pp. 108–129*).—Analyses of the following fertilizing materials available for use in England are reported and discussed: Barnyard manure, guanos (nitrogenous, phosphatic, ichaboe, meat, and fish), sewage sludge, rape-oil residue, cotton-seed cake, husks of coffee berries, malt dust, bone, basic slag, superphosphate, greaves, silk waste, horn shavings, carpet waste, cloth cuttings, shoddy, wool waste, wool dust, hair, hair and wool, hair waste, horse hair, calf hair, American rabbit waste (fur, etc.), fur waste, leather waste, rags (linen, silk, and flannel), flock dust, leather dust, nitrate of soda, sulphate of ammonia, kainit, and lime ashes.

FIELD CROPS.

Report of the experimentalist, C. A. ZAVITZ (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 105–138*).—The experiments here reported consisted largely of variety and culture tests, which have mostly been in progress for some years (E. S. R., 13, p. 1032). The work of the season is reviewed in general, and the improvement of seed selection as indicated by the results of experiments is discussed.

For 6 years oats, spring wheat, barley, and peas have been grown separately and in various combinations for the production of grain and straw. Taking the average of 3 years with mixtures of oats and barley, the greatest yields of grain were as follows: 1 bu. of oats and 1 bu. of barley, 2,201 lbs.; 1 bu. oats and 1½ bu. barley, 2,178 lbs.; 1 bu. oats and ½ bu. barley, 2,161 lbs. per acre. These mixtures and the

mixtures of 1½ bu. oats and 1½ bu. barley also produced the best average yields of straw. In 1902 a mixture of 1 bu. of oats and 1½ bu. of barley was compared with several mixtures containing the same quantities of oats and barley, and in addition ½ bu. of either Wild Goose spring wheat, emmer, grass peas, or flax. The experiment was conducted in duplicate and the average yield of oats and barley was 2,183 lbs.; of oats, barley, and spring wheat, 2,273 lbs.; of oats, barley, and emmer, 2,207 lbs.; of oats, barley, and grass peas, 2,159 lbs.; and oats, barley, and flax, 2,180 lbs. per acre. In 1 test equal quantities of seed of 12 different farm crops were sown to determine how these crops would stand crowding. Beginning with the largest yield of grain, the crops stood in the following order: Manshury barley, Joanette oats, Black Hulless barley, Siberian oats, rye, White Hulless barley, emmer, Wild Goose spring wheat, Prussian Blue peas, flax, grass peas, and common vetches.

The results of treating oats and winter wheat for the prevention of smut are reported. Untreated seed oats produced 5½ per cent of smut in the crop. The hot water and formalin treatments were very effective. The average results for 4 years show that untreated winter wheat contained 456 smut balls per pound of wheat; treated with potassium sulphid, 11; with copper sulphate, 2; and with hot water, 1.

A comparison of leading varieties of different field crops grown under similar conditions was made and the results are given in the following table:

Comparative tests of ten different field crops.

Varieties.	Date of ripening.	Average height.	Amount lodged.	Amount of rust.	Yield of straw per acre.	Yield of grain per acre.
		Inches.	*Per cent.*	*Per cent.*	*Tons.*	*Pounds.*
Emmer	Aug. 12	35	1	1	1.7	2,334
Joanette oats	Aug. 7	35	1	5	1.5	2,217
Manshury barley	July 30	35	3	2	1.3	2,113
Wild Goose spring wheat	Aug. 25	42	1	2	1.8	1,853
Black Hulless barley	July 29	28	9	3	1.2	1,825
Alaska oats	July 30	37	2	4	1.3	1,783
White Hulless barley	July 29	28	12	4	1.1	1,541
Spring rye	Aug. 12	48	0	2	1.6	1,364
Prussian Blue peas	Sept. 2	52	0	0	2.5	1,279
Common vetches	Sept. 3	41	0	0	2.0	1,040

The results obtained with these same crops in cooperative tests throughout Ontario show that the comparative order in yield of grain is very similar to that in the above test.

Red Fern and Red Fife spring wheat were found to be among the best varieties for the production of flour. The average of 10 years' results with macaroni wheats gave the following yields: Wild Goose 38.4 bu., Medeah 33.8 bu., Bart Tremenia 33.4 bu., Sorentina 33 bu., Algiers 31.4 bu., and Ontario 20.9 bu. per acre. For general cultivation in Ontario Wild Goose is considered the leading variety.

Descriptions of spelt and emmer are given and the results of culture tests are reported. The following yields of varieties of spelt were obtained in 1902: Red spelt 1,661 lbs., Alstroum 1,466 lbs., German spelt 1,420 lbs., White Summer spelt 1,263 lbs. of grain per acre. Emmer has been under test for 3 years, and has given an average yield of grain per acre of 2,327 lbs. The weight per measured bushel for the 3 years varied from 33.8 to 43.8, with an average of 38 lbs. Emmer gave better results than spelt in an experiment at the college, and it is believed that this crop will be more generally grown for feed for live stock. The results of variety tests with spring rye, oats, 6-rowed barley, 2-rowed barley, Hulless barley, winter barley, winter wheat, winter rye, buckwheat, and corn are reported. Dakota Mammoth, Prolific Spring, Common, and Colorado Giant spring rye grown from 3 to 5 years yielded on an average 40.2, 36.9, 34.9, and 25.8 bu. per acre respectively. In 1902, 72 varieties of oats were under test. Some of these varieties have been grown for

12 to 14 years in succession. The average yield for 12 years of Siberian oats was 88.6 bu. per acre, and of American Banner, 84.7 bu. Oderbrucker, Probsteer, Waterloo, and Bavarian have also given good average results for a series of years. Of oats, 22 varieties, mostly imported, were grown for the first time this year, but none equaled Siberian nor American Banner in yield. The best yielding varieties of 6-rowed barley in 1902 were as follows: Manshury 86 bu., California Brewing 80 bu., Common Six-Rowed 77 bu., and Oderbrucker, 75 bu. per acre. Of 10 varieties grown for 9 years in succession the greatest yields in the order given were produced by Manshury, California Brewing, Scotch Improved, Common Six-Rowed, and Oderbrucker. Among 8 varieties of 2-rowed barley tested for 9 years, French Chevalier and New Zealand Chevalier, with an average yield of 62 bu. per acre, were the leaders. Of hulless barley 11 varieties were tested this season, and of these, 8 under test for 9 years have given the following average results: Guy-Mayle 48 bu., Black Hulless 45 bu., Purple 44 bu., Guymalaya 42 bu., Winnipeg No. 2 41 bu., Hungarian 41 bu., Large Skinned 40 bu., and Smooth Hulless 38 bu. per acre. With winter barley the experience has been that the crop usually winterkills in unfavorable seasons, but that it gives exceedingly good yields when the winters allow it to survive.

Of 95 varieties of winter wheat grown this season Extra Early Windsor, Dawson Golden Chaff, Imperial Amber, Pedigree Genesee Giant, Prize Taker, Economy, New Columbia, White Golden Cross, Early Ontario, and Johnson, in the order mentioned, gave the highest yields. Dawson Golden Chaff, Extra Early Windsor, Clawson Longberry, and American Bronze possess the stiffest straw. Among the red wheats, Michigan Amber and Turkey Red, and among the white varieties, Early Genesee Giant and Bulgarian are considered good milling wheats.

The average yields obtained by sowing 1, 1½, and 2 bu. of winter wheat per acre for 6 years were 40.2, 43.3, and 43.9 bu. per acre, respectively. Drilling and sowing broadcast have given practically the same results. The average results of experiments for 8 years favor sowing winter wheat the last week of August or the first week of September. For 4 years, field peas as a green manure, have given an annual average of 22.1 per cent more wheat than buckwheat used in the same way. Winter wheat after clover, in a 1-year test, yielded 20.7 per cent more grain than when grown after timothy. The average results of experiments in progress for 7 years to determine the value of seed from wheat cut at different stages of maturity show that the heaviest grain and the largest total yield were produced from seed taken from very ripe crops. The average yields of winter rye for 4 years were as follows: Mammoth 57.4 bu., Monster 54.9 bu., and Common 52 bu. per acre. The variety tests of buckwheat show that on the average for 7 years Japanese has given 20.8 bu. per acre, Silver Hull 17.8, and Common Grey 16. In the yield of straw these varieties stood in the same order.

Of 19 early varieties of flint and dent corn grown in 1902 the following in the order given led in productiveness: Dakota Gold Dollar, Longfellow, Farmers' Friend, Baily Mahogany, and Canada Yellow. The best average yields for 3 years were as follows: King Phillip 64.2, Genesee Valley 62.7, North Star Yellow Dent 61.1, Pride of Canada 59.9, and Longfellow 58.9 bu. per acre. The percentage of cob to ear in the different varieties showed wide variations.

The 3 best kinds of sunflowers under test for 5 years and the average yields of seed per acre were White Beauty 66.3, Mammoth Russian 64, and Black Giant 57.5 bu. per acre. In 1902 the yields were 80.9, 60.7, and 67.5 bu. per acre, respectively. California and Siberian varieties of millet have given the best yields of seed for a series of years.

Field peas planted as late as June 25 did not escape the ravages of the pea weevil. The culture and uses of the grass pea are described and the results of culture tests reported. The plant is considered good for forage, but as not replacing the garden

peas for table use or the field peas for export. For 7 years the average annual yield of grain of the grass pea has been 25.7 bu. and the yield of straw 2.7 tons per acre. The yields also compared very well with the yields of vetch. The chick pea (*Cicer arietinum*) has given an average yield of 35.6 bu. of grain and 1 ton of straw per acre. In a cooperative test of 4 years the average annual yield of 180 successful experiments was 21.1 bu. of grain per acre. Cowpeas did not generally mature at the college. Neither did lupines, lentils, and horse beans give very satisfactory results.

Vetches grown for seed produced a little more than 7 bu. per acre from fall seeding. This return is considered profitable, as the seed sells at from $5 to $7 per bushel.

The average results for 6 years show that the following varieties of field beans have given the highest yields: White Wonder, Day Improved Leafless, Medium or Navy, Pearce Improved Tree, and Schofield Pea. Based on the experiments with soy beans at the college, the Early Yellow is recommended for the production of grain for feed, and the Medium Green for ensiling with corn.

Of flax, 3 varieties grown in 1900 gave the following results: Manitoba 16.8, Common 15.7, and Russian 10.5 bu. of seed per acre. The average yields for the number of years these varieties have been grown are 13, 11.4, and 10.8 bu. per acre, respectively.

This season 124 varieties of potatoes were under test. The following varieties lead in yield: Empire State, Molly Stark, White Elephant, Conroy, Rural New Yorker No 2, The Daisy, Rose New Invincible, Uncle Sam, Salzer Earliest, New Queen, and Carman No. 1. Of 21 varieties grown for 9 years the following lead in average production: Empire State 244, Convoy 242, Rose New Invincible 241, Rural New Yorker No. 2 234, and American Wonder and White Elephant each 232 bu. per acre. Empire State was found to be one of the best varieties for table use. An experiment to show the varieties producing the largest average yields 9, 12, and 15 weeks after planting is reported. In selecting seed potatoes it has been found that large potatoes or large pieces of potatoes produce greater yields than either small potatoes or small pieces. The results of planting 1, 2, and 4 pieces per hill, using equal weight of seed are in favor of planting 1 piece, both in total yield and in percentage of marketable potatoes. Coating potato sets by sprinkling them with lime and plaster increased the yield at the college and in cooperative experiments throughout Ontario. It is shown by tests that it is best to plant potato sets immediately after they are cut. A fertilizer experiment with potatoes conducted in duplicate gave the following average results: No manure 105 bu., 5 tons barnyard manure per acre 144 bu., 1 ton of poultry manure per acre 125 bu., and 2 tons of poultry manure per acre 158 bu. The use of a corrosive sublimate solution was effectual in reducing the amount of scab in potatoes grown from scabby potatoes. Different methods of combating the potato beetle are reported.

The yields of varieties of sugar beets grown for feed are tabulated. The average yields for 9 years were as follows: Red Top 19.7, White Silesian 19.3, Lane Improved 19.3, Champion 18.6, White French 17.5, Red Skinned 16.4, Kleinwanzlebener 16.3, and Improved Imperial 14.3 tons per acre. The results of distance experiments in this connection show that as the distance between the rows increased the average size of the roots increased and the yield decreased. Extensive experiments made in past years have shown that the following are among the leading varieties of root crops for field culture: Swedish turnips—Sutton Magnum Bonum, Improved Purple Top Yellow, Buckbee Giant, Hartley Bronze Top, and Kangaroo; fall turnips—Red Top, White Globe, Cow Horn, and Jersey Navet; mangels—Yellow Leviathan, Sutton Mammoth Long Red, Evans Improved Mammoth Sawlog, and Steele Long Red Selected; carrots—Mastodon White Intermediate, Mammoth Intermediate, Smooth White, and Pearce Improved Half Long White; parsnips—New Ideal, Hollow Crown, and Improved Half Long.

For a series of years large seed of root crops has given better yields than medium and small-sized seed. Whole seed of mangels and sugar beets produced a greater

yield than a similar quantity of broken seed. An experiment conducted this season resulted in the best yields of sugar beets and carrots when the seed was planted only ½ in. deep. Level culture is reported as having given better yields of sugar beets than ridge culture. A mixed fertilizer, consisting of 52¼ lbs. each of nitrate of soda and muriate of potash and 106⅔ lbs. of superphosphate, increased the yield of Swedish turnips about 4 tons per acre, at a cost of about $1 per ton.

In a test of 135 varieties of corn grown for fodder or silage New Delaware Dent and Pedrick Perfected Golden Beauty gave the greatest total yields, being 24 and 23.8 tons per acre, respectively. The greatest yields of husked ears were produced by Golden Leneway Dent, Snow White Dent, and Black Mexican Sweet corn, the yields being 4.3, 4.3, and 4.2 tons per acre, respectively. Salzer North Dakota, Compton Early, and King Phillip, flint varieties, and North Star Yellow Dent, a dent variety, are recommended for central and southern Ontario. An average of 4 years' tests from planting at different depths gave the following total yields: 2 in., 13.2 tons; 1½ and 3 in., each, 11.8 tons; 1 in., 11.7 tons; ½ in., 10.6 tons; and 4 in., 9.8 tons.

Other forage crops under test were millet, rape, sorghum, grasses, and clovers. The average yield of green crop per acre for 8 years for Golden Wonder, Holy Terror, Gold Mine, Japanese Panicle, Japanese Barnyard, and Magic varieties of millet was 11.6, 11.4, 10.4, 10.3, and 10.3 tons per acre, respectively. The results of an 8-year test with rape show that Dwarf Essex and Dwarf Victoria yielded 23.4 and 21.8 tons of green fodder per acre. Buckbee Wonderful Bonanza rape, grown for the first time, gave a satisfactory yield.

The average yields of 16 varieties of sorghum, including sugar cane, broom corn, Kafir corn, millo maize, Jerusalem corn, etc., under test for 3 years are tabulated. Early Minnesota sugar cane has given the highest average yields of green fodder per acre. Of 16 different leguminous forage crops, hairy vetch led in the production of green fodder, with an average yield for 2 years of 13.9 tons per acre. The yields of all the crops are recorded.

The following mixtures of annual crops are recommended for pasture: Oats, hairy vetches, and Early Amber sugar cane; spring rye, hairy vetches, and Hungarian grass; and barley, crimson clover, and Early Amber sugar cane.

For permanent pasture the following mixture of grasses and clovers has given the best results in several years' experiments: Orchard grass 4 lbs., meadow fescue 4 lbs., tall oat grass 3 lbs., timothy 2 lbs., meadow foxtail 2 lbs., alfalfa 5 lbs., alsike clover 2 lbs., white clover 1 lb., and trefoil 1 lb., making a total of 24 lbs. of seed per acre.

Among the mixtures of grasses and clovers for hay tested for several years, tall oat grass and alfalfa; tall oat grass, orchard grass, Mammoth red clover, and alfalfa; and timothy and alfalfa have given the best results, the yields of hay being 3.2, 3.1, and 3.1 tons per acre, respectively. The best yields in 1902 were produced by timothy with Mammoth red clover, tall fescue with Mammoth red clover, tall oat grass with Mammoth red clover, and orchard grass with Mammoth red clover. Cereal crops after clover gave on an average for 3 years, 833 lbs. of grain more per acre than the same crops grown after grass.

A rotation study, F. S. Shiver (*South Carolina Sta. Bul. 79, pp. 62*).—The object of the experiments here presented was to ascertain the effects of different rotations on the composition of the soil, and whether or not there is any relation between the amounts of phosphoric acid and potash removed by the crops and the amounts of these constituents shown to have been removed from the soil by the present methods of analysis. The work was conducted on 24 plats, 12 of which received 200 lbs. each of cotton-seed meal and acid phosphate and 100 lbs. of kainit per acre and the rest no fertilizer at all. Cowpeas were removed from the fertilized plats, but were plowed under on the plats receiving no fertilizer. A 3-year rotation was practiced, and the soil and subsoil of each plat was analyzed before and after the experiment. The

composition of the annual crops was also determined and all results are here reported in tables.

A loss of humus was found to have taken place in a large number of fertilized and unfertilized plats, this loss being especially evident on the plats on which cotton was grown continuously. The maintenance of the supply of humus in the soil was fully as good on fertilized plats with only the roots and stubble of cowpeas turned under as on the unfertilized plats on which the whole growth of the cowpeas was turned back to the soil. On 13 of the plats a more or less close agreement between the yields of wheat in the fourth year and the losses and gains of nitrogen, humus, and humic nitrogen was observed, while in the other cases the results appeared contradictory.

With reference to the relations between the quantities of phosphoric acid and potash removed by the crops and the quantities shown to have been removed from the soil by the present methods of analysis, the author concludes from the data that none of the methods employed give absolutely reliable results for available phosphoric acid and potash, and he believes that field experiments are much less adapted to the solution of the question than pot experiments, because the conditions can be better controlled in the latter.

Culture trials on Swedish moor soils, 1900-1902, H. von Feilitzen (*Svensk Mosskult. Tidskr., 17 (1903), No. 2, pp. 105–135*).—Accounts of a number of different experiments conducted by the Swedish Moor Culture Association during the years are given. The experiments include trials on moor soils with oats and barley, as to time of sowing and size of seed grain; inoculation experiments with soils and pure cultures of bacteria from legumes; green manuring; and tests of the value of barnyard manure with peat litter, straw, or shavings used for bedding, etc.—F. W. WOLL.

Continuous culture without manuring for 75 years, W. Christiani (*Deut. Landw. Presse, 30 (1903), Nos. 26, pp. 217, 218; 27, pp. 226, 227; 28, p. 236*).—On the humus alluvial soil on which these experiments were conducted good yields of cereals were obtained after 75 years continuous culture. The soil, however, had become "beet sick."

Growing and preparing agricultural crops for exhibition, B. C. Buffum and A. Nelson (*Wyoming Sta. Bul. 58, pp. 12*).—This bulletin gives detailed directions for the growing and preparation of grains, grasses, vegetables, and fruits for exhibition purposes. Suggestions for the selection of specimens and their exhibition are given, and the methods of labeling them are presented.

Cassava, S. M. Tracy (*U. S. Dept. Agr., Farmers' Bul. 167, pp. 32, figs. 11*).—The varieties of cassava are described, the history of the plant briefly noted, and the region suited to its culture shown on a map. The soil and moisture requirements and the climatic conditions suitable for the growth of the crop are discussed, and directions for the use of fertilizers, preparation of the ground, and planting, cultivating, harvesting, and storing the crop are given. Diseases attacking the plant and preventive measures for the same are noted. The yields and profits of cassava culture are estimated and the uses of the crop as a feed for cattle, hogs, and poultry, and its value for the manufacture of starch are pointed out.

Selecting and preparing seed corn, P. G. Holden et al. (*Iowa Sta. Bul. 68, pp. 273–286, figs. 11*).—This bulletin gives information regarding the purchasing and testing of seed corn and its preparation for planting. The importance of planting a uniform number of kernels per hill is dwelt upon and it is recommended that the planter used should drop 93 to 96 times out of a hundred the number of kernels desired. Planter tests showing the number of kernels dropped when they were uniform and unequal in size are reported. When uniform-sized kernels were used the planter in one test dropped 2 kernels 8 times and 3 kernels 92 times out of a hundred. With kernels irregular in size the number of times 1, 2, and 4 kernels

were dropped per 100 was largely increased. Methods of selecting seed corn and making germination tests are described, and a score card for corn with an explanation of the points is presented.

Cotton culture in Servia, V. I. MASALSKI (*St. Petersburg: Min. Agr. and Imp. Domains, Dept. Agr., 1902, Nos. 45, 46; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 2, p. 235*).—Experiments are in progress to determine whether or not cotton can be profitably grown in Servia. Thus far American cotton from Turkestan seed has given the best results, while Egyptian and Sea Island varieties were the least promising. Owing to the climatic conditions of the country the results were not encouraging. Further experiments are considered necessary for definite conclusions.—P. FIREMAN.

Forage crops, B. C. PITTUCK (*Texas Sta. Bul. 66, pp. 16, figs. 6*).—This bulletin discusses the value and importance of alfalfa, peanuts, velvet beans, millet, and rape for forage and presents the experience of farmers with reference to the growth and adaptability of these various crops. The directions for the culture and uses of forage crops are largely based on the results obtained at other experiment stations. The larger portion of the bulletin is devoted to alfalfa.

At the station alfalfa seed from Utah and seed obtained in Texas gave practically equal yields the first year, but the second season the Utah-grown seed produced 2,071 lbs. of hay more per acre than the other.

Some experiments on the ensiling of grass and beets, L. BAUWENS (*Jour. Soc. Cent. Agr., Belg., 50 (1903), Nos. 5, pp. 200, 201; 6, pp. 229, 230*).—Brief notes on simple methods of ensiling in pits, trenches, etc.

The cowpea and soy bean in Illinois, D. S. DALBEY (*Illinois Sta. Circ. 69, pp. 15, figs. 5*).—The value of cowpeas and soy beans for Illinois is discussed and the results of variety tests of the 2 crops are reported briefly. Popular directions for the culture of the crops are given and their feeding and fertilizing value are pointed out. Drilling about $\frac{1}{3}$ bu. per acre in rows 32 in. apart is considered best for the production of seed. Among 22 varieties of cowpeas grown at the station Warren Extra Early and Warren New Hybrid were the most prolific varieties, yielding 38.7 and 38.3 bu. per acre, respectively. Whippoorwill, which is very commonly grown, yielded only 15.6 bu. per acre in this test. A comparative test was made of 8 varieties of soy beans. Medium Green headed the list with a yield of 41.7 bu. per acre, followed by Early White with a yield of 38.2 bu. Late Mammoth did not mature seed.

Further experiments in top-dressing grass land, H. J. WHEELER and G. E. ADAMS (*Rhode Island Sta. Bul. 90, pp. 69–86, figs. 4*).—This work is in continuation of experiments previously reported, and a description of the plats and their treatment has been given in a former abstract (E. S. R., 14, p. 32). This bulletin is mainly devoted to the results of the fourth year.

The plat receiving the full application of 63 lbs. of nitrogen per acre in the form of nitrate of soda yielded 3.4565 tons of hay per acre in 1899, 4.1 tons in 1900, 4.695 tons in 1901, and 4.1 tons in 1902, the value of the hay exceeding the cost of the fertilizers by \$19.62 per acre the first year, \$30.40 the second year, \$40.70 the third year, and \$32.74 the fourth year. The total excess in the value of hay over the cost of fertilizers for the 4 years was \$123.46 per acre, or an average of \$30.87 per acre for each year. The use of the full application of nitrogen gave much greater financial returns than the use of one-third of the application or the total omission of the same. In 1901 and 1902 the losses in weight of hay during storage ranged from 13.3 to 19.6 per cent.

Redtop, grown on the same area and at the same time as timothy, was richer in nitrogen and also contained more silica, lime, magnesia, phosphoric acid, and potash than the timothy, but a greater percentage of nitrogen in the timothy than in the redtop had been changed to albuminoids. The amounts of plant food furnished by the fertilizers and removed by the crops are given as follows:

Plant food furnished per acre in the fertilizers and removed by the crops.

Fertilizer.	Plat 17, no nitrogen.		Plat 19, one-third ration of nitrogen.		Plat 21, full ration of nitrogen.	
	Quantity in fertilizers.	Quantity in crops.	Quantity in fertilizers.	Quantity in crops.	Quantity in fertilizers.	Quantity in crops.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
Nitrogen	0.00	40.01	21.00	33.56	63.00	49.70
Potash	150.00	47.87	150.00	55.64	150.00	123.35
Phosphoric acid	130.00	10.78	130.00	13.30	130.00	25.58

Plant food removed per 1,000 lbs. of field-cured hay in 1901–2.

Fertilizer.	Plat 17, no nitrogen.		Plat 19, one-third ration of nitrogen.		Plat 21, full ration of nitrogen.	
	1901.	1902.	1901.	1902.	1901.	1902.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
Nitrogen	6.5	13.6	5.6	6.9	5.8	6.1
Potash	14.9	16.2	14.7	11.5	16.2	15.0
Phosphoric acid	4.1	3.9	3.5	2.7	3.3	3.1

From the results of all the experiments up to date it is concluded that an application of 400 lbs. acid phosphate, 200 to 250 lbs. muriate of potash, and 350 lbs. nitrate of soda per acre would probably have given better net returns than the quantities employed in this experiment. "Top-dressing 'run out' land which is not filled with the proper kinds of grass roots" is considered a waste of the fertilizer. For such grass lands plowing and reseeding heavily is recommended.

Flax and flaxseed selection, H. L. Bolley (*North Dakota Sta. Bul. 55, pp. 171–186, figs. 8*).—This bulletin reviews flax culture in the United States and other countries, contrasts European and American conditions with reference to the culture of the crop, and summarizes the difficulties affecting the flax industry in this country. In discussing flax culture in North Dakota the author points out the use of mixed seed of poor quality, poor soil culture, and the lack of proper crop rotation as unsatisfactory practices, and outlines methods of procedure to improve the culture of flax in general and to obtain more profitable results.

Influence of kainit on the yield of flax, A. Alexandrov (*Dokl. i Soobshch. 2. Syezda Dyegat. Selsk. Khoz. Opuitn. Dyelu, St. Petersburg, 1902, pt. 1, pp. 104–110; abs. in Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4* (*1903*), *No. 1, p. 93*).—In experiments conducted at the Vyatka Experiment Station and the Okunyen Farm kainit increased the yield of the seed as well as the straw of flax, the proportion of increase being the greater in the straw. The increase in the yield of straw was partly due to the increase in the length of stem.—P. FIREMAN.

Pearl millet, C. R. Ball (*U. S. Dept. Agr., Farmers' Bul. 168, pp. 16, figs. 3*).—This bulletin gives a description of pearl millet with directions for its culture and uses. The origin and history of the plant are reviewed and the different names applied to it are pointed out. A test of seed sold under the different names showed the resulting plants to be practically identical. The uses of the crop for soiling, ensilage, and hay are briefly noted. The composition of pearl millet cut at different stages of growth, as determined at different experiment stations, is compared with the average analyses of cured corn stover and corn fodder, and of sorghum used as green fodder.

The anatomical structure of cultural varieties of millet, A. L. Winton (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6* (*1903*), *No. 8, pp. 337–345, figs. 8*).—On the basis of microscopical studies the author discusses the anatomical structure of sorghums, broom corn, Kafir corn, etc., and related topics.

The ash constituent of potato leaves at different stages of growth and under different systems of fertilizing, J. Seissl (*Ztschr. Landw. Versuchsw. Oesterr.,*

6 (1903), No. 5, pp. 537–554).—The mineral constituents at five different stages of growth of leaves of potatoes grown without fertilizers and with applications of kainit, superphosphate, and a mixture of kainit and superphosphate are reported in detail. The results show that fertilizing with kainit in connection with superphosphate often caused, in some cases a direct and in other cases an indirect increase of the lime and magnesium content of the leaves. The maximum content of the potash and phosphoric acid was observed about the first of July, and also about the time of blooming. In the case of other constituents the maximum content was always observed at a later period. The ratio of phosphoric acid to potash was on the average about 1:3–4. The proportion of magnesium oxid to calcium oxid was on the average of 1:2.6–2.9. This relation varied very slightly with different systems of fertilizing and periods of growth.

Modern rice culture, W. J. Boudreau (*Philippine Bureau Agr., Farmers' Bul. 3, pp. 46, figs. 16*).—This is a popular bulletin discussing methods of rice culture as adapted to the Philippine Islands. The subject matter is presented in English and in Spanish. The topics discussed are the soil and its preparation, together with the construction of ditches and levees, the planting of rice, the treatment of the crop, its drainage and irrigation, and the methods of harvesting and thrashing. The application of fertilizers is briefly explained and short notes on varieties of rice are given.

The influence of soil and climate upon the composition of the sugar beet, 1901, H. W. Wiley (*U. S. Dept. Agr., Bureau of Chemistry Bul. 74, pp. 42, charts 3*).—The experiments here reported have been previously described and the data obtained in 1900 have been given in a former bulletin (E. S. R., 13, p. 736). The results here shown were derived in the same manner as those of the previous year. In addition to these data the analyses of the soils upon which the experiments are in progress are given. The average results for the season are summarized in the following table:

The average results with Dippe Kleinwanzlebener Elite sugar beets grown under different conditions of soil and climate in 1901.

Locality.	Analytical data.			
	Weight.	Yield per acre.	Sugar in the beet.	Coefficient of purity.
	Ounces.	*Tons.*	*Per cent.*	
Washington, D. C	7.9	8.1	8.5	67.3

Geneva, N. Y	65.5	18.03	66.00	14 44	42 53 00	453.0

In several instances the meteorological data in the above table are taken from the records of the station nearest to the locality recorded. The analytical data shown from Layfayette, Ind., are based on one sample only; and the mean weight of topped beets with the estimated yield reported from Agricultural College, Mich., represents the average of early and late planting. As in the previous year, the results in general show that the sugar content varies with the latitude. The percentage of sunshine seems to have but little effect upon the percentage of sugar in the beet and the actual predominance of clear days, in so far as it does not indicate drought, is not regarded as an important factor. The percentage of sugar was found to increase with the length of the day, and attention is called to the fact that these results coincide with the theory of the correlation of the functional activity of the chlorophyll cells and the light of the sun. The data with reference to the relation of temperature to sugar content show more irregularities than those representing latitude and length of day, still they indicate the tendency of the sugar to diminish as the temperature increases. A striking effect of altitude upon the composition of the beet is shown in the data obtained at Blacksburg, Va., and at Washington, D. C. Blacksburg, with the lowest latitude, shows almost the average sugar content produced at the other stations, while Washington, with a low latitude and the lowest altitude, gives the lowest percentage of sugar. As an illustration that altitude does not in every case tend to increase the content of sugar the author cites the results obtained at Geneva and Ithaca, N. Y., during the two seasons covered by the experiments, which show that although Geneva is almost 400 ft. lower than Ithaca the beets produced there were higher in sugar content. With reference to rainfall, it is concluded that the actual amount does not have as great an influence on the composition of the beet as does its distribution.

Sugar-beet experiments, 1902, C. D. SMITH (*Michigan Sta. Bul. 207, pp. 63–75*).—The work with sugar beets in 1902 was largely in continuation of experiments reported in former bulletins of the station (E. S. R., 14, p. 244). The results of analyses of sugar beets by the station chemist for the years 1897 to 1902, inclusive, are tabulated. From these results the author concludes that it is practicable to grow beets rich in sugar in all parts of the State, but in general the beets are richer in sugar the farther north they are grown.

Twenty-four varieties were tested at the station and on 2 different farms. The results of germination tests of the seed of the different varieties showing the number of sprouts from 100 fruits in 7 and 14 days and the total number for the entire period are reported. The data obtained in connection with the variety tests show that individual beets from the same plat vary as widely in sugar content as samples from different plats. With these facts in view the author calls attention to the inability to secure representative samples and dwells upon the consequent unreliability of tables comparing different varieties, and of the inaccuracy of paying for beets according to the sugar content of samples taken at the factory. On one of the farms the beets were grown on a low, wet, mucky soil; still, the average sugar content in the samples of the different varieties was higher than at the station and at the other farm. Owing to a wet season no conclusions as to the adaptation of the different varieties to various soils and conditions are drawn. The yields of beets and the yields of sugar, based on the sugar content of the samples analyzed, are tabulated. Cooperative experiments with this Department to determine the value of Bordeaux mixture for the prevention of the leaf blight were ruined by frequent rains.

The results of distance experiments show that the average yield of beets and the sugar content did not vary greatly for the several distances, 16, 18, 20, and 22 in. between rows. Where the beets were grown in rows 2 ft. apart a slight decline in the yield was noticeable, but there seemed to be no decrease in the sugar content. As in a previous report it is again recommended that the rows be placed 21 in. apart.

A report of progress on an experiment to test the exhaustion of the soil by beets is presented. The tabulated results show a significant reduction in the yields of oats, beets, and corn on plats which had produced beets 2 and 3 years in succession followed by 1 year of oats. Cooperative work with this Department in the production of beet seed is also in progress.

Sugar beets in the Upper Peninsula, C. D. SMITH and L. M. GEISMAR (*Michigan Sta. Spec. Bul. 18, pp. 8*).—This bulletin reports the results of culture tests with sugar beets in the Upper Peninsula of Michigan. This is the first season's work and no conclusions are drawn.

Attention is called to the fact that from April 15 to October 15 the sun is above the horizon for 69.13 hours longer at 47° north latitude than at 42°, and this is considered a dominant influence on the sugar content of beets grown at the higher latitude. The beets in the samples sent to the college for analysis dried out considerably and hence the results are inaccurate. An experiment was made by the station chemist to determine the loss of weight in beets subjected to conditions similar to those of the samples sent to the college, which were in transit for 3 days. The loss of weight varied from 16.8 to 21.6 per cent, the sugar content in the juice before drying from 14.68 to 16.6 per cent, and after drying from 18.6 to 20.9 per cent.

Sugar-beet experiments, R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 42–47*).—A report is given on testing sugar beets grown for feeding and for factory purposes. The beets grown for feed, judged by their sugar content, were all excellent for the purpose. They were cultivated in general as other root crops grown for forage.

The results of cooperative tests of sugar beets to demonstrate the possibility of producing beets for the manufacture of sugar are presented. The average results obtained in 6 districts in 1902 by 189 experimenters show 16 per cent of sugar in the juice with a purity of 88.1; in 1901, the average of 15 districts with 335 experimenters was 16.4 per cent of sugar in the juice with a purity of 87.5; and in 1900 the average of 3 districts with 116 experimenters amounted to 14.4 per cent of sugar in the juice with a purity of 85.4. In connection with this work several fertilizer experiments were conducted. The use of Thomas slag apparently increased the average weight of the beets and decreased the percentage of solids not sugar in the juice, thereby increasing the yield and the purity. The results of a comparison of superphosphate, nitrate of potash, and nitrate of soda gave no other indication than that phosphatic fertilizers improve the purity of the juice. The culture of sugar beets in Ontario is discussed and the condition of the beet-sugar industry described.

Culture of sweet potatoes in the Azores, BERNEGAU (*Tropenpflanzer, 6 (1902), No. 6, pp. 285–295, figs. 9*).—A detailed account of methods of sweet-potato culture in the Azores.

Irrigation of Sumatra tobacco, C. J. BLANCHARD (*Forestry and Irrig., 9 (1903), No. 6, pp. 292–295, figs. 2*).—A brief description is given of the methods of culture and irrigation practiced with Sumatra tobacco grown under shade in Florida. The method of irrigation considered most satisfactory is spraying by means of overhead pipes and nozzles.

HORTICULTURE.

Tomato culture, F. A. HUNTLEY (*Idaho Sta. Bul. 34, pp. 108–117, pl. 1, fig. 1*).—Directions are given for the culture of tomatoes in Idaho. Methods of treating the plants in the hotbed and cold frame, as well as transplanting to the field and field management, are discussed. One of the new features brought out in experiments at the station is the use of coal ashes in cold frames where tomato plants are grown. After the cold frame is made the bed is given a slight elevation with earth and then covered over with 2 in. of sifted coal ashes. The coal ashes are watered thoroughly, and on top of these is placed about 3 in. of deep, rich, mellow soil composed of

about $\frac{1}{3}$ well-rotted stable manure. The roots of plants grown in this soil do not permeate the coal ashes and hence are easier to transplant in the field than plants grown in deep soil where the roots grow long and are likely to be mutilated in taking out for transplanting.

Tomato plants were successfully grown from cuttings taken from the vines in the fall after a crop of tomatoes had been secured. Plants thus grown were always larger and stronger than plants grown from seed, ripened about 10 days earlier, and the total yield to the end of the season was about 5 per cent greater. In one experiment tomatoes were seeded in the hotbed on March 1 and again March 22. The older plants made a slower, better growth in the beginning and ripened their fruit from 3 to 10 days before the others. They also gave a slightly better yield. In a test of growing tomato plants on land that had never been manured and on the same soil heavily manured, plants on the unmanured portion of the field ripened their fruit earlier, but the yield of every one of 18 varieties tested was larger on the manured plat.

As a result of a test of 18 varieties the author recommends for the vicinity of the station the varieties Atlantic Prize, Spark Erliana, Trucker Favorite, Ignotum, Matchless, Noble, Ponderosa, and Stone. For northern Idaho and high latitudes where the season is shorter the varieties Atlantic Prize, Dwarf Champion, Spark Erliana, Fordhook First, and Ignotum are recommended. Atlantic Prize is specially recommended for the home garden.

A cooperative experiment with tomatoes was carried out with 2 farmers living in the higher regions of the State. The same varieties used were also grown at the station. The ripening period at Lewiston began nearly 2 weeks earlier than at Moscow and the relative rate of ripening was as 5 to 1 in favor of the higher locality. A successful method of culture in one of these experiments was worked out by plowing the rows east and west to more than a foot in depth. The plants were then set to within about 3 in. of the bottoms of the furrows and on the north side of the ridges. "These furnished shade from the hot sun at midday and protected the moisture at the roots, thus rendering each irrigation more effective and the necessity of application less frequent."

As in previous years, blight was found most prevalent on poor untilled soils. In one experiment on well-manured plats only 2 out of 80 plants blighted. In another test where the land was unmanured and the plants watered sparingly during the season, 30 per cent of the plants were lost by blight. On well-manured ground at the station only 1 plant out of 400 was lost by blight.

A manual of Egyptian farm crops and vegetables, G. BONAPARTE (*Ghizeh: School of Agriculture, 1903, pp. 81*).—Methods of growing various farm crops and vegetables common in Egypt are described and an account given of their uses.

The new ideals in the improvement of plants, L. H. BAILEY (*Country Life in America, 4 (1903), No. 3, pp. 181–185, figs. 21*).—The new idea in plant breeding is defined by the author as breeding for certain definite attributes "that will make the new generation of plants more efficient for certain purposes." Thus, in corn breeding the object is not simply to produce a new variety, but to get a variety that will contain more protein or oil or starch in the grain, or that will give a heavier yield per acre. The work of the Illinois Station in corn breeding is noted at some length, as well as that of Professor Hays in Minnesota with wheat and corn, and that of Professor Webber, of this Department, with cotton, grains, fruits, etc.

Systematic pomology, F. A. WAUGH (*Trans. Massachusetts Hort. Soc., 1903, I, pp. 51–69*).—A plea for the greater development of systematic pomology in this country, more particularly descriptive pomology. Forms of blanks used in describing fruits at the Massachusetts Agricultural College and the United States Department of Agriculture are given, together with the rules of the Horticultural Club of Cornell University for pomological nomenclature.

Fruits for the home garden: Varieties and culture, F. A. WAUGH (*Massachusetts Crop Rpt., May, 1903, pp. 29–39*).—The author enumerates and briefly describes the varieties of orchard and small fruits most desirable for the home garden in Massachusetts.

The experimental fruit garden, A. D. HALL (*Jour. Southeast. Agr. Col., Wye., 1903, No. 12, pp. 48, 49, pl. 1*).—The experimental fruit garden here noted was set out at Wye College in the winter of 1899–1900. One series of plats which was fertilized at the rate of 1,200 lbs. sulphate of potash, 400 lbs. sulphate of potash, and no potash per acre, respectively, show the best wood growth of trees on the plat heaviest fertilized with the sulphate of potash. Black currants which were planted among the trees also appeared much more vigorous and healthy and produced a larger growth on the plat which had received the largest amount of fertilizer. In another series of plats trees set out on deeply trenched ground were much more vigorous than trees set on ground simply dug over.

Report of South Haven Substation, T. A. FARRAND (*Michigan Sta. Bul. 205, pp. 23–49*).—An account in continuation of previous work (E. S. R., 14, p. 143) of the behavior at the station of a large number of varieties of raspberries, blackberries, currants, gooseberries, cherries, peaches, pears, plums, grapes, apples, crab apples, quinces, chestnuts, filberts, and walnuts, with descriptive notes in many instances of the more promising varieties. One of the features of the year has been the determination of the best methods of marketing different fruits. Red raspberries brought a good price throughout the whole season, but with black raspberries, and also with blackberries, the best prices were obtained for the very earliest and very latest varieties. Cherry varieties of currants sold for $1.25 for a 16-qt. crate, while all other varieties brought only 40 to 60 cents a crate. In the case of cherries no satisfactory commercial results were secured with sweet varieties, and the latest varieties of the sour cherries were most profitable.

In marketing peaches it was found that some of the better white varieties, well packed in open-slat, $\frac{1}{5}$-bu. baskets sold for a higher price in Chicago than many of the later yellow varieties. Plums were shipped on the same date to the same market in the following packages: One 16-qt. case, two $\frac{1}{5}$-bu. baskets, and one 4-basket crate, such as is used for tomatoes. The two $\frac{1}{5}$-bu. baskets equaled in size the one 4-basket crate. The 16-qt. case sold for $1. The 4-basket crate, containing 5 qts. less, also sold for $1, while the two $\frac{1}{5}$-bu. baskets sold for 35 cents each. There was thus a difference of 75 cents a bushel in favor of the 4-basket crate. The fruit in all the different baskets was as near alike as it was possible to grade it.

Four-pound baskets of Delaware grapes sold for the same price as 8-lb. baskets of large blue grapes. Oldenburg and Jonathan brought the highest price among apples. The demand for crab apples was found to begin the first week in September and to continue well into October. Hyslop brought the highest price throughout the season. In this connection it is stated that in harvesting crab apples the fruit must be picked while firm and crisp. If an attempt is made to hold it over it becomes mealy and sells for a lower price.

April 1 was found to be the latest practicable date at which trees could be sprayed with copper sulphate for the prevention of leaf curl. In a test of pruning peaches in the spring and in the fall better results were obtained from spring pruning. In some instances trees pruned in the fall killed back during the winter, and generally the wounds did not heal over as well as when pruned in the spring. A test in thinning peaches to distances apart of 8 in., 5 in., and not thinning at all was started during the season, to continue for 3 years. The good results of thinning on the appearance of the tree was noted during the first season, and the fruit from the thinned trees sold for nearly double as much as that from unthinned trees. Like results of thinning were also noted with plums. Plums thinned so that the fruit did not touch each other were larger, brought a better price in the market, and were less

affected by brown rot than plums on unthinned trees. The foliage was also of a better color and hung on the trees longer in the season.

An experiment was also carried out during the season with various kinds of cover crops in the orchard. Different plats were all seeded August 10. Cowpeas used as a cover crop were practically a failure. Oats proved especially valuable during the season, followed in order by barley, buckwheat, and sand vetch. Crimson and mammoth clover proved about equally valuable.

Report of the professor of horticulture, H. L. HUTT (*Ont. Agr. Col. and Expt. Farm Rpt. 1902, pp. 77–85*).—An outline of the horticultural work of the year with an account of the growth of orchard and small fruits at the college.

Experiments in orchard culture, W. M. MUNSON (*Maine Sta. Bul. 89, pp. 24, figs. 15*).—This bulletin contains accounts of fertilizer, culture and mulching experiments with apple orchards, a test of the value of potash in controlling apple scab, and directions for topworking orchards. In the first experiment one half of an orchard of 80 trees was kept thoroughly cultivated and the other half mulched with meadow hay or sawdust. Twelve trees on each half were left unfertilized, 14 were manured with stable manure, and 14 with commercial fertilizers. The work was begun in 1898 and the growth and condition of each tree in 1902 are commented upon. In general the trees on the cultivated area made the larger growth and produced the heavier yield of fruit. The growth in inches of the trees on the differently treated areas and the average yield per tree is shown in the following table:

Growth and yield of apple trees differently treated.

Variety.	Treatment.	Unfertilized.	Stable manure.	Commercial fertilizer.	Average yield per tree.
		Inches.	*Inches.*	*Inches.*	*Barrels.*
Gravenstein	Cultivated	7.50–9.66	7.00–8.00	8.5– 9.0	0.72
	Mulched	5.50–7.50	7.00–8.50	10.0 12.0	.59
Tallman	Cultivated	....	6.66–8.33	7.0– 8.5	.44
	Mulched	2.66–4.33	6.50–8.33	5.0– 6.5	.50

In the experiment to determine the effect of potash fertilizers on the development of apple scab, muriate of potash, sulphate of potash, and kainit, respectively, were used on the different plats at the rate of 1,000 lbs. per acre over an area of 15 ft. radius around each tree. The orchard was about 25 years old when the experiments began in 1898, and each year since then the trees have been regularly fertilized as noted. An examination of sample lots of apples of differently treated plats in 1902 shows 24 per cent of the fruit on the kainit plat free from scab, 28 per cent on the sulphate of potash plat, 47 per cent on the check plat, and 58 per cent on the muriate of potash plat free from scab. It appears from the figures given "that an excess of potash, in whatever form applied, has no effect whatever in warding off attacks of the apple scab."

Work in the renovation of an old orchard is announced as under way and the plan of the undertaking is outlined. Several different fertilizers were applied experimentally in 1902 and cultivation given. At the end of the season the good effects of both could be readily observed. The use of nitrogenous fertilizers alone greatly increased wood growth, but there was a noticeable lack of color in the fruit. Trees fertilized with acid rock alone did not appear better than those in the check plat. Potash alone, however, produced a distinct improvement.

One of the lessons learned in this work was that in order to control the bud moth and leaf roller the trees must be fed and cultivated as well as sprayed. Spraying to be effective must be done before the buds unfold for the bud moth and as soon as the leaves appear for the leaf roller.

Apple growing in Montana, R. W. FISHER (*Montana Sta. Bul. 44, pp. 59–71*).—Directions are given for the culture of apples in Montana and varieties suggested for planting at high altitudes. It is believed that sufficient apples for home use can be grown anywhere in the State below an altitude of 5,000 ft. Lists prepared from data obtained from growers are given showing the varieties of apples best suited to the different sections of the State.

The apple: Propagation, planting, pruning, and culture, W. F. MASSEY (*North Carolina Sta. Bul. 182, pp. 5–13, fig. 1*).—Popular directions are given for the planting and management of apple orchards in North Carolina.

Apples in North Carolina, T. K. BRUNER (*North Carolina Sta. Bul. 182, pp. 14–30, pl. 1, figs. 16*).—A list is given of the apples grown in North Carolina, with brief descriptions of the different varieties most suited for the family orchard and for commercial orchards. Varieties most suitable for culture in central and eastern North Carolina are also noted.

Preparing apples for market, T. K. BRUNER (*North Carolina Sta. Bul. 182, pp. 31, 32, figs. 3*).—Popular directions are given for barreling apples.

How to utilize the surplus apple crop, G. MCCARTHY (*North Carolina Sta. Bul. 182, pp. 34–38, figs. 3*).—A discussion of the preparation of dried and evaporated apples and the making of apple butter, marmalade, jelly, and fruit juices. It is believed much more advantageous to evaporate apples than to sun dry them, since evaporated apples sell for about 6 cents a pound, while sun-dried apples bring only $2\frac{1}{2}$ to $3\frac{1}{2}$ cents a pound. A profitable evaporator should have a capacity of not less than 300 lbs. of dried fruit per day. Such a machine costs about $100. The author deprecates the bleaching of fruits by fumes of burning sulphur and suggests instead that they be dropped into a tub of weak salt brine, made in the proportion of 1 lb. of clean table salt to 16 gal. of water, and boiled together for 10 minutes.

Cider vinegar, G. MCCARTHY (*North Carolina Sta. Bul. 182, pp. 39, 40*).—Brief directions are given for the home making of cider vinegar.

Peach growing in Missouri, W. L. HOWARD (*Missouri State Bd. Agr., Mo. Bul. 3 (1903), No. 3, pp. 20–34*).—Popular directions are given for the planting, growing, and marketing of peaches in Missouri.

Pruning peach trees, J. C. WHITTEN (*Missouri Sta. Bul. 55, pp. 211–240, figs. 15*).—An account of some experiments following the severe winter freezes of 1898–99 in pruning back peach trees. The cold had killed practically all the fruit buds, while the wood of the trees was badly discolored even to the heart. In the experimental work some of the trees were left unpruned for comparison. With others the new wood was pruned back about half, as is the customary yearly practice. In the majority of cases with the older trees the limbs were cut back into 3 or 4-year-old wood, leaving arms on the main branches 3 to 5 ft. long. Most of the pruning was done in February soon after the freeze, though in some instances it was continued until the leaves were just starting. The following spring the trees which were not pruned at all started into leaf growth first. They made a feeble growth during the summer, the growth being confined principally to the tips of the branches. There was almost no indication of growth in the body of the tree. Trees that had been pruned back severely were rather tardy in beginning growth in the spring. When growth finally started, however, it was very vigorous and continued throughout the season, some 6 to 9 ft. of new wood being made, which ripened up well during the season. Old trees that were cut back to the ground leaving only a stump died in many cases. Those that did sprout made an unsatisfactory growth. Trees pruned back by cutting away $\frac{1}{3}$ to $\frac{1}{2}$ of the 1-year-old wood also made unsatisfactory growth, but little better than where the trees were left unpruned entirely.

The best results were secured in pruning back into the 2 to 4-year-old wood, the severity of the cutting depending upon the age and vigor of the tree. It was observed that trees with smooth, bright-looking bark sent out branches from their trunks more

readily than those whose bark was thick, rough, and dull colored. There was practically no difference in the results obtained in cutting back the trees at different times from just after the freezing until the leaves had made some growth. In the rejuvenation of orchards thus severely pruned, good cultivation to properly aerate the soil in spring and to conserve moisture during the summer is advised.

Olive growing in Spain, J. G. LAY (*U. S. Consular Rpts., 72 (1903), No. 274, pp. 422, 423*).—A brief account of the pickling of green olives in Spain, with some statistics on the imports and exports of olive oil.

Olives and olive oil in France, R. P. SKINNER (*U. S. Consular Rpts., 72 (1903), No. 274, pp. 403–422, figs. 3*).—A rather detailed account of methods observed in France in preserving olives, treatment of olive-oil cake, clarification and filtration processes in olive-oil making, and the classification and uses of olive oil and cake. The idea that any considerable quantity of the olive oil imported into the United States from France is adulterated with cotton-seed oil is believed to be erroneous.

The mandarin orange group, H. H. HUME (*Florida Sta. Bul. 66, pp. 571–594, pls. 2*).—This study of the mandarin group of oranges contains a discussion of its present horticultural status in Florida and an account of its origin, history, and introduction into America, and scientific and common name. Descriptions are given of 9 varieties of these oranges, together with physical and chemical analyses of the 6 varieties commonly cultivated in Florida. The mandarin orange is essentially a fancy fruit. The variety Satsuma, which belongs to the group, is the hardiest known variety of oranges. According to the author the mandarin oranges had their origin in Cochin China. They were introduced into England about 1805 and into America at New Orleans between 1840 and 1850. The group is referred to the species *Citrus nobilis*. The fruiting period of the different varieties in Florida extends from October to the last of April. The most important sorts, noted in the order of fruiting, are Satsuma, China, Dancy, Oneco, and King. The author's estimation of the different varieties is as follows:

"Satsuma, China, and Dancy are well worthy of cultivation, but Satsuma is not recommended for planting in the extreme southern end of the State, and Dancy brings more money in most markets than China. Oneco is a variety of very fine quality, and if its bearing capacity equals its quality it will indeed prove a valuable acquisition. King has some excellent qualities and brings a good price in its season. . . . Cleopatra and Kino Kuni are worthy of cultivation only as ornamentals. Mikado is in no wise superior to Satsuma, which it closely resembles, and it is not so nearly seedless. Beauty, a variety of merit but untried, is recommended for trial. It is one of the best varieties grown in Queensland, Australia."

The physical and chemical analyses of 6 varieties are shown in the following table:

Physical and chemical analyses of mandarin oranges.

Varieties.	Average weight.	Seeds.	Pulp.	Rind.	Acid in juice.	Total sugar.	Total potash.	Total phosphoric acid.	Total nitrogen.
	Ounces.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Satsuma	4.35	0.0	76.2	23.8	1.019	7.80	0.2121	0.0386	0.1661
China	4.96	3.6	75.0	21.4	.838	7.49	.2576	.0758	.1404
Dancy	3.70	2.0	79.4	18.6	.884	9.51	.1903	.0591	.1500
Oneco	6.34	2.0	73.4	24.6	.807	9.48	.2732	.0573	.1653
Cleopatra	2.25	4.3	58.4	37.3	1.564	7.20	.3199	.0529	.1639
King	8.04	2.3	57.6	40.1	1.564	8.95	.2791	.0531	.1506

The largest percentages of phosphoric acid, potash, and nitrogen were found in the pulp of the fruit. The rind contained less than the pulp and the seed less than the rind. Estimates based on the above analyses are given for the amounts of fertilizer

elements removed by bearing trees and the amount of commercial manures necessary to use to replace them. Generally speaking, a fertilizer analyzing 8 per cent phosphoric acid, 12 per cent potash, and 3 per cent of nitrogen it is believed will meet the requirements of most citrus soils in Florida.

A new species of coffee from German East Africa, W. Busse (*Tropenpflanzer, 6 (1902), No. 3, pp. 142–144, fig. 1*).—A new species of coffee (*Coffea schumanniana*) found in German East Africa is described. It differs from *C. arabica* in that the latter has thicker leaves, more abundant bloom, larger fruit, and longer seed.

Bush fruits, F. W. Card (*Rhode Island Sta. Bul. 91, pp. 89–116, pls. 4*).—Besides some work with fertilizers for blackberries and raspberries and an account of the variation of yields with different plants and different varieties, which have been previously noted (E. S. R., 13, p. 740), data are given on the yields of varieties in hills and in hedges and on the culture of blueberries. When red raspberries and blackberries were grown in hedge rows nearly 3 times as heavy yields were obtained as when they were grown in hills. Crimson clover was tried as a cover crop for berries and gave very promising results. The strawberry weevil was found doing considerable damage to wild blackberries, but was not present to any extent in cultivated patches. Early Cluster and Taylor blackberries, Kansas, Eureka, and Nemaha black raspberries, and Cuthbert red raspberries have been found the most satisfactory varieties of these berries thus far grown. Experimental work with these fruits shows that in crossing it is necessary to remove the stamens of the flowers to prevent self-fertilization. Attempts have been made to propagate the swamp blueberries (*Vaccinium corymbosum*) by means of root cuttings, stem cuttings, and root grafts. These attempts have been only moderately successful, for while shoots were readily produced it was difficult to get the plants to root. Better results were secured when soil was used in which the blueberries had been previously grown. A fungus is nearly always found growing with the roots of the blueberries, and it is suggested that this fungus, together with an acid condition of soil, may be one of the essential conditions to the best development of blueberries.

Notes on small fruits, M. L. Dean (*Michigan Sta. Bul. 206, pp. 51–60*).—Notes are given on a number of varieties of strawberries, raspberries, blackberries, currants, and gooseberries grown at the station during the season of 1902, with descriptions of some of the most promising varieties.

The Lucretia dewberry, J. B. Gilchrist (*Delaware State Bd. Agr. Rpt. 1902, pp. 112–114*).—The author experimented with a number of systems of training the dewberry, as a result of which he has settled on the following method: No. 12 galvanized wire is stretched taut on cypress posts 3½ ft. long and driven 18 in. into the ground. The vines are trained on this wire. About 6 vines are left in each hill. Each branch is cut off about 4 ft. long and wound around the wire 2 or 3 times, 3 branches in each direction. The vines are fastened to the wire by a single piece of fine wire in the center. Thus treated, the approximate cost of growing an acre of Lucretia dewberries is placed at \$79.50. The average net receipts per acre for 4 years has been \$70.61 and the average yield 2,640 qts.

Strawberries for forcing, C. E. Hunn (*Amer. Florist, 20 (1903), No. 781, pp. 640, 641, fig. 1*).—The author considers Beder Wood the earliest variety of any value for forcing. The next in succession is Glen Mary which, all things considered, is the best variety ever used for forcing in the author's experiments. Other good varieties for forcing are Brandywine and Sharpless. Of 20 new varieties tested during the past winter but one, the President, proved of value for forcing.

Nitrate of soda in the culture of grapes, G. Chappaz (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 18, pp. 545–550*).—The effect of the different forms of nitrogen as represented in manure, nitrate of soda, and sulphate of ammonia, respectively, on the yield of grapes and quality of wine produced is being studied experimentally.

The data secured in 1901 have already been noted (E. S. R., 14, p. 358). In 1902 the heaviest yields were again secured on the nitrate of soda plat though the differences were not quite so striking as the year before. Classed according to the yield of grapes, the fertilizers rank in the decreasing order of importance as follows—nitrate of soda, barnyard manure, and sulphate of ammonia. Classed according to the quality of the products for wine, they rank as follows—sulphate of ammonia, nitrate of soda, and barnyard manure.

Phosphoric acid and the quality of wines, G. PATUREL (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 20, pp. 607–610*).—The author notes briefly the work done along this line and gives the results of analyses of a number of samples of red and white wines in which it is brought out that those wines which sell for the highest prices contain the largest percentage of phosphoric acid.

Composition and waste of fruits and nuts, W. R. LAZENBY (*Proc. Soc. Prom. Agr. Sci. 1903, pp. 101–108*).—The author made a study of the proportion of edible matter and waste of a number of varieties of grapes, apples, and nuts, and these data are here recorded in detail. Generally speaking, the better specimens of fruits contain the largest percentages of water. Thus in "nubbin" strawberries, "cull" peaches, and "runty" apples less than 80 per cent of water was found, while in the finest specimens of each of these fruits over 90 per cent was found. The total percentage of edible matter in such varieties of grapes as Jefferson, Brighton, Concord, Niagara, and Catawba was found to vary between 71.5 and 75 per cent. With wild grapes only about 40 per cent was edible, the seed and skins constituting 60 per cent of the fruit. The number of grapes in a pound, the number of seeds in each grape, and the weight of the seed for 7 varieties are shown in the following table:

Number and weight of seeds in grapes.

Variety.	Number of grapes in a pound.	Average number of seed for each grape.	Average weight of seed in one berry.
			Gram.
Niagara	168	2.7	0.035
Wilder	180	2.1	.042
Jefferson	200	2.6	.046
Catawba	200	1.7	.063
Brighton	216	2.2	.042
Delaware	480	1.3	.032
Wild Grape	1,984	1.2	.056

The composition of the juices of 4 popular sorts of grapes is shown in the following table:

Composition of grape juice.

Variety.	Juice in grapes.	Sugar.	Acid.	Proportion of acid to sugar.
	Per cent.	*Per cent.*	*Per cent.*	
Salem	55.5	7.1	0.59	1 to 12
Delaware	69.5	10.3	.59	1 to 17.4
Niagara	50.0	6.5	.48	1 to 13.5
Woodruff Red	70.0	8.8	.67	1 to 13.1

The edible portion of 25 varieties of apples as bought in the market was found to vary between 61 and 82.1 per cent, averaging 76.2 per cent; the average waste being 23.8 per cent. There was a tendency toward a higher percentage of waste in the smaller apples.

A large number of nuts were examined. The results obtained are summarized in the following table:

Analyses and value of nuts.

Kind of nut.	Number in 1 pound.	Shell or waste.	Kernel or edible part.	Quantity of kernel purchased for 5 cents.
		Per cent.	*Per cent.*	*Ounces.*
Large black walnut	20	82	18	7.2
Small black walnut	56	79.7	20.3	8.1
English walnut	54	58	42	1.7
Butternut	41	79.4	20.6	8.2
Large hickory	54	80	20	5.3
Shell-bark hickory	179	68	32	8.5
Spanish chestnut	37	12.5	87.5	4.6
American chestnut	230	25	75	3.9
Filbert	222	55	45	2.3
Large pecan	100	51	49	1.9
Small pecan	216	61.8	38.2	2
Brazil nut	48	62.3	37.7	1.9
Almond	83	72.5	27.5	1.1
Peanut	256	26.5	73.5	5.8

The author calls attention to the fact that the Brazil nuts examined were poor specimens, which reduced the percentage of kernel materially. There was also a loss of about 2 per cent of the weight of all varieties of kernels in cracking.

The culture and preparation of vanilla in German East Africa, R. BLITZNER (*Tropenpflanzer, 6 (1902), No. 4, pp. 164–174*).—This article deals with the planting and after culture of vanilla and with the fermentation, curing, and packing of the product.

Trees, shrubs, and vines of the northeastern United States, H. E. PARKHURST (*New York: Charles Scribner's Sons, 1903, pp. 451, pls. 50*).—This is a popular work describing more particularly the trees and shrubs found in Central Park, New York City. The second part of the book consists of descriptions of native and naturalized trees found in the northern United States from Maine to Virginia and west to the Mississippi, classified by their leaves. The work is designed more particularly for the nonbotanical reader.

Report of the committee on school gardens and children's herbariums for the year 1902, H. L. CLAPP (*Trans. Massachusetts Hort. Soc. 1902, II, pp. 232–263, figs. 15*).—This gives an account of the school garden work now being carried on in a number of different sections of the country, together with a chronological list of the articles published in this country on school gardens since 1890. In addition a list of persons actively engaged or interested in children's garden work is given and of the prizes and gratuities awarded for school gardens and children's herbariums during the year.

Chrysanthemums and fertilizers, A. BUYSSENS (*Rev. Hort. Belge, 26 (1902), pp. 265–270, figs. 3*).—This is an account of growing 10 different varieties of chrysanthemums with different fertilizers. All the plants were potted in a soil composed of 3 parts decomposed sod, 1 part vegetable mold, and 1 part sand. One lot of plants was used as a control and received no fertilizer. Another lot had fertilizers mixed with the soil. With a third lot a solution of fertilizers was made and the plants watered with this. In a fourth lot fertilizers were mixed with the soil in the pot and the plant was also watered with a solution containing fertilizers. With a fifth lot the fertilizers recommended by G. Truffaut and based on an analysis of chrysanthemum plants was used. In this case part of the fertilizer was placed in the pot and a part in the water used for watering the plants. In the sixth lot a trade fertilizer designated as "Papillon" was used. The best results in these experiments were

obtained with lot 4 in which fertilizers were mixed with the potting soil and also dissolved in the water used for watering the plants. Next in value stood lot 3 where no fertilizer was mixed with the soil but all used in a solution for watering the plants. The special fertilizer recommended by Truffaut gave the next best lot of chrysanthemums, while the control lot gave the poorest results.

Multiplication of the Dutch hyacinth, S. Mottet (*Rev. Hort., 75 (1903), No. 12, pp. 282–284, figs. 3*).—The various methods of treating hyacinth bulbs to obtain a large number of bulblets are illustrated and described.

Alpine flowers for gardens, W. Robinson (*London: John Murray, 1903, 3. ed., pp. 344, pl. 1, figs. 112*).—The author states that Alpine plants are easily grown in English gardens. Directions are given for the culture of Alpine plants, and the plants that can be best grown are arranged alphabetically and briefly described.

Manures for passion vines (*Agr. Gaz. New South Wales, 14 (1903), No. 3, pp. 252–255*).—The effect of a number of different fertilizers and combinations on the yield of passion vines is reported. The best results were obtained by the use of 4 different formulas, 3 of which are as follows: (1) 52 oz. dried blood, 9 oz. superphosphate, 6½ oz. potassium chlorid per vine; (2) 43 oz. nitrate of soda, 9 oz. superphosphate, 6½ oz. potassium chlorid per vine; (3) 32 oz. sulphate of ammonia, 18 oz. superphosphate, 8 oz. sulphate of potash per vine. The vines manured with complete fertilizers in this experiment gave heavy yields of fruit and appeared in a thrifty condition, while unmanured vines appeared to have become exhausted, although producing little if any fruit.

The largest mint farm in the world, W. E. Andrews (*World To-day, 5 (1903), No. 1, pp. 917–920, figs. 2*).—An account of the development of the mint industry in Michigan, by A. M. Todd, including the culture of mint and refining of peppermint oil.

Luther Burbank—an appreciation, E. J. Wickson (*San Francisco: Southern Pacific Company, pp. 48, pl. 1, figs. 40; reprinted from Sunset Mag.*).—The methods of work and the achievements of Luther Burbank in breeding plums, stoneless prunes, beach plums, quinces, apricots, almonds, blackberries, blueberries, daisies, lilies, amaryllis, clematis, gladiolus, cannas, columbine, roses, eschscholtzia, etc., are popularly reviewed, and an appreciative account given of the man.

FORESTRY.

The woodlot, H. S. Graves and R. T. Fisher (*U. S. Dept. Agr., Bureau of Forestry Bul. 42, pp. 89, pls. 4, figs. 30*).—This bulletin, which is called a handbook for owners of woodlands in southern New England, describes the forests of southern New England and suggests methods for the improvement of their condition. The handbook is prepared especially for the owners of woodland and its purpose is to show how second-growth wood, which comprises the principal forest area of New England, may be treated in order to yield larger returns than under the present methods. The methods of cutting which are recommended are simple and can be applied with beneficial results under conditions now existing in that region. The practice recommended by the authors for these second-growth forests consists of thinning the woods which are not mature so as to improve the conditions of growth and utilize material which is otherwise wasted, cutting in mature woods in such a way that the succeeding growth will follow quickly and be composed of valuable species, the pruning—which is only practicable in certain sorts of stands—protecting forest property against fire, and restocking waste land by planting and sowing. A number of diagrams are given which are sketched from actual conditions showing the application of the methods suggested for improvement cuttings.

Forestry and the lumber supply (*U. S. Dept. Agr., Bureau of Forestry Circ. 25, pp. 14*).—This circular consists of 3 addresses in which it is shown that forestry is

necessary for the perpetuation of the lumber industry of this country. The papers are entitled Forestry and Foresters, by President Theodore Roosevelt; The Exhaustion of the Lumber Supply, by R. L. McCormick; and The Lumberman and the Forester, by G. Pinchot.

Continual supply of forest products, E. Bruncken (*Tradesman, 49 (1903), No. 10, p. 52*).—The author attempts to show the importance of systematic forest conservation as a means for providing a continual supply of forest products, and adapts his remarks to the conditions found in the Southern States adjacent to and embraced within the proposed Appalachian Forest Reserve.

Railroad ties and forest supply (*Tradesman, 49 (1903), No. 10, pp. 77, 78*).—It is stated that 7,000,000 railroad ties are annually required for the renewal of those worn out on the various railroads throughout the country, and for the production of this number more than 300,000,000 linear feet of timber is required. An account is given of experiments which are being conducted by the Great Northern Railroad with a tie which is triangular in section instead of the ordinary 6 by 8 rectangular tie. This railroad tie presents a bearing surface of 12 in., and being triangular in section economizes very materially the amount of timber required. A number of these ties have been under observation in the terminal yard of the railway and it is claimed that the results show that this new form of tie is more effective under heavy service than that usually employed.

A new method of turpentine orcharding, C. H. Herty (*U. S. Dept. of Agr., Bureau of Forestry Bul. 40, pp. 43, pls. 15, figs. 5*).—This bulletin is an elaboration of Circular 24 of the Bureau of Forestry (E. S. R., 14, p. 874), in which a description is given of the proposed method of turpentine orcharding. In the bulletin this method is described in detail and the results of several years' tests are given. This new method consists in using galvanized iron troughs leading to earthen cups, instead of box cutting as in the former method. This new method has been given practical tests, in one of which the first, second, third, and fourth year crops were selected, and half of each crop was worked by the old box system, the other half by the cup system. The results obtained showed an increase of 23½ per cent in the output from the cupped half of the first-year crop, with a corresponding increase for the other crops. In addition to this increased production the trees are said to be left in a better condition, as they are not so deeply cut in preparation. The cost of this new method, while somewhat larger than the old one, can probably be reduced, and is more than fully offset by the increased production. There is also less waste, and a better quality of resin is obtained.

Seasoning of timber, H. von Schrenk and R. Hill (*U. S. Dept. Agr., Bureau of Forestry Bul. 41, pp. 48, pls. 18, figs. 16*).—This bulletin, which relates principally to the seasoning of railroad ties, telegraph poles, and railroad timber, gives a discussion of the distribution of water in timber, the relation of water to the decay of timber, the methods and objects of seasoning, and the advantages to be derived from the use of seasoned timbers. The principal investigations have been conducted with the seasoning of railroad ties. Different methods have been tested, and, so far as the authors' investigations have gone, the open piling is to be preferred at least with the lodge pole pine, which is principally used in Montana and elsewhere. It is believed that this method is to be preferred in the case of oak and other timbers. Whenever timbers have been given a treatment to preserve them from decay they should invariably be thoroughly seasoned after coming from the retorts in which they are treated. This seasoning by crystallizing the chemicals in the wood tends to materially prolong its efficiency against the entrance of destructive fungi. The general recommendations for seasoning timber are as follows: Green timber should be piled in as open piles as possible as soon as it is cut and so kept until it is air dry. No timber should be treated with chemicals until it is air dry, and timbers treated with a

preservative dissolved in water should be piled after treatment for several months to allow the water forced into the wood to evaporate. Under no circumstances should timber freshly treated with the water solution be exposed to weather conditions.

Forestry in the United States, W. SCHLICH (*Nature [London], 67 (1903), No. 1737, pp. 353, 354*).—A review is given of the forestry situation in the United States and an account presented of the organization of the forest schools, the policy of the Government as illustrated in the Forestry Bureau of this Department, and the forest reservation system of the Interior Department, and brief accounts of a number of the more recent publications relating to forestry in this country. The author highly recommends the beginnings that have been made, but points out that what has thus far been done will in no wise supply the threatening deficiency in forest products. On this account the author believes that more reservations should be established and greater care exercised in exploiting the forests yet remaining.

Eighth annual report of the chief fire warden of Minnesota, 1902, C. C. ANDREWS (*St. Paul: 1903, pp. 132, pls. 22*).—The author submits his annual report giving in some detail the results of the fire-protection system of Minnesota. During the year covered by this report forest fires were less destructive than formerly, due in part to the wet summer and autumn as well as to the more efficient patrol and suppression of incipient fires. The number of forest fires reported was 34, in which the damage is estimated at $3,820, and 46 prairie and field fires were reported in which the loss was estimated at $12,318. The location of these different fires, the area burned over, and the causes of fire as far as known are given. The reports of the various county officers, who are made fire wardens under the law, are briefly given and the modifications of the law passed by the last legislature are shown. The condition of forests in a number of parts of the State is briefly described, and the report concludes with a review of European forestry, different countries being discussed in some detail.

The forest policy of Pennsylvania, G. H. WIRT (*Jour. Franklin Inst., 155 (1903), No. 5, pp. 341–355*).—In this paper, which is a lecture delivered before the Franklin Institute, January 23, 1903, the author, who is State forester of Pennsylvania, outlines the forest policy of the State. This policy consists in aiding private forestry to become profitable and in promoting public forestry by acquiring the forest about the headwaters of principal streams. These forests are managed for the protection of the watersheds as well as for working out other forest problems.

Report on the forest administration in the Andamans, 1901–2, G. ROGERS (*Forest Dept., Andaman Islands, India, Rpt. 1901–2, pp. 46*).—A progress report is given of the forest operations under the direction of the writer, and general statements are given regarding the regulation and management of the state forests, the operations of the year, the preparation of working plans, and the exploitation of forests and collection of forest products.

Report on the forest administration of the Lower Provinces of Bengal, 1901–2, J. H. LACE (*Forest Dept., Bengal, India, Rpt. 1901–2, pp. 48 + IX*).—During the period covered by this report but slight changes have been made in the forest area. The area under the control of the forest department June 30, 1902, was 13,579 square miles of reserved, protected, and unclassified forest. A detailed account is given of the management of the state forests, the working plans discussed, and other administrative features presented. The improvement of forest growth by natural reproduction, artificial reproduction, thinnings, and various forms of cuttings are described at some length. A special report is given on the experiments being conducted with rubber-producing trees, and while the number of plants is somewhat limited the experiment with some species seems to be sufficiently promising to warrant its continuance. More than 42,000,000 cu. ft. of timber were removed by the various cuttings during the period covered by the report.

Report on the forest administration of the Central Provinces, 1901–2, B. ROBERTSON (*Forest Dept., Central Provinces, India, Rpt. 1901–2, pp. 50 + LXXXIX*).—A report is given of the chief forest commissioner, in which the annual reports of the conservators for the northern and southern circles of the Central Provinces are included. On account of a reclassification of the forest there was a decrease of 111 square miles in the total under the management of the forest department. Considerable progress is reported in the scientific working of the forest, and an increase of more than 400,000 cu. ft. of timber is reported as having been removed. The financial returns from both divisions are stated, showing not only increased gross receipts but a decided increase in the net proceeds. The system of forest-fire protection is reviewed at considerable length, and very satisfactory results have been secured by a very simple method of fire protection.

Report on the forest administration in the Punjab, 1901–2, F. B. BRYANT (*Forest Dept., Punjab, India, Rpt. 1901–2, pp. 22 + LV*).—A progress report is given of the operations that have been conducted in the forest administration of Punjab in 1901–2. Considerable development is shown in the resin and turpentine production. The cutting of timber and fuel was considerably in excess of any previous year, and the net profit for the year 1902 was 533,000 rupees, or about $200,000.

SEEDS—WEEDS.

Clover and its impurities, D. FINLAYSON (*Aynsome Agr. Sta., Grange-over-Sands, Cent. Seed-Testing Lab. Farmers' Bul. 2, pp. 8, pl. 1*).—Popular notes are given on the purity, germination, and specific gravity of white and alsike clovers. Both of these seeds frequently contain numerous weed seeds, the more common of which are figured and described.

Germination of maize, L. H. PAMMEL and G. M. LUMMIS (*Proc. Soc. Prom. Agr. Sci. 1903, pp. 92–96*).—According to the authors, a considerable portion of the corn in Iowa during 1902 did not mature properly and the question of the influence of immature ripening on germination was investigated. Samples of seed were tested from different localities and the results of the germinative tests are shown in tabular form. Wide variation is shown in the different lots, and accompanying the germination was noted a considerable development of different molds and other fungi. These are believed to have affected the germination of the corn to a considerable extent.

The effect of coal tar, coal oil, gasoline, etc., on the germination of maize, G. M. LUMMIS (*Proc. Soc. Prom. Agr. Sci. 1903, pp. 96–100*).—On account of the widespread belief that soaking corn in coal tar, coal oil, gasoline, benzine, etc., will repel troublesome enemies, the author investigated the effect of these substances upon the germination and subsequent growth of corn. The seed was soaked in the different solutions and planted in alternating rows with untreated seed. Seed that had been soaked in coal tar or coal oil was considerably injured, the germinative ability being reduced and the subsequent growth very greatly retarded. Plants grown from treated seed were yellow, weak, and decidedly inferior to those grown from the untreated seed. In duplicate tests conducted in the greenhouse about 90 per cent of the grain was killed by the treatment. Where more dilute solutions were tried it was found that while the percentage of germination was greater there was still some evidence of injurious effect. Gasoline, benzine, and the more volatile oils had little if any effect upon the germination of corn.

The grading and selection of seeds, C. D. GIROLA (*Elección y selección de las semillas. Buenos Ayres: P. Gadola, 1902, 2. ed., pp. 32, figs. 4*). An account is given of the agricultural condition of Argentina so far as the subject of seed selection and seed control is concerned, and the author gives suggestions for the grading and testing of seeds.

The germination of weed seeds, L. H. PAMMEL and G. M. LUMMIS (*Proc. Soc. Prom. Agr. Sci. 1903, pp. 89–92*).—For several years the authors have been carrying on investigations in weed studies, paying particular attention to the germination of weed seed. In the report given the results of experiments on the germination of weed seeds are noted, the germinative power of the seed immediately after maturity, after being stratified, and also of mature and immature seed being tested. It was found that most of the weed seeds would not germinate readily in the autumn after their production; some biennials and winter annuals, as shepherd's purse, dandelion, prickly lettuce, burdock, and others, being exceptions to the rule. A number of recently matured seed tested in a Geneva germinating apparatus failed to give any germinations, while the same seed stratified in sand and allowed to freeze germinated readily. The results of the germination of weed seed on a bench in a greenhouse, and also the results of stratification of the same seed are shown in tabular form.

Loco weed, L. E. SAYRE (*Trans. Kans. Acad. Sci., 18 (1903), pp. 141–144*).—A review is given of the popular beliefs regarding the loco weed (*Astragalus mollissimus*) and statements given regarding observations of the author and others upon its alleged poisonous properties. Attempts have been made to isolate alkaloids from this plant, but the results showed that the amount present was so small that the so-called locoism could not be produced by any alkaloid formed in the plant. The author thinks possibly some changes are undergone in the digestive tract of the animal that may result in the formation of some poisonous compounds, and this subject is to be one of further investigation.

Weeds, L. R. WALDRON (*North Dakota Sta. Spec. Bul. 2, pp. 4*).—This bulletin consists of a circular asking information regarding the distribution of weeds, their relative importance, means of dissemination, and methods of eradication. The information sought is preliminary to an extended study of the subject of weeds and their control.

DISEASES OF PLANTS.

Combating smut of cereals, S. TOPORKOV (*Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4 (1903), No. 1, pp. 58–64*).—Results of experiments in treating summer wheat and millet for the prevention of smut are given. These crops seem to be very subject to the destructive effect of smut, especially in the southwestern part of Russia. Preliminary experiments with soaking seed in ½ per cent solution of copper sulphate gave excellent results with summer wheat, less than 3 per cent of the crop produced from treated seed being affected as compared with 13.8 per cent of that from untreated. This treatment was continued for about 16 hours and proved somewhat detrimental to the germination of the seed. In subsequent investigations the author has found that soaking millet seed 5 minutes in a 1 per cent solution of copper sulphate was efficient in reducing the amount of smut and did not seriously depreciate the germination of the seed. In an experiment reported, the seed treated as above produced a crop about 4 per cent of which was more or less attacked by smut and the total yield of seed was about 1,876 lbs. per acre, while similar plats sown with untreated seed were attacked to the extent of 56.3 per cent and yielded only 960 lbs. of seed per acre. For the practical treatment of seed for the prevention of smut the author recommends dipping the seed inclosed in coarse sacks, which contain about 25 lbs. each, for 5 minutes in a 1 per cent copper sulphate solution, after which the seed is removed and may be dried.

Wheat smut experiments in 1901, W. FARRER (*Agr. Gaz. New South Wales, 14 (1903), No. 3, pp. 206–216*).—In continuation of previous experiments (E. S. R., 13, p. 659) the author has been investigating the subject of the prevention of stinking smut of wheat. The resistance of different varieties to this disease has been investigated, and wide variation was observed in the behavior of the varieties at different

times and in different soils. A number of fungicides were tested as preventive treatment when applied to the seed, and eau celeste was found to give such poor results as to be abandoned from further investigation. In the treatments which were carried out comparison was made of solutions of copper sulphate, corrosive sublimate, and formalin. In the trials made copper sulphate has proved quite satisfactory and being less poisonous is to be preferred to corrosive sublimate, although the latter is somewhat more efficient. The experiments, so far as they have been concluded, have shown the efficiency of formalin, and the author believes that subsequent investigations will show that this substance is to be preferred to either corrosive sublimate or copper sulphate for treating seed of wheat for the prevention of the stinking smut.

Experiments on the brown rust of brome grasses, E. M. FREEMAN (*Ann. Bot., 16 (1902), No. 63, pp. 487–494*).—The experiments here reported were undertaken to ascertain the relative capacity of infection of different species and the determination of some whose systematic position was somewhat doubtful. In all 40 species of Bromus were inoculated with spores from *B. sterilis* and *B. mollis*. The spores were placed upon the first foliage leaves of the plants and the plants given protection by bell jars against injurious influences. The weather throughout the period of the experiments was colder than normal, and the long period of incubation of many of the spores is attributed to this fact. Each experiment was continued for about 3 weeks, although a period of incubation of about 12 days was sufficient to demonstrate the ability of the fungus to infect the host. Of the species inoculated, 22 did not show any infection; 12 were successfully infected with the spores from *B. mollis* but not with *B. sterilis* spores. One species (*B. sterilis*) was only infected with the spores from that species, while 5 species of Bromus were equally infected with the spores of both species of rust.

Critical notes on Sclerospora of Gramineæ, G. B. TRAVERSO (*Malpighia, 16 (1902), No. 5–7, pp. 280–290, fig. 1*).—A study has been made of the various species of Sclerospora which are reported as occurring parasitically upon various grasses, and the author concludes that there are not more than 2 species of that fungus which attack the grasses. These species are *S. graminicola* and *S. macrospora*. The species which has been described as *S. kriegeriana* he says is undoubtedly the same as *S. macrospora*. The species described by Peglion as occurring on wheat is *S. macrospora* instead of *S. graminicola*, as that author has claimed.

The histology of Uredo dispersa and the mycoplasm hypothesis, H. MARSHALL WARD (*Proc. Roy. Soc. [London], 71 (1903), No. 473, pp. 353, 354*).—An abstract is given of a detailed study of the histological features of the germination, infection, and growth of the mycelium of the Uredo in the tissues of grasses, the work referring especially to the uredo form of *Puccinia dispersa* in the tissues of *Bromus secalinus*. The author critically examined the relation of the hyphæ and haustoria to the cell contents of the host, and the evidence obtained not only failed to support Ericksson's mycoplasm hypothesis (E. S. R., 10, p. 316) but so far as the histological facts observed are concerned they would indicate that Ericksson's observations are entirely reversed from the true order of events. The so-called special corpuscles observed by Ericksson are said by the author to be the cut-off haustoria of the fungus, and have no relation whatever with the subsequent development of the mycelium. The haustoria have been formed by the hyphæ, and not vice versa.

Diseases of flax and flax-sick soil, H. L. BOLLEY (*North Dakota Sta. Bul. 55, pp. 186–198, figs. 5*).—Since the previous publication regarding the flax wilt (E. S. R., 14, p. 55) a number of new points regarding the disease have come to light. In addition to the fungus (*Fusarium lini*) which was described as the cause of the characteristic wilt, a number of other fungi are now known to destroy the young plants and persist in the soil so as to seriously interfere with the growth of flax. Examinations of flaxseed and soil from a number of localities have shown the presence of the wilt organism, and in addition to the Fusarium there was found a species of Colletotrichum

and a species of Alternaria, both of which are very destructive to young plants in damp soils. The effect of these fungi upon the flax is described, and according to the author they may be carried not only in the soil but in the seed. On this account the selection of pure, clean, mature seed is highly important; and where the seed is suspected of being infected it is recommended that the flaxseed be treated with formaldehyde by spraying it with a fine spray and raking or shoveling over the grain until the surfaces are equally moist. If properly applied this can be done without the matting together of the seed. About ½ gal. of solution is required to wet a bushel of flaxseed. Investigations are also reported on the immunity of different races or varieties of flax to the disease, as well as the possible effect of the separation and use of different sized seed.

A study of Phoma betæ, J. HENRY (*Bul. Agr. [Brussels], 19 (1903), No. 1, pp. 156–163, fig 1*).—During 1901, in a season of a remarkably wet spring followed by a prolonged summer drought, the beets were severely attacked by the dry rot (*Phoma betæ*). The nature of the attack of the fungus and its effect upon the host are shown. As a result of the disease the sugar content as well as purity are very materially diminished. Beets which contained an average of 15.6 per cent sugar with a purity coefficient of 88 per cent were compared with badly diseased ones in which the sugar content was 10.9 per cent, and the purity coefficient of the juice 71 per cent. The results of analyses of the soils in which these different lots of beets were grown led the author to believe that the disease is largely influenced by the deficiency in certain fertilizers, principally in nitrogenous ones. For the prevention of the disease he recommends the thorough preparation of the soil and subsoil and the application of fertilizers which will supply any deficiency in mineral nutrients. He suggests that particular attention be paid to the presence of an abundance of organic material in the soil. So far as possible, varieties should be selected which are resistant to the disease and which are well adapted to the climatic and soil conditions where grown.

The protection of cane cuttings during transportation, A. HOWARD (*Reprint from Internat. Sugar Jour., 5 (1903), pp. 113–116*).—An account is given of experiments to test the shipping qualities of canes and means for protecting them against disease when shipped to a considerable distance. It was found that by treating the cane cuttings with Bordeaux mixture and afterwards packing them in pulverized charcoal they could be readily shipped to great distances without losing their vitality. If the cuttings and charcoal are kept too dry there will be a loss of vitality, but the proper amount of moisture has not yet been determined.

Combating black rot of cabbage by the removal of affected leaves, F. C. STEWART and H. A. HARDING (*New York State Sta. Bul. 232, pp. 43–64, pls. 2*).—An account is given of some recent field experiments on the treatment of the black rot of cabbage by the prompt removal of affected leaves. This method of treatment was investigated on account of the suggestion made by other investigators as to its being a possible means for the control of the disease. The effect of the black rot, mode of infection and dissemination of the organism are described. The method of treatment was the removal of all diseased leaves once a week from the first appearance of the disease until the end of the season. The theory upon which this treatment is based is that the bacteria gain entrance to the leaves along their margins or on wounds made by insects, and then pass downward along the fibrovascular bundles into the stem of the plant. The treatment aims at the saving of plants already slightly affected and the prevention of the spread of the disease by removal of the organism. Experiments along this line were carried on in 1899, 1900, and 1901, but the principal investigations were made in 1902. A field of cabbage was divided into equal parts and the diseased leaves removed from half the rows of 2 varieties, the other half-acre remaining as a check. The picking of the leaves began July 22 and was continued until September 16, the total time required being the services of one man for 46½ hours. Although the disease was so abundant that on the check plat

scarcely a plant was free from it, yet only a few plants were completely ruined. When the cabbage was harvested comparisons were made of the yield from each of the half-acres. As the result of the treatment it was found there was a loss at the rate of 5¼ tons per acre due to the removal of the leaves, in addition to the expense of the treatment, which is estimated at $11.62 per acre. The pulling of the leaves seems to check the formation of the heads and there is apparently evidence to show that the disease spreads not only through the leaves, but can gain entrance to the plants coming from the soil to the stems through the roots. Infection can also occur at the base of the leaves close to the stem, the organisms passing down the fibrovascular bundles into the stem, where it is beyond control.

Experiments with cauliflower for the prevention of the same disease have given results which warrant the continuation of the experiments of spraying the cauliflower with a resin-Bordeaux mixture. An experiment was conducted to determine how the removal of the lower leaves affects the yield of the cabbage plant. In this experiment alternate rows of cabbage had the 10 lower leaves removed with the result that the check rows gave a larger number of marketable heads of greater average weight than those which had had their lower leaves removed. The difference in this case was at the rate of 3 tons per acre.

An unsuccessful cabbage-rot remedy, F. H. Hall, F. C. Stewart, and H. A. Harding (*New York State Sta. Bul. 232, popular ed., pp. 9, fig. 1*).—A popular summary of the above bulletin.

A disease of the branches of fig, A. Prunet (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 6, pp. 395–397; Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 10, pp. 315, 316*).—According to the author, fig trees in the southwest of France are particularly subject to a disease which destroys the younger branches. This disease is attributed to attacks of Botrytis which is developed in the fruit remaining upon the trees during winter. Ordinarily the immature fruits in autumn remain on the trees and are attacked by this fungus. The fruits become mummified and bear upon their surfaces the fructification of the Botrytis. During mild weather the spores begin germination and spread through the peduncles of the fruits to the young twigs, causing their destruction. Another method of distribution is through the softening and falling from the branches of the decaying fruits. These frequently fall upon other branches and remaining there spread the infection from these centers. As a means for the prevention of this disease the author suggests the removal from the trees of all fruit at the end of the season.

The control of the sooty mold of the olive, D. Vidal (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 14, pp. 439, 440*).—The relationship between insects and fungi in producing the sooty mold of olives is shown, and the results given of a number of treatments in which Bordeaux mixture was used in connection with kerosene emulsion and Bordeaux mixture and turpentine. These treatments were found to be quite efficient, and in combating this disease a combined insecticide and fungicide should be used. The best results in his experiments were obtained with the Bordeaux mixture and turpentine solution. The spraying should be thorough, and can be done at a cost of about 5 cts. per tree per year.

The bitter-rot fungus, H. von Schrenk and P. Spaulding (*Science, n. ser., 17 (1903), No. 436, pp. 750, 751*).—As a result of the study of the synonymy of the bitter-rot fungus (*Glœosporium fructigenum*) the authors claim that the name should be *Glomerella rufomaculans*, n. sp., the previous names being preoccupied. The other well-known species of Glœosporium of this same group, according to the authors, would become *Glomerella cingulata*, *G. piperatum*, *G. cinctum*, and *G. rubicolum*.

Collar rot of the orange, C. Fuller (*Agr. Jour. and Min. Rec., 6 (1903), No. 5, pp. 150, 151*).—The occurrence of collar rot, root rot, gum disease, yellow leaf disease, etc., in Natal is noted, and the author points out the identity of the diseases which have been given these various names. The collar rot, as he prefers to call the trouble,

occurs in Natal under almost all conditions of soil, and in many cases it may be attributed to bad drainage, although in some instances a lack of drainage will not explain the occurrence of the disease.

The peach; its diseases and suggested remedies, W. A. BOUCHER (*New Zealand Dept. Agr. Rpt. 1902, pp. 456–460, pl. 1*).—The peach is said to be almost entirely free from insect pests in New Zealand, but is subject to considerable injury from a number of fungus diseases. Among the diseases described are peach curl, shot-hole fungus, peach rust, and attacks of *Clasterosporium amygdalearum.* This last fungus attacks both the bark and leaf, resulting in the defoliation of trees and their subsequent weakness. The author recommends early and persistent spraying with Bordeaux mixture composed of 10 lbs. of copper sulphate, 10 lbs. of lime, and 40 gal. of water.

Peach-leaf curl, G. E. STONE (*Massachusetts State Bd. Agr. Nature Leaflet 13, pp. 4, figs. 2*).—A description is given of the peach-leaf curl, due to *Exoascus deformans*, and spraying with Bordeaux mixture is recommended as an efficient means for its prevention. This fungus is said to annually cause a loss to the peach industry of the United States amounting to from two and a half to three million dollars.

Quince rust, G. E. STONE (*Massachusetts State Bd. Agr. Nature Leaflet 11, pp. 3, figs. 2*).—Brief illustrated notes are given on the quince rust caused by *Gymnosporangium* spp., for the prevention of which the author recommends thorough and repeated spraying with Bordeaux mixture.

The witches' broom disease of cacao (*Agr. News [Barbados], 2 (1903), No. 26, p. 117, fig. 1*).—An illustrated description is given of the witches' broom disease of cacao which was first noticed in Surinam in 1898. This disease greatly damages the trees and is accompanied by a hardening of the cacao pods to such an extent that their production is seriously diminished. In the absence of more definite knowledge of the fungus the only remedy to be suggested is the cutting out of the tufted branches and burning them as soon as observed.

The alternate form of Æcidium hibisciatum, W. A. KELLERMAN (*Jour. Mycol., 9 (1903), No. 66, pp. 109, 110*).—The occurrence of the æcidium of this rust in great abundance on plants of *Hibiscus moscheutos* led the author to search for its teleutosporic form. A number of plants were investigated which grew in the immediate vicinity and finally by means of cultures and inoculations the author discovered that the Puccinia form was *Puccinia muhlenbergiæ*, a common rust on *Muhlenbergia mexicana.*

A rust of the cultivated snapdragon, W. C. BLASDALE (*Jour. Mycol., 9 (1903), No. 66, pp. 81, 82*).—In 1895 the author reported the presence of the uredo stage of a rust on cultivated forms of snapdragon. Later the teleuto stages were produced and the fungus was determined to be a new one and named by Holway and Dietel *Puccinia antirrhini.* Since that time the fungus has appeared every season when attempts were made to grow this plant, completely destroying all plants before they reached the flowering stage. There appears to be no record of the occurrence of similar disease in other parts of the country, and the author suggests that on account of its destructive character it would be well to guard against introducing it into other regions.

Grape mildew and the use of sulphur, L. DEGRULLY (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 14, pp. 417, 418*).—Attention is called to the fact that for some years complaint has been made by certain viticulturists that the use of sulphur does not prevent the attacks of the powdery mildew of the grape. A number of these complaints were analyzed and the author concludes that the failure to prevent the development of the fungus was due in part at least to an insufficient use of sulphur. For the thorough protection of the grapevines at least 3 treatments should be given them in which either 130 kg. per hectare of triturated sulphur or 90 kg. of sublimated sulphur should be used. These figures are given as the maxima, which it is not always necessary to attain, but they should be fairly well approximated.

Brunissure of grapes; its cause and remedies, L. DEGRULLY (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 15, pp. 449–452*).—A discussion is given of some of the supposed causes of this disease, among them various fungi, insects, the lack of nutrition, the effect of overbearing, etc.; and a review is given in which it is shown that there seems to be some relationship between production and occurrence of the disease. Differences in susceptibility of varieties are also shown, those of the Vinifera, Labrusca, and Æstivalis types being quite subject to disease, while Riparia, Berlandieri, and Cordifolia are seldom or never attacked. The author seems to incline to the opinion that this disease is due to a lack of nutrition as well as overbearing. For its prevention he recommends thinning grapes to prevent overproduction, and better cultivation of the vines, furnishing them with an abundance of water and fertilizers.

The conidial form of the black-rot fungus, G. DELACROIX (*Compt. Rend. Acad. Sci. Paris, 135 (1902), No. 26, pp. 1372–1374*).—In a previous publication (E. S. R., 13, p. 366) the author described a conidial form of the black-rot fungus (*Guignardia bidwellii*) which he stated was more or less common in the United States and occasionally met with under favorable conditions in France. Other investigators have since contested the accuracy of this description, and the author gives an account of investigations conducted during 1902 which have confirmed his previous conclusions.

The bluing and the red rot of the western yellow pine, H. VON SCHRENK (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 36, pp. 40, pls. 14*).—An account is given of the cause of the blue timber of dead wood of western yellow pine (*Pinus ponderosa*) and the effect of the coloring on the value of the wood, together with a description of the red rot of the same tree, the investigations being conducted with special reference to the Black Hills Forest Reserve. As a result of ravages of the pine bark beetle (*Dendroctonus ponderosæ*) a large amount of the bull pine has been destroyed. This wood seems to have undergone certain changes which result in its becoming of a decided bluish color. The effect of the insect attack is shown by the changed appearance in the color of the leaves following the attacks of the insects in July, August, and September. The leaves turn yellowish in color, the bright green fading almost imperceptibly, and later the yellow increases and is sometimes replaced by a reddish coloration. The third year the leaves drop from the trees, when they are known as "black tops." Soon after the attack of the bark beetles the wood of the pine begins to turn blue. This color at first is very faint but soon becomes deeper. The first signs of this change in color are observed several weeks after the attacks of the beetles at points on the trunk in the immediate vicinity of the attack. The color develops rapidly when once the tree is attacked, and standing trees examined in July, 1902, showed signs of blue coloration in 3 weeks after the appearance of the beetles. In general appearance the blue timber differs but little from the sound wood except in its color. The wood dries very rapidly and is said to become much tougher than green wood, and tests of the compression and breaking strength showed that blue timber 2 years old was stronger than the green timber.

The blue color of the wood is due to the growth of a fungus in the wood cells and it is believed that the fungus is the same as that described by Hartig as occurring in Europe. This fungus (*Ceratostomella pilifera*) occurs on coniferous woods, mostly on pine and develops rapidly in the medullary rays of the timber. The mycelium of the fungus can be readily observed in the split wood and the fruiting organs may be seen on the surface of the wood on which it is growing. A technical description is given of the fungus, its growth in various media, the dissemination of spores, and nature of the color. So far all attempts at extracting the color have failed but investigations show that changes of some kind have taken place in the wood fiber, the nature of which is not definitely understood. The changes brought about by this fungus can hardly be called a decay as the wood is sound to all ordinary appearances, and only after some time do the ordinary processes of decay set in.

The red rot described usually starts at the top of the "black topped" trees. This is caused by one of the higher fungi which grows in the wood and causes its decay. The conditions favoring the growth and development of the fungus, as well as its different stages of growth, are described, and a technical description given of the organism which, according to the author, is *Polyporus ponderosus*, n. sp.

The amount of diseased timber in this forest reserve is very great, and as the bark beetles are continuing their attack the amount is increasing. The investigations of the author show that if promptly used the timber is valuable and, so far as the blue timber is concerned, is not injured for the ordinary purposes to which this class of trees are put.

Some nematode diseases of tropical plants, G. DELACROIX (*Reprint from Agr. Prat. Pays Chauds, pp. 19, figs. 2*).—Descriptions are given of a number of nematode diseases which are caused by the widely distributed *Heterodera radicicola*. To this nematode the author attributes the banana disease of Egypt and a disease of black pepper in Cochin China (E. S. R., 14, p. 460), as well as a coffee disease in the West Indies. Associated with the nematode in the coffee disease is the mycelium of one or more fungi which cause the rotting of the roots of the plants.

Disease-resisting varieties of plants, L. LEWTON-BRAIN (*West Indian Bul., 4 (1903), No. 1, pp. 48–57*).—A critical review is given of some of the more important investigations that have been conducted in various parts of the world on the breeding and introduction of disease-resistant varieties of cultivated plants.

Notes on albinism among plants, E. PANTANELLI (*Malpighia, 16 (1902), No. 11–12, pp. 487–517*).—A critical study is reported of various forms of albinism, together with an inquiry into their causes and the various phenomena which attend this abnormal condition.

Fungus diseases and spraying, H. H. LAMSON (*New Hampshire Sta. Bul. 101, pp. 55–67, pl. 1*).—A brief general account is given descriptive of fungus diseases, and directions are given for the preparation and use of a number of the more common fungicides. Descriptions are given of a number of the more common diseases, special attention being given to those of the apple, grape, peach, plum, and potato. Where remedial or preventive treatments are known they are suggested.

Spraying for the control of insect pests and fungus diseases, T. W. KIRK (*New Zealand Dept. Agr. Rpt. 1902, pp. 434–449*).—The author gives in tabulated form the answers to a circular which was extensively distributed making inquiry regarding the results of spraying experiments for insect pests and fungus diseases. The tables show the fungicide or insecticide used and the effects produced, and the consensus of opinion was almost unanimous in favor of the value of spraying when considered from the commercial standpoint.

Combined fungicides and insecticides, L. DEGRULLY (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 19, pp. 565–568*).—On account of the possibility of combating fungus diseases and insects with a single treatment, the author has suggested spraying with a combined solution which consists of a copper fungicide and an arsenical insecticide.

ENTOMOLOGY.

The enemies of agriculture, A. L. HERRERA (*Las plagas de la agricultura. Mexico: Ministerio de Fomento, 1902, 1903, pts. 3–7, pp. 179–434, pls. 5*).—This is a continuation of the work of which the first and second parts have already been noted (E. S. R., 14, p. 467). The author discusses insects injurious to fruit trees; the economic importance of birds; the enemies of cacao, coffee, sugar cane, cereals, peas, asparagus, ornamental flowers; insect enemies of domestic fowls; ants, injurious locusts, etc.

Some injurious insects and fungus diseases of the year 1902, W. LOCHHEAD (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 19–28, figs. 10*).—Notes are given on the sawfly (*Taxonus nigrosoma*), which commonly lives on species of jointweed, but which was found to be injurious to apples. Brief accounts are also presented of the injuries caused by woolly aphis, bronze birch borer, leaf spot of sugar beet and horse chestnut, shot-hole disease of plum and cherry, apple scab, pear scab, sooty fungus of apple, late blight of potatos, etc. T. D. Jarvis calls attention to the dangers from close proximity of mountain ash, wild plum, and chokecherry to fruit trees. These wild trees are infested with a number of insect and fungus pests which may readily spread to cultivated trees.

Entomological notes (*Jour. Bd. Agr.* [*London*], *9* (*1903*), *No. 4, pp. 519–525*).—Brief accounts of carrion beetles, *Hydræcia micacea*, *Cetonia aurata*, *Hedya ocellana*, *Laverna atra*, and *Phædon betulæ*. The last-named insect is reported as very injurious to mustard. It is recommended that all mustard plants be burned in the fall after being allowed to dry out. The destruction of these plants, together with other rubbish under which the beetles might hibernate, has been found to check the multiplication of the insects and to prevent a portion of the spring injuries.

Indian Museum notes (*Indian Mus. Notes, 5* (*1903*), *No. 3, pp. 61–216, pls. 14*).—As with the previous numbers of this publication, this number is occupied with original communications on injurious insects and with numerous miscellaneous notes on economic entomology. W. H. Ashmead (pp. 61, 62) describes as new the genus Eurycephalus, which belongs to the family Chalcididæ. E. E. Green (p. 63) describes a new species of scale insect under the name *Chionaspis decurvata*, which was found attacking rice. E. P. Stebbing (pp. 64–91) presents an account of insect pests of sugar cane in India. A large number of species are described and notes are given on the nature of the injury done by the different species and on means of combating them. J. Durrant (p. 92) describes a new genus of Tineid moth under the name Dasyses. E. E. Green (pp. 93–103) describes a number of new species of scale insects throughout India. These species belong to the genera Lecanium, Aspidiotus, Tachardia, Monophlebus, etc.

The remainder of this publication is occupied with notes on insect pests from the entomological section of the Indian Museum and includes brief accounts of insect enemies of forest trees, fruit trees, garden vegetables, cereals, corn, indigo, sugar cane, tea, opium, cotton, etc. A "lake fly" nuisance due to a species of Chironomus was investigated. It was found that this insect could be controlled by cleaning the borders of the lake, removing all weeds, and dredging away weeds and low mud banks which occur above the surface of the lake. The eggs of the fly are usually laid in such material.

The chinch bug in Maine, H. W. BRITCHER (*Maine Sta. Bul. 91, pp. 41–52, figs. 2*).—Descriptive biological and economic notes are given on this insect. The chinch bug is said to have been observed in Maine for the past 35 years. It is chiefly injurious to grasses and the remedies suggested are burning, spraying with kerosene or kerosene emulsion, and plowing under. A number of experiments were made for the purpose of testing the power of the chinch bug to withstand unusual conditions. As a result of these experiments it was found that the hibernation of the chinch bug does not represent a period of continuous torpidity, but a period which may be interrupted at any time during the winter by seasons of warm weather. Complete submersion in water, even for a considerable period, did not always prove fatal. Freezing in water was almost always fatal to chinch bugs, while freezing in a dry or moist atmosphere proved to be a less effective check.

The root borer of sugar cane, N. B. WATSON (*West Indian Bul., 4* (*1903*), *No. 1, pp. 37–47, figs. 3*).—Notes are given on the habits and life history of *Diaprepes abbreviatus*. The insect is described in its various stages. The unusual increase of this species is believed to be due to the destruction of birds and reptiles by the

mongoose. In order to control the insect it is recommended that sugar cane should not be planted on fields which have previously borne sweet potatoes, peanuts, or guinea corn, all of which serve as host plants for the borer. The use of lime on the land is believed to have a beneficial effect.

The yellow-winged locust (Camnula pellucida), C. B. SIMPSON (*U. S. Dept. Agr., Division of Entomology Circ. 53, pp. 5, fig. 1*).—This locust is said to have occurred in large numbers in Idaho and Utah during the last few years. Notes are given on its habits and life history. For controlling the insect the author recommends plowing the fields, spraying with oil, the use of hopperdozers, and arsenical baits.

The codling moth, E. D. SANDERSON (*Delaware Sta. Bul. 59, pp. 22, pl. 1, fig. 4*).—The codling moth is described in its various stages and notes are given on its life history. In Delaware there appears to be only a partial second brood and the insect winters almost without exception as a caterpillar. Brief notes are presented on its natural enemies and on the results of insecticide experiments. As a result of banding apple trees, from 4 to 15 per cent of the larvæ were caught. The use of trap lanterns was found to be of little value. Insecticide experiments were largely confined to spraying with arsenite of lime, Paris green, and Disparene, at the rate of 1 pt. per barrel, 1 lb. per 150 gal., and 3 lbs. per 150 gal., respectively. Arsenite of lime sprayed twice gave 20 per cent of benefit; Paris green sprayed twice, 61 per cent; Disparene with 1 application, 60 per cent, and with 2 applications, 87 per cent. Similar results were obtained in other series of experiments. The addition of 20 per cent of kerosene or crude oil appeared to have no bad effect upon the trees, but seemed to increase the number of wormy fruits. The addition of permanganate of potash, resin soap, molasses or glucose had no beneficial effect in increasing adhesion. Three applications of the insecticides appeared to be no better than 2. It was also found that the use of more than 1 lb. of Paris green to 200 gal. of water was no more effective than smaller quantities. Green arsenoid appeared to be equally effective with Paris green.

The codling moth, J. M. ALDRICH (*Idaho Sta. Bul. 36, pp. 137–155*).—Descriptive and biological notes are given on this insect. There are said to be 4 apple growing regions in Idaho. In southwestern Idaho, the most important apple shipping section of the State, great damage is done by codling moth, from 50 to 100 per cent of untreated apples being effected. Southeastern Idaho suffers but little injury from codling moth. In northern Idaho it is not a serious pest. Around Lewiston it once caused great damage, but at present apple trees are being replaced with other fruits which are not attacked by this insect. Observations made on the biology of the codling moth at Lewiston showed that the first worms entered the apples on June 19, the calyces of the apples having been open as late as May 10. The first moths appeared July 14 and moths from the larvæ of the second brood appeared on September 3 and 4. On unsprayed trees 52 per cent and on once-sprayed trees 44 per cent of apples were found to be infested when examined in October. This loss was believed to be almost wholly due to the third brood. In another instance the third brood appeared between September 15 and 21. As a rule, however, there are 2 broods in Idaho. Four series of spraying experiments were made to determine the comparative effectiveness of Paris green and arsenate of lead, to compare one application of spray at the time the blossoms fall with one made just before the worms enter the apple, and to compare 1 spraying with 2 or more. The results of these experiments show that Paris green is more effective than arsenate of lead and also more resistant to rain. Spraying just after the blossoms fall was more beneficial than applying as the worms were about to enter the apples. Two sprayings were recommended, where the larvæ appear in large numbers.

The control of the codling moth, C. B. SIMPSON (*U. S. Dept. Agr., Farmers' Bul. 171, pp. 24, figs. 4*).—Descriptive and economic notes are given on the codling moth.

An account is presented of the distribution of the insect, its natural enemies, and the artificial remedies to be adopted in controlling it. These remedies include spraying with arsenical insecticides, such as Paris green, London purple, and white arsenic compounds, and banding the trees. When these remedies are applied intelligently from 85 to 98 per cent of the fruit is saved, while without the application of any remedial measures from 85 to 100 per cent of the fruit becomes infested.

Two common scale insects of the orchard, W. E. Britton (*Connecticut State Sta. Bul. 143, pp. 10, pls. 2, figs. 5*).—Biological and economic notes are given on scurfy bark-louse and oyster-shell bark-louse. There is but 1 generation of these scales in Connecticut. The scurfy bark-louse is chiefly injurious in nursery and rows of newly set orchards, while the oyster-shell bark-louse is said to be found on nearly every old apple tree in Connecticut. Applications should be made during the first half of June or just after the eggs hatch. For this purpose common soap at the rate of 1 lb. in 8 gal. of water, or kerosene emulsion may be used.

Report of the inspector of San José scale, 1902, G. E. Fisher (*Toronto: Ontario Dept. Agr., 1903, pp. 24*).—The author discusses the general status of the San José scale problem in Ontario and gives notes on the entomological discussions held at the Pittsburg meeting of the Association of Economic Entomologists. Brief notes are also given on nursery inspection, municipal inspection, and the distribution of whale-oil soap, crude petroleum, lime-sulphur-salt, and other insecticides to the owners of infested orchards. The experiments conducted by the author during the season included tests of whale-oil soap, fish-oil emulsion, crude petroleum, crude oil and soap, lime-sulphur-salt wash, fumigation, and other methods for the destruction of the San José scale. Whale-oil soap was found to be an effective but costly remedy. An emulsion of fish oil, with or without potash, proved quite satisfactory. Diluted crude oil also proved to be an excellent remedy, but undiluted crude oil should be applied with care. Lime-sulphur-salt wash gave excellent results and was found to be quite safe for any kind of fruit trees. Formulas are given for the preparation of these various insecticides.

The scale insects of the lesser Antilles, II, H. Maxwell-Lefroy (*Imp. Dept. Agr. West Indies, Pamphlet 22, 1903, pp. 50, figs. 47*).—In this pamphlet the author continues his discussion of the scale insects of the Lesser Antilles, 31 species being dealt with. This makes a total of 51 species which are at present of economic importance or likely to prove so in the West Indies. Notes are given for the purpose of rendering identification of these species comparatively simple for fruit growers, and approved remedies are briefly discussed.

Scale insects of the West Indies, H. Maxwell-Lefroy (*West Indian Bul., 3 (1903), No. 4, pp. 295–319*).—Notes are given on the native and introduced species of scale insects in the West Indies and lists are presented of these species, together with others which are likely to be introduced into foreign countries from the West Indies. Special attention is given to the habits, food plants, predaceous and parasitic enemies, fungus diseases, and means of controlling these insects.

Scale insects and mites on citrus trees, C. L. Marlatt (*U. S. Dept. Agr., Farmers' Bul. 172, pp. 43, figs. 34*).—This bulletin contains in a condensed form material already published on the same subject in the Yearbook of this Department for 1900 (E. S. R., 13, p. 266).

Two insects injurious to the strawberry, J. M. Stedman (*Missouri Sta. Bul. 54, pp. 187–210, figs 5*).—The strawberry false worm (*Harpiphorus maculatus*) develops only 1 brood per year in Missouri. The larvae hatch out about the time the first strawberry blossoms appear and remain on the plants until the berries are ripe. Descriptive and biological notes are given on this species. The insect may be controlled by thorough dusting with pyrethrum. This substance may be sprayed upon the plants at any time, even when the fruit is ripe. It may be necessary to make 2 or 3 applications to control the pest. The larvae may also be destroyed by spraying

with powdered hellebore or Paris green, using the former in the proportion of 1 lb. to 3 gal. of water, and the latter at the rate of 1 lb., together with 3 lbs. fresh lime, in 150 gal. of water. These remedies, however, must not be applied after the berries begin to ripen. White hellebore is considered the best and safest remedy.

The common strawberry-leaf roller (*Phoxopteris comptana*) produces 3 broods annually and the insect is found in one or more stages throughout the summer. No practical remedy was found for the first brood, but the second and third broods may be destroyed by mowing the strawberry plants immediately after harvesting and burning them as soon as dry.

The organization of a campaign against the enemies of grapes, I. Pachoski (*Zap. Imp. Obshch. Selsk. Khoz. Yuzh. Ross., 72 (1902), No. 11–12, pp. 34–41*).—On account of the serious injuries to grapes from the attacks of insects in the region of Odessa, the author recommends that the government be requested to establish 2 experiment stations for the protection of cultivated plants. It is also recommended that the regular agricultural societies be urged to distribute instruments and insecticides such as would be required for carrying out the instructions of experts.

A disease of grapevines caused by Dactylopius vitis and Bornetina corium, L. Mangin and P. Viala (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 6, pp. 397–399*).—It was found that *Dactylopius vitis* causes considerable injury to grapevine roots in Palestine where this disease was investigated. The scale insects puncture the roots and cause an escape of sap, which is used by the fungus for its own growth. The fungus mycelium finally covers the scale insects so that they are protected against insecticides and other unfavorable conditions. The authors consider this to be a case of symbiosis. Experiments with remedies indicate that the scale insects are easily killed by injecting bisulphid of carbon into the soil before the fungus mycelium becomes too thick.

The white fly of greenhouses, C. M. Weed and A. F. Conradi (*New Hampshire Sta. Bul. 100, pp. 45–52, fig. 1*).—Various greenhouse crops in New Hampshire are said to be commonly attacked by the white fly. According to the observations of the authors the eggs hatch within 13 days. No evidence was obtained to show that the insect can pass the winter out of doors. Brief notes are given on the injuries produced by this insect upon plants. Experiments were made with Kerowater sprays, and with hydrocyanic-acid gas. The adult white flies were readily killed by spraying with a mechanical mixture of kerosene and water containing 5 per cent kerosene. The most successful and most satisfactory remedy, however, was fumigation with hydrocyanic-acid gas. A portion of a greenhouse containing 2,833 cu. ft. of space was treated by mixing 12 oz. of strong sulphuric acid, 12 oz. of potassium cyanid, and 1 gal. of water. The house was kept closed for 15 minutes. This and similar experiments were repeated, with the result that all adult flies appeared to be killed and none of the plants were injured. Directions are given for estimating the cu. ft. of space in greenhouses and for producing the gas.

Pests of coffee and means of combating them, J. Rossignon (*Cafetal, 1 (1903), No. 1, pp. 9, 10*).—The author discusses briefly the habits and life history of *Dactylopius destructor*, *Melolontha vulgaris*, *Lecanium coffeæ*, and *Hemileia vastatrix*. Formulas are presented for insecticides and fungicides which have been found effective in destroying these pests.

Animal pests of the rose, and means of controlling them, F. R. von Binnenthal (*Die Rosenschädlinge aus dem Tierreiche, deren wirksame Abwehr und Bekämpfung. Stuttgart: Eugen Ulmer, 1903, pp. X+392, figs. 50*).—This volume constitutes a handbook of information regarding insect pests of rosebushes, and various natural and artificial remedies for the control of these pests. The author presents an account of the typical forms of injuries to plants by insects, and also of the biology and life history of insects. One chapter is devoted to a discussion of remedies for the control of insects. These include the ultilization of natural enemies of insects and the

artificial application of various insecticides, such as tobacco decoction, Nessler's fluid, quassia, pyrethrum, hellebore, turpentine oil, kerosene, crude petroleum, carbolic acid, cresol, napthaline, Paris green, caustic lime, corrosive sublimate, carbon bisulphid, kainit, copper sulphate, copperas, proprietary remedies, and fumigation with various gases, including hydrocyanic-acid gas. The numerous insects which are known to be injurious to roses are classified according to their systematic position, and discussed under the orders to which they belong, including Coleoptera, Hymenoptera, Lepidoptera, Diptera, Neuroptera, Orthoptera, and Hemiptera. The author also discusses the injurious effects of red spiders and nematode worms. The volume is provided with an index which renders the information contained in it very accessible.

Antheræa cytherea on Pinus insignis at Fort Cunynghame plantation, J. SIMS (*Agr. Jour. Cape Good Hope, 22 (1903), No. 4, pp. 446–454, pls. 3*).—The caterpillars of this insect are reported as having defoliated *Pinus insignis* to a large extent and to cause some doubts as to the feasibility of successfully growing this tree in plantations. The depredations caused by the insects are becoming less pronounced from year to year, and the author believes that the tree can be cultivated despite the attacks of the caterpillars. Notes are given on the habits and life history of this insect. It is parasitised in the egg and caterpillar stages, and is also affected by a bacterial disease. No birds or mammals were observed feeding upon it.

The net-winged midges (Blepharoceridæ) of North America, V. L. KELLOGG (*Contrib. Biol., Hopkins Seaside Lab., Leland Stanford Jr. Univ., 1903, No. 30, pp. 183–232; pls. 5, fig. 1*).—Notes on the anatomy, habits, and life history of species of this family, a number of species being described as new.

Intraradical nutrition of diseased trees for the purpose of curing them and destroying parasites, I. SHEVUIREV (*Selsk. Khoz. i Lyesov., 209 (1903), Apr., pp. 58–103, figs. 5*).—The author describes a number of experiments in which various substances were introduced directly into the trunks and roots of trees, especially birch and apple trees, for the purpose of testing the absorptive power of these trees and the effect of the substance upon injurious insects. A list of substances thus used included potassium silicate, copper sulphate, various solutions of eosin, fuchsin, carmin, etc. These substances were introduced into the tree in openings produced by means of an auger. As a result of these experiments the author believes that a means has been found of benefiting the tree by nutrient solutions at the same time that insects are prevented from committing depredations upon the treated trees. A brief bibliography of this subject is presented.

The [Alabama] horticultural law. Notes on some of the insects and fungus diseases affecting horticultural crops, R. S. MACKINTOSH (*Alabama Sta. Bul. 124, pp. 73–104, figs. 8*).—A copy is given of the recent act passed by the Alabama legislature providing means for the protection of horticulture, fruit growing, and truck gardening. The horticulturist of the station is made State horticulturist in charge of the enforcement of this act. The pests specified in the act as dangerous are San José scale, new peach scale, black knot, crown gall, peach yellows, peach and plum rosette, and woolly aphis. Notes are given on the appearance, habits, and means of combating these pests and formulas are suggested for the preparation of suitable fungicides and insecticides.

Report of the inspector of fumigation appliances, 1902, P. W. HODGETTS (*Toronto: Ontario Dept. Agr., 1903, pp. 15, figs. 2*).—The condition of districts infested with San José scale is said to be quite serious. Brief notes are given on spring and fall inspection for this insect and on the results of experiments to determine the influence of hydrocyanic-acid gas on plants. Extensive tests with this insecticide showed that plants of all species bear treatment without harm.

Crude oil and soap, a new general insecticide, H. MAXWELL-LEFROY (*West Indian Bul., 3 (1903), No. 4, pp. 319–326*).—Attention is called to the desirability of using crude oil in the place of kerosene wherever possible on account of the much

greater cost of the latter. A number of kinds of crude oil have been used in the West Indies in combination with soaps. One formula which has been found to be quite effective is as follows: 10 lbs. whale-oil soap, $5\frac{1}{2}$ pts. crude Barbados oil, 4 oz. naphthalene. Kerosene emulsions were tested at the rate of 1 lb. to 10 gal. water and were found effective against plant lice, mealy bugs, and the majority of scale insects.

Spraying calendar for 1903, C. F. CURTISS, H. C. PRICE, and H. E. SUMMERS (*Iowa Sta. Spraying Calendar, 1903, pp. 8, fig. 1*).—This spraying calendar contains a list of economic plants, with notes on pests which attack them and approved remedies for controlling these pests. Formulas are also given for the preparation of the more important fungicides and insecticides.

Spraying calendar, L. R. TAFT and C. D. SMITH (*Michigan Sta. Spec. Bul. 19, folio*).—Formulas are given for the preparation of the more common insecticides and fungicides and a short list of economic plants is presented, showing the more important pests to which these plants are subjected, the remedies which should be applied, and the time of application.

Mosquitoes and other insects of the year 1902, R. H. PETTIT (*Michigan Sta. Spec. Bul. 17, pp. 26, figs. 26*).—Representatives of the genera Culex, Anopheles, Psorophora, Conchyliastes, and Urotænia are found in Michigan. An experiment was made on the college grounds in treating ponds with kerosene oil. The oil was applied at the rate of 1 oz. for 15 sq. ft. of water by the use of a knapsack pump. Applications were made at various intervals from April 26 to July 15. The season was unusually wet and strong winds helped to blow other mosquitoes into the grounds, so that the results of the experiment were left somewhat doubtful. Notes are given on the numbers of larvæ and pupæ in a given area. The effect of the oil persisted for about 3 weeks. A fungus belonging to the genus Entomophthora was observed living parasitic upon mosquitoes. The same fungus was found also on a fly and a species of Diplax.

Notes are given on the habits and injuries caused by *Lecanium longulum.* This scale was found to be parasitised by a fungus which is described as a new species, under the name *Isaria lecanifera.* Notes are given on the growth of this fungus on agar, potato, and corn meal.

Brief notes are also presented on *Pseudococcus acericola,* periodical cicada, Angoumois grain moth, hickory-bark beetle, and *Basilarchia arthemis.* The last-named insect is reported as injurious to young apple trees. Periodical cicada was found to be parasitised by the fungus *Massospora cicadina.*

Mosquitoes and other insects of the year 1902, R. H. PETTIT (*Michigan Sta. Bul. 204, pp. 13–20, figs. 4*).—A popular edition of Special Bulletin 17 noted above.

Mosquito extermination in practice, E. M. BENTLEY ET AL (*Lawrence, L. I.: Board of Health [1903], pp. 42, dgm. 1*).—The Board of Health of Lawrence, L. I., has undertaken the problem of destroying the mosquitoes in the vicinity of the town. The destruction of fresh-water mosquitoes was found to be very simple, while much more trouble was experienced in fighting the salt-water mosquito (*Culex sollicitans*). The use of oil or drainage of pools was found to be quite efficient in destroying the fresh-water mosquitoes. The observations made in Lawrence indicate that *C. sollicitans* may deposit eggs not in water but on mud at the roots of grasses. Another important fact was determined, viz, that this mosquito does not breed in places where the daily tides enter freely. Two plans were followed in fighting these mosquitoes—the use of petroleum on breeding pools, and ditches. The petroleum method was found to be too expensive, although quite effective. During the season about 6 miles of shore line was treated by the ditching method. During the progress of this work about 20 miles of ditches were made at a cost of about $1,700. The results were very encouraging. Brief notes are given on breeding of mosquitoes in

barrels, cans, and small pools in out-of-the-way places. C. B. Bennett presents biological and economic notes on *C. sollicitans*, *C. pipiens*, and Anopheles.

The fly and mosquito as carriers of disease, H. D. GEDDINGS (*Ohio Sanitary Bul., 7 (1903), No. 2-3, pp. 31-39*).—A popular discussion of the agency of flies and mosquitoes in carrying malaria, yellow fever, typhoid fever, and filariasis, together with notes on the means of eradicating the fly and mosquito nuisance.

Report of lecturer on apiculture, H. R. ROWSOME (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 147, 148*).—As a result of a number of experiments in stimulative feeding of bees it was found that the temperature of the hive could not be reduced without injury. Feeding with sirup containing a large proportion of water proved to be injurious, especially to old bees. Feeding with honey or properly prepared sirup indicated an advantage for this system of stimulative feeding. Notes are also given on the protection of bees in winter in chaff hives, storing honey in paper sacks and using unfinished sections.

Apiculture (*Jour. Jamaica Agr. Soc., 7 (1903), No. 4, pp. 145-148*).—Statistics are presented concerning the importation of honey into Great Britain, and the production of honey in California, Italy, and France. Brief notes are also given on the quality of honey produced in Jamaica.

Modern bee keeping, W. F. REID (*Jour. Soc. Arts, 51 (1903), No. 2631, pp. 522-529, figs. 9*).—The author presents an historical account of the development of knowledge concerning the habits and life history of bees and of the production of various devices for the more convenient management of bees and for increasing the production of honey.

Bee matters, A. GALE (*Agr. Gaz. New South Wales, 14 (1903), No. 3, pp. 247-251, figs. 2*).—The author briefly discusses the care of young swarms and the regulation of the time of swarming, together with an account of wire section-cradles and the use of these devices in ordinary hives.

An outline of the conditions and means of increasing the production of honey, A. KIRILLOV (*Selsk. Khoz. i Lyesov., 208 (1903), Feb., pp. 389-422; Mar., pp. 603-637, figs. 6*).—This article contains a general account of the various practices which have been found beneficial in increasing the yield of honey. The author devotes particular attention to a discussion of the location of the apiary, the construction of hives, efficiency of various breeds of bees, artificial feeding of bees, and care of swarms.

Bees as related to fruit growing, T. W. DITTO (*Agr. Student, 9 (1903), No. 8, pp. 165, 166*).—A popular account of the agency of bees in the fertilization of fruits.

The causes of the sexual differentiation in colonies of bees, F. DICKEL (*Arch. Physiol. [Pflüger], 95 (1903), No. 1-2, pp. 66-106, fig. 1*).—This article is of a controversial nature and in it the author seeks to show that the queen bee does not have the power of predetermining the sex of the bees which hatch from different eggs. It is maintained as a result of an extensive series of experiments carried on by the author that the queen bee lays but one kind of egg, and that all eggs are fertilized. The production of workers, queen bees, and drones from these eggs is brought about by different care and food which is provided by the worker bees. According to the author's experiments the worker bee appears to be the only possible source of the peculiar nutritive or stimulating food which is required to produce a queen bee from an egg which, if treated in the ordinary manner, would have given rise to a worker bee.

A new beehive with trapezoidal frames, J. FARCY (*Jour. Agr. Prat., n. ser., 5 (1903), No. 9, pp. 287-290, figs. 3*).—The author describes the details of structure of a hive used by P. Chiris, and containing trapezoidal frames. The external wall may be double, and the chief advantages of this form of frame are the case with which swarms may be protected against cold and the great convenience in removing frames for inspection.

Foul brood of bees; the symptoms, treatment, and means of preventing the infection of hives, A. Butkevich (*Selsk. Khoz. i Lyesov., 208 (1903), Jan., pp. 36–60*).—A detailed description is given of the symptoms of this disease and of the usual methods by which it is conveyed from one hive to another. For controlling the disease the author makes a number of recommendations based on his own observations and those of others. It is stated that foul brood is not as infectious or as difficult to eradicate as has usually been assumed. On the contrary, it appears to yield readily to treatment. In treating swarms for the presence of this disease the author recommends that the queen be removed and that the bees be kept in a swarming basket for about 3 days, after which they may be placed in the hive on clean comb and fed for a short time on sirup containing a small quantity of salicylic acid. In order to prevent the development of foul brood it is recommended that all colonies be fed in the spring on sirup containing salicylic acid and that all sour honey be removed.

Bacillus mesentericus and B. alvei, F. C. Harrison (*Rev. Internat. Apicult., 25 (1903), No. 2, pp. 29–32*).—This is a controversial article in which the author presents a number of arguments against the identity of these 2 organisms as claimed by Lambotte. The author believes that if these organisms were identical, foul brood of bees should occur spontaneously in countries where bees have never been imported from infected localities.

Raising silkworms in Algeria (*Bul. Agr. Algérie et Tunisie, 9 (1903), No. 6, pp. 121–128*).—Experiments have shown that both the mulberry and the silkworm thrive well in Algeria. The first definite experiments in this direction were begun in 1842. Notes are given on the life history of the silkworm, the feeding, and various other processes connected with the development of the worms, and the diseases to which silkworms are subject in Algeria.

FOODS—NUTRITION.

Studies on the digestibility and nutritive value of bread, H. Snyder (*U. S. Dept. Agr., Office of Experiment Stations Bul. 126, pp. 52, pls. 3*).—A number of experiments are reported on the digestibility and nutritive value of bread made from whole wheat, patent, and graham flours ground from hard spring wheat and soft winter wheat. In every case the different grades of flour were ground from the same lot of grain.

Briefly stated, the most important deductions from the results of these investigations with hard and soft wheat are in accord with the conclusions drawn from the earlier investigations of this series (E. S. R., 14, p. 770). The nutritive value of flour, in so far as the quantities of digestible protein, fats, and carbohydrates, and available energy are concerned, is not increased by milling the wheat in such a way as to retain a large proportion of bran and germ. The differences in the amounts of total nutrients furnished the body by the various grades of flour are, however, relatively small, all grades being quite thoroughly digested. The coarser flours have a tendency to increase peristaltic action, and are on this account especially valuable for some persons. Judged by composition and digestibility, all the flours are very nutritious foods, which experience has shown are wholesome as well. When also the fact is taken into account that they furnish nutritive material in an economical form, their importance is evident. The fact must not be lost sight of that using different grades of flour for bread making and other household purposes offers a convenient method of adding to the variety of the daily diet, a matter which is of undoubted importance.

The digestibility by man of peas cooked in soft and hard water, A. P. F. Richter (*Arch. Hyg., 46 (1903), No. 3, pp. 264–273*).—The author was himself the subject of experiments, each of 2 days' duration, in which about 600 gm. of cooked peas were eaten per day. In the first test the peas were cooked to a purée in dis-

tilled water and in the second in hard water, and in both cases the cooked material was passed through a sieve. The food and feces were analyzed. The peas cooked in distilled water were better borne and caused less digestive disturbances than the others. When cooked in distilled water the peas had the following coefficients of digestibility: Dry matter 92.86, protein 89.84, fat 87.56, and ash 81.09. When the peas were cooked in hard water the coefficients were as follows: Dry matter 91.08, protein 83.40, fat 58.92, and ash 51.78. Data are also given regarding the amount of calcium and magnesium oxid consumed and excreted in the urine and feces in the 2 experiments. The observed inferior assimilation of peas cooked in hard water the author attributes in part to the formation of alkaline earth albuminates and alkaline earth soaps which are not broken down by cooking or by the digestive juices, and in part by digestive disturbances caused by the alkaline earth salts, especially magnesium chlorid present in the hard water used.

Hens' eggs, E. CARPIAUX (*Bul. Agr.* [*Brussels*], *19* (*1903*), *No. 2, pp. 200–212*).—The importance of eggs as food is pointed out and a number of analyses, including determinations of phosphoric acid and lime, are reported of the eggs (whole egg, white, and yolk) of several different breeds of hens. In every case the eggs were cooked for an hour in a steam bath. It is stated that the loss in weight during cooking was insignificant, ranging from 0.03 to 0.1 gm. per egg. As was to be expected the weight of the eggs varied within rather wide limits, the Braekel eggs weighing on an average 66.45 gm. each, being the heaviest, and the eggs of bantams (Barbu d'Anvers), weighing 29.55 gm., being the smallest. The author notes that the proportion of yolk is greatest with the eggs of bantams and, generally speaking, with the eggs of the breeds best suited for fattening. Both the yolk and the white of the eggs of the different breeds varied somewhat in composition and the author discusses the differences at some length. Attention is especially called to the lecithin content of the yolk and its importance in nutrition.

Physiological economy in nutrition, R. H. CHITTENDEN (*Pop. Sci. Mo.*, *63* (*1903*), *No. 2, pp. 123–131*).—The author briefly reports an experiment with man in which the average amount of protein consumed per day was 44.9 gm. and the energy value of the diet 1,606 calories, the subject being practically in nitrogen equilibrium, the amount excreted in the urine and feces being on an average 6.90 gm. per day as compared with an income of 7.19 gm. The diet was very simple and the subject was careful to masticate it very thoroughly. The food is said to have been very thoroughly digested. On the basis of this experiment the possibility of the ordinary dietary standards being too large is discussed. However, it should be noted that the values chosen for comparison represent total nutrients and not digestible nutrients, the former being considerably in excess of the latter.

Metabolism of matter and energy at high altitudes, F. HUEPPE (*Arch. Physiol.* [*Pflüger*], *95* (*1903*), *No. 9–10, pp. 447–483*).—A summary and discussion of experiments on metabolism at high altitudes, with special reference to the needs of the body and the relative value of different nutritive materials.

The calculation of the heat of combustion from the elementary composition, E. VOIT (*Ztschr. Biol.*, *44* (*1903*), *No. 3, pp. 345–361*).—The author gives a formula which he has found to be useful for calculating the heat of combustion of chemical compounds by means of elementary composition, and discusses it at considerable length.

The fuel value of the oxygen in some substances of physiological importance, O. KRUMMACHER (*Ztschr. Biol.*, *44* (*1903*), *No. 3, pp. 362–375*).—Experiments which are reported lead the author to conclude that the heat of combustion of materials of complex composition can be calculated by the method proposed by E. Voit. (See above.)

Examination and valuation of preserved fruits and fruit marmalades, VON RAUMER (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, *6* (*1903*), *No. 11, pp. 481–492*).—

Chemical studies are reported and discussed which had to do with the fermentation and the adulteration of preserves and marmalades, the presence of added coloring matter, preservatives, etc.

Sustaining power of Demerara sugar (*Internat. Sugar Jour., 5 (1903), No. 52, p. 157*).—A brief note quoting Sir Martin Conway to the effect that he found a quarter of a pound of sugar per man per day of advantage as a food in mountain climbing.

Concerning respiratory metabolism during static work, A. Bornstein and E. Poher (*Arch. Physiol. [Pflüger], 95 (1903), No. 3-4, pp. 146-157*).—The effects of static work as distinguished from dynamic work were studied with special reference to changes in the respiratory quotient. The work consisted in holding a weight in the right hand, the arm being raised perpendicularly and the subject being in a reclining position. The authors conclude that metabolism is increased by static work, the amount being greater rather than directly proportional to the weight sustained, and also greater rather than directly proportional to the duration of the work.

The article is followed by a brief note by N. Zuntz.

The lecithans, their function in the life of the cell, W. Koch (*Univ. Chicago Decen. Pubs., 10 (1902), p. 1; abs. in Jour. Phys. Chem., 7 (1903), No. 3, pp. 230, 231*).—"Lecithan" is proposed as a name for the group including such compounds as egg lecithin, kephalin, myelin, paramyelin, etc. Data regarding the estimation of such bodies is given and their importance is discussed.

Contribution to the study of diuresis. VII, Diuresis when excretion is hindered, W. Filehne and W. Ruschhaupt (*Arch. Physiol. [Pflüger], 95 (1903), No. 9-10, pp. 409-438*).—Experimental data reported and discussed.

Contribution to the subject of diuresis. VIII, Further experiments on water absorption, W. Filehne and Biberfeld (*Arch. Physiol. [Pflüger], 95 (1903), No. 9-10, pp. 439-446*).—Continuing work noted above, experimental data are reported and discussed.

The tramp's handbook, H. Roberts (*London and New York: John Lane, 1903, pp. 175, pls. 9, figs. 34*).—In this volume the author pays especial attention to methods of camp cookery and gives information regarding the use as food of many sorts of game, fish, and vegetable products found in Great Britain, a number of which are not commonly eaten.

Progress in the examination of foods and condiments, including fats and oils, during the year 1902, Utz (*Oesterr. Chem. Ztg., 6 (1903), Nos. 6, pp. 121-124; 7, pp. 148-150; 10, pp. 221-224*).—A general summary.

Regulations of the superior board of health of Porto Rico (*San Juan: Board of Health, 1903, pp. 34*).—The text of the regulations governing the importation, sale, etc., of foods and drugs is given.

ANIMAL PRODUCTION.

Decomposition of feeding stuffs and foods by micro-organisms. IV, Cleavage of vegetable materials by bacteria, J. König, A. Spieckermann, and A. Olig (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), Nos. 5, pp. 193-217; 6, pp. 241-258; 7, pp. 289-296*).—An extended review of the literature of the subject is given and experiments are reported on the decomposition of cotton-seed meal by micro-organisms. The principal conclusions follow: The different sorts of micro-organisms decomposing cotton-seed meal have similar physiological characteristics and are affected by the composition of the meal and also by the air supply. When air is entirely excluded rod-like micro-organisms of the *Bacterium coli* type, which form sugar with the evolution of gas, develop freely, as well as the coccus types, which produce sugar without gas evolution. Indifferent varieties are also observed which do

not cause fermentation and require only a small amount of material for their nourishment. Obligate anaerobies do not ordinarily grow in cotton-seed meal. The acids produced by the bacteria which form sugar hinder the development of such forms.

When the amount of air is limited, only the sugar-fermenting varieties are observed in the inner portion of the decomposing meal. On the surface, bacilli with very resistant spores, which attack protein violently, soon gain the upper hand. These penetrate into the mass as the acid formed by the coli types is neutralized by the ammonia which they form. The bacterial growth is always accompanied by a measurable loss of organic material. When air is excluded this loss is largely carbohydrates. When the air supply is limited the loss at the beginning is almost entirely this nutrient. Later on protein and pentosans are actively attacked. Fat is generally only a little changed. Crude fiber is at first markedly increased and later diminished. The sugar fermenting bacteria decompose pentosans, fat, and probably proteids also, though in a less degree. They cause a marked fermentation of raffinose, producing gases and acids.

Bacteria which attack the proteids of cotton-seed meal cause the same kind of cleavage in vegetable and animal proteids, including fibrin. The following cleavage products were identified: Albuminose, peptones, amin bases, volatile fatty acids such as butyric and valeric acids, aromatic acids as phenylacetic and phenylpropionic acids, succinic acid, skatolcarbonic acid, aromatic oxygen acids, indol, skatol, phenol or kresol, ammonia, carbon dioxid, and volatile sulphur compounds. At no stage of the decomposition of cotton-seed meal were poisonous bodies formed by the bacteria commonly present, a fact which was brought out by physiological experiments.

Meat meal, V. SCHENKE (*Landw. Vers. Stat.*, *58* (*1903*), *No. 1–2*, *pp. 9–35*).—The available information regarding the composition and feeding value of meat meal has been summarized and discussed, experiments on the feeding value of this material for different farm animals being referred to in considerable detail.

Meat meal made from diseased animals, V. SCHENKE (*Landw. Vers. Stat.*, *58* (*1903*), *No. 1–2*, *pp. 36–54*).—The author has summarized the available information regarding the composition, feeding value, and wholesomeness of meal made from contaminated meat, diseased animals, etc. ("*Kadavermehl*"), the product being, of course, sterilized during the process of manufacture. A bibliography is included.

Fish meal, V. SCHENKE (*Landw. Vers. Stat.*, *58* (*1903*), *No. 1–2*, *pp. 55–64*).—On the basis of available information the composition and feeding value of fish meal is discussed at length. The article contains a bibliography.

The feeding value of fish meal, S. HALS and A. KAVLI (*Norsk. Landmandsblad*, *22* (*1903*), *No. 3*, *pp. 38–41*).—Analyses of fish meal made from slightly salted herring and from the offal of heavily salted herring are given. The percentage composition of the former was as follows: Water 11.11, protein 61.11, fat 14.06, and ash 11.79; of the latter, water 10.81, protein 49.29, fat 13.17, and ash 23.06. As shown by artificial digestion experiments the meal from whole herring furnished 12.7 lbs. of digestible fat and 56.3 lbs. of digestible protein per 100 lbs. Similar values for the offal meal were 11.9 and 42.6 lbs. The 2 kinds of fish meal, taking into account the fertilizer value, are to each other according to the author as 100 to 75.—F. W. WOLL.

New food for live stock in Germany, B. F. LIEFELD (*U. S. Consular Rpts.*, *71* (*1903*), *No. 268*, *pp. 79, 80*).—The manufacture and use of a blood molasses feed is described.

The use of molasses in feeding farm animals, B. DE LAUJARDIÈRE (*Bul. Agr. Algérie et Tunisie*, *9* (*1903*), *No. 7*, *pp. 153–155*).—The value of molasses is pointed out in this article, which is quoted from *Annales du Mérite Agricole*.

Cane-sugar molasses, A. and P. ANDOUARD (*Bul. Sta. Agron. Loire-Inférieure*, *1901–2*, *pp. 39–42*).—Proximate and ash analyses of cane and beet molasses are reported. Cane molasses is regarded as superior for animal feeding on account of its

low ash content, which was found to be 2.23 per cent as compared with 11.45 per cent in the beet molasses.

Cocoanut-oil meal (*Agr. News [Barbados], 1 (1902), No. 17, p. 259*).—Statistics are given concerning the production of cocoanuts and data are quoted regarding the composition and value of the nut and cake.

Local [peanut] oil cake (*Agr. Jour. and Min. Rec. Natal, 6 (1903), No. 5, pp. 151, 152*).—A brief note on the use of a peanut cake made from nuts grown in Natal.

Composition of green feed stuffs, J. C. Brünnich and W. Maxwell (*Queensland Agr. Jour., 12 (1903), No. 5, p. 356*).—Analyses are reported of samples of fresh *Panicum maximum*, *P. muticum*, and fresh and drought-dried *Paspalum dilatatum*.

Additional notes on West Indian fodders, F. Watts (*West Indian Bul., 3 (1903), No. 4, pp. 353–362*).—This paper includes analytical data and a discussion of the feeding value of guinea grass (*Panicum maximum*), para grass (*Panicum muticum*), bed grass (*Sporobolus indicus*), hay grass (*Andropogon caricosus*), guinea corn (*Sorghum vulgare*), *Stylosanthes procumbens*, and sugar-cane tops.

Analyses of some of the commercial feeding stuffs of Michigan, F. W. Robison (*Michigan Sta. Bul. 203, pp. 11*).—Feeding stuffs gathered from different parts of the State were analyzed. These include cotton-seed meal, oil-cake meal, oil meal (old process), gluten meals and feeds, malt sprouts, oat middlings, bran, mixed commercial feeds, breakfast food by-products, starch refuse, starch feed, and dried sugar-beet pulp. The approximate cost of protein in the different feeding stuffs is discussed.

Feeding stuffs, E. J. Russell and F. T. Holbrook (*Jour. Southeast. Agr. Col., Wye, 1903, No. 12, pp. 129–143*).—Analyses of a number of feeding stuffs are reported, including among others compound cakes and meals, cocoanut meal, urhur (an Indian pea meal), peanut cake, malt coombs (the rootlets of germinating barley), brewers' grains (fresh and dried), bean meal, and rice meal. The feeding value of a number of materials is discussed as well as the subject of balanced rations.

Glycogen, E. Pflüger (*Arch. Physiol. [Pflüger], 96 (1903), No. 1–8, pp. 1–398*).—An exhaustive summary of the subject, dealing with the origin, occurrence, and estimation of glycogen and related topics.

Concerning the nucleo-proteid of liver, I, J. Wohlgemuth (*Ztschr. Physiol. Chem., 37 (1903), No. 5–6, pp. 475–483*).—Experiments which are reported led to the conclusion that the carbohydrate of the liver nucleo-proteid is l-zylose.

Concerning resorption in the intestine, IV, R. Höber (*Arch. Physiol. [Pflüger], 94 (1903), No. 5–6, pp. 337–346*).—A continuation of earlier work (E. S. R., 13, p. 775) on the rapidity of resorption in the intestines, especially of salts of heavy metals which unite with proteids or proteid derivatives.

Chemical composition of the carcass of farm animals, L. Grandeau (*Jour. Agr. Prat., n. ser., 5 (1903), No. 20, pp. 626, 627*).—Data are quoted regarding the elementary composition of beef, mutton, and pork, mineral constituents present, etc.

Experiments with fattening steers, G. E. Day (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 69–71*).—Several recent tests carried on at the station are reported. In the first the comparative value of roots and silage was studied in continuation of previous work (E. S. R., 13, p. 1075). Five animals fed roots (turnips and mangels) and hay 2:1 in addition to grain made an average daily gain of 1.78 lbs. throughout the feeding period, which covered 119 days, 4.53 lbs. grain, 6.57 lbs. hay, and 13.94 lbs. roots being required per pound of gain. During the same time 8 steers fed corn silage and hay 2:1 in addition to grain made an average daily gain of 1.76 lbs. per steer, 4.32 lbs. grain, 6.48 lbs. hay, and 13.21 lbs. silage being required per pound of gain. The cost of a pound of gain in the 2 rations was 8.09 and 7.80 cents, rating roots and silage at the same price per ton.

"In this experiment, therefore, a ton of silage showed a higher feeding value than a ton of roots; and in this respect the result is similar to that of last year, though the difference in favor of silage was greater last year."

To determine whether it is more satisfactory in fattening steers to buy moderately heavy animals and feed them for a short period or lighter, thinner animals and continue feeding them for a longer period, 7 large steers were fed for 119 days and 6 smaller steers for 174 days, the larger animals being given 0.94 and the smaller animals 0.59 lb. of grain per day per 100 lbs. live weight. The heavy steers gained 1.83 lbs. per head per day, consuming 16.15 lbs. dry matter per pound of gain. Similar values for the other steers were 1.6 lbs. and 13.52 lbs.

The author notes that although the results were markedly in favor of the longer feeding period it would be unsafe to draw conclusions from a single test and proposes to make further trials.

In connection with the feeding experiments reported the relative gains made by 3-year-old and 2-year-old steers on the same ration were noted. The 3 older animals made an average daily gain of 1.87 lbs. per head for 119 days and the 4 younger animals of 1.82 lbs., the dry matter required per pound of gain in the 2 cases being 16.95 lbs. and 15.74 lbs. "While the 3-year-old steers made slightly the larger gains, they required more food for a pound of gain than the 2-year-old steers."

Phosphates for cattle, E. RYLEY (*Agr. Jour. and Min. Rec., 6 (1903), No. 4, pp. 130, 131*).—Directions are given for preparing a mixture of phosphates and other salts for use as a cattle lick.

Sheep breeding at the Agricultural College, J. MAHON (*Queensland Agr. Jour., 12 (1903), No. 5, pp. 313, 314*).—Brief notes regarding the breeding and management of sheep at the Queensland Agricultural College.

Fattening lambs, G. E. DAY (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, p. 71*).—Using 2 lots of 10 lambs each the comparative merits of roots and silage supplementing a ration of hay with 1.5 lbs. mixed grain per head was studied in a test covering 15 weeks. The roots and silage were fed with the hay in the proportion of 2:1. The average gain per lamb per week on the root ration was 2.12 lbs. and on the silage ration 1.81 lbs., the dry matter required per pound of gain in the 2 cases being 11.1 and 12.94 lbs., respectively.

Pig feeding experiments with cotton-seed meal, R. R. DINWIDDIE (*Arkansas Sta. Bul. 76, pp. 133–148*).—With a view to securing information regarding the harmful effects observed when cotton seed is fed to pigs, a number of tests were undertaken in which this material constituted a larger or smaller part of the ration. In the first series, which included 12 pigs, averaging from 30 to 50 lbs. in weight, 9 of the animals died in from 34 to 64 days when given a daily allowance per head of 0.6 to 0.8 lb. cotton-seed meal mixed with ground bran or corn. Three pigs fed bran and corn chops 1:3 only remained in good health, gaining 0.9 lb. per day for 56 days. It was noted that when mixed with wheat bran or wheat chops the cotton-seed meal was less dangerous than when mixed with ground corn. It is suggested that possibly this is because the corn mixture is not bulky enough. It is pointed out that the ration containing wheat bran or wheat chops, though the more satisfactory, is badly balanced and therefore wasteful.

In a later test with more bulky feed 14 pigs were given a mixture of cotton-seed meal, wheat bran, wheat chops, and cut cowpea hay for a period of 6 months without evident harmful effects, the quantity of cotton-seed meal eaten per day averaging from 0.8 to 1.4 per cent of the body weight, or from 0.4 to 0.7 lb. for a pig weighing 50 lbs. In one test cotton-seed meal in the same proportion was fed to a sow during the last 80 days of pregnancy without harm to mother or progeny.

It has been suggested that the harmful effects following cotton-seed feeding are due to the oil contained in the seed; therefore 3 pigs were fed for 20 weeks a ration of corn meal and wheat bran 1:2 (with some green feed during a part of the time) with from 1 to 4 oz. of crude cotton-seed oil added, an amount which is greater than that contained in a quantity of seed which proved fatal. No evil effects were noted

"and it is probable that the harmful effects of overfeeding with cotton-seed meal are not attributable to the oil which it contains."

In all cases post-mortem examinations were made of the pigs which died after consuming a ration containing cotton-seed meal. "The characteristic post-mortem feature of cotton-seed-meal poisoning in all our cases was an acute dropsy of the pleural and heart sacs with intense congestion (probably secondary) of the liver and kidneys, [the] immediate cause of death being suffocation from compression of the lungs." . . .

"The economy of feeding cotton-seed meal to pigs is a question which our experiments were not especially designed to solve, except in so far as this is influenced by the mortality of the feeding animals. Unless the percentage of deaths can be reduced to insignificant proportions, it is obvious that cotton-seed meal never can be an economical food. After a method of feeding has been evolved which secures this end, the comparative value of the food from an economic standpoint may be determined by appropriate tests.

"As we have seen, the maximum amount in which cotton-seed meal can be fed to hogs is about one-half pound per day to [young] pigs, and for larger animals probably about 1 lb. It can therefore only form a small proportion—one-sixth or so—of any purely grain ration fed, but even in this proportion may prove to be of economic value since it contains the most expensive elements of the ration. . . .

"As to the length of time which [a small quantity of] cotton-seed meal can be fed, it appears to be, if not indefinite, at least long enough to secure any economic advantages which this food could supply. A condition of relative immunity is probably acquired since none of our experimental animals died if they survived the first two months. On the other hand the poison of cotton-seed meal, when it produces symptoms at all, is evidently cumulative in its action, its effects being latent during the first month or more, abrupt and violent when they do appear."

Experiments with swine, G. E. DAY (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 72, 73*).—Continuing earlier work (E. S. R., 13, p. 1078) brief notes are given on the comparative merits of pasturing and soiling pigs, the green materials used being vetch and later rape. The grain fed in addition consisted of barley and middlings 3:1 during a greater part of the time. The pigs on pasture required 5.45 lbs. of grain per pound of gain and those fed in pens 5.47 lbs. Taking into account the fact that the pigs fed on pasture were superior at the start, the author concludes that inside feeding gave rather more economical gains.

"In each of 2 years, hogs pastured on rape, with a liberal allowance of meal, and hogs fed in pens, with a small allowance of rape, in addition to a full meal ration, gave bacon of excellent quality as to firmness.

"There seems to be no doubt that a moderate allowance of succulent food, such as clover, rape, vetches, or roots, has a beneficial influence upon the firmness of bacon."

The feeding of hay to pigs, A. E. MACLEOD (*Agr. Students' Gaz., n. ser., 11 (1903), No. 3, pp. 85, 86*).—The author states that he successfully employed chopped hay mixed with grain in feeding pigs in West Virginia. Wheat seeded down with timothy and clover or with clover alone, the latter being preferred, was followed by cut clover, and this by maize, the last crop in the rotation being oats.

The range hog as a forest problem, C. H. SHINN (*Forestry and Irrig., 9 (1903), No. 6, pp. 295–297, fig. 1*).—According to the author range hogs injure the seedling trees and pasturage in the Sierra forest reserves. The different plants eaten by the hogs are discussed.

Bacon curing as carried out at the Hawkesbury Agricultural College (*Queensland Agr. Jour., 12 (1903), No. 5, pp. 327, 328*).—Dry curing and brine curing of bacon are described.

A digest of recent experiments on horse feeding, C. F. LANGWORTHY (*U. S. Dept. Agr., Office of Experiment Stations Bul. 125, pp. 75*).—The principles of nutrition with especial reference to horses are discussed as well as the comparative value of feeding stuffs, methods of feeding, digestibility of feeding stuffs, watering, muscular work and its effect on food requirements, and related topics, the attempt being made to summarize available information on the subject, especially that afforded by the studies carried on at the experiment stations in the United States. Data were also collected showing the rations fed by express companies, cab companies, and others using large numbers of horses, and these rations are compared with those fed the farm horses of the experiment stations, army horses, etc.

Considering the data as a whole, the ratio by weight of coarse fodder or bulky feed to concentrated feed in the ordinary ration was found to be about 1:1. Crude fiber may perhaps be fairly considered as the characteristic constituent of coarse fodder. The ratio of crude fiber to protein in the average of a large number of American rations was found to be about 2:1.

From the available information it seems fair to conclude that, theoretically at least, any sufficient and rational mixture of wholesome grains, by-products, roots, and forage crops, green and cured, may be used to make up a ration, though there is a very general prejudice in favor of oats and hay, corn and hay or corn fodder, and barley and hay (frequently that made from cereal grains), the first-named ration being perhaps that most commonly regarded as satisfactory for horses. A corn ration is very commonly fed in the middle West and Southern United States—that is, in the corn-producing belt. The barley ration is quite characteristic of the Pacific coast region. In the semiarid regions of the United States Kafir corn and alfalfa have proved to be of great value, owing to their drought-resisting qualities. Both crops have been found useful for horse feeding. Of the two alfalfa has been used much more commonly, and has given very satisfactory results.

Horses require a considerable amount of water daily, the quantity varying with different seasons of the year, the amount of work performed, etc. The time of watering, whether before or after feeding, is a matter of little importance, and, generally speaking, may be regulated to suit the convenience of the feeder. Horses become used to either method of watering, and irregularity should be avoided, as sudden changes are apt to prove disturbing.

Judging by the average results, representing the practice of a large number of successful American feeders, and also the results of many tests at the experiment stations in different parts of the United States, horses with light work consume on an average a ration furnishing per day 0.99 pound of digestible protein and 14,890 calories of energy per 1,000 pounds live weight. Similar values for horses at moderate work are 1.49 pounds digestible protein and 22,710 calories.

Generally speaking, all these average values are less than those called for by the commonly accepted German feeding standards for horses performing the same amounts of work, yet from what is known regarding the American horses it seems fair to say that they were well fed.

Generally speaking, horses digest their feed, and especially the nitrogen-free extract and crude fiber in it, less thoroughly than ruminants.

Principles of horse feeding, C. F. LANGWORTHY (*U. S. Dept. Agr., Farmers' Bul. 170, pp. 44*).—The general principles of feeding are discussed with special reference to horses, and the results of recent experimental work, particularly that carried on at the experiment stations of the United States are summarized. The material in its present form is very largely an abridgment of the bulletin of the Office of Experiment Stations noted above.

Green food for farm horses (*Agr. Gaz. New South Wales, 14 (1903), No. 1, pp. 87, 88*).—The value of green feed for farm horses is insisted upon, alfalfa and sainfoin being considered the most useful. Methods of feeding green crops are briefly discussed.

Report of manager of poultry department W. R. GRAHAM (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 139–146*).—Brief statements are made regarding the poultry kept at the station farm, the eggs laid, and related topics. Considerable attention has been given to hatching hens' eggs and ducks' eggs with incubators, very poor results, it is stated, being obtained with ducks' eggs. The desirable characteristics for market poultry are also discussed and 3 feeding experiments are reported.

In the first test different breeds were compared when fattened in crates under uniform conditions. Twelve Barred Plymouth Rock cockerels, weighing together 37 lbs., gained on an average 2.1 lbs. each in 4 weeks, requiring 3.2 lbs. of grain per pound of gain. Eight high-grade Leghorns, weighing 18.25 lbs., made an average gain per fowl of 1.28 lbs., the grain required per pound of gain being 3.4 lbs. The ration fed to all consisted of barley meal, corn meal (or chop), shorts (or middlings), finely ground oats, and animal meal 2:2:2:1:1 mixed with about 1.5 times its weight of skim milk.

In the second test the merits of cooked food only (rolled oats, barley, and corn meal 2:1:1 fed with a cramming machine) was studied. In one instance 12 grade Plymouth Rock cockerels, weighing together 35.75 lbs., were fed 103 lbs. of the cooked feed (equivalent to about 34 lbs. of uncooked grain) in 2 weeks and made a total gain of only 5 lbs. "At the end of the 2 weeks the birds were very thin and sickly, their digestion being very bad. One of them died. The others were turned out on a grass run, and 2 of them died the second day they were out." The remainder improved in health after a time. After a week on raw feed the cooked grain mixture was given for 7 days to 12 Plymouth Rock chickens having a total weight of 62 lbs. They all lost in weight and 3 died. "The remaining 9 were placed on uncooked food the next week, and made a gain in weight of more than three-quarters of a pound each."

When the cooked grain was fed to a lot of 200 chickens for a week the majority lost in weight, although a few made small gains. A few of the best chickens were marketed, but were in poor condition and the test was discontinued.

"The chief difficulty with the cooked food appears to be that it damages the chicken's digestion. Some of the birds that were put on the grass run after being fed on cooked food, [had] not recovered . . . 3 weeks after being turned out. Cooked food can, no doubt, be fed to advantage in conjunction with raw food, but an all-cooked ration that is of a forcing nature appears to be entirely unsuitable for fattening fowls. These chickens were practically a total loss. Those that were turned loose never fully recovered."

In the third test, using 8 lots of 20 chickens each, the relative value of a mixed grain ration wet with whey, with skim milk, and with water was studied. In 2 cases in which the ration was mixed with water, animal meal, equivalent in amount to 12 per cent of the grain, was added before mixing. In one instance the grain and skim milk ration was supplemented by milk.

Considering the test as a whole, the lots fed grain mixed with skim milk, grain mixed with 12 per cent animal meal wet with water, and grain wet with skim milk and given milk to drink in addition made practically the same gains, namely, 20.5 lbs. per lot on the first, and 20 lbs. per lot on the last 2 rations mentioned. The smallest gain, 9 lbs., was made by the lot fed grain mixed with water. The grain required per pound of gain ranged from 2.45 lbs. with the lot fed grain wet with skim milk and given milk to drink in addition, to 7 lbs. in the case of the lot receiving the grain mixed with water. The cheapest gain, costing 3.9 cts. per pound, was made with the former lot and the most expensive, costing 9.8 cts., with the latter.

The author's principal conclusions were in effect as follows: Where a white skin is in demand for dressed poultry the skim-milk ration is the most satisfactory. The most economical gain was made when skim milk was given to drink, in addition to

the grain mixture being wet with it; but this mixture is not entirely satisfactory, as the chickens require very careful attention to keep them healthy. The grain ration to which 12 per cent animal meal was added, and the whole mixed with water, was very satisfactory, but the flesh has a yellowish tinge. The grain mixture wet with whey gave much better returns than was expected and it seemed to be fairly satisfactory. A grain mixture wet up with water is not to be recommended. All these rations, however, require further testing before definite conclusions can be reached.

Raising chickens, C. J. CALLOWAY (*Tuskegee Norm. and Inst., Farmers' Leaflet No. 14, pp. 8, figs. 7*).—Breeds, feeding, and other topics connected with chicken raising are discussed, and a few notes on farm management are given.

The egg-producing hen, T. E. ORR (*Missouri State Bd. Agr. Mo. Bul., 3 (1903), No. 2, pp. 16, fig. 1*).—The possibilities of profitable egg production are discussed with reference to breeds, feeds, etc., and statistics are quoted of the poultry and egg industry in Missouri and other States. The author briefly describes some experiments with laying hens conducted under his direction a number of years ago, and also quotes from work of the Utah Station previously noted (E. S. R., 12, p. 674).

Preservation of eggs, E. BROWN (*Jour. Bd. Agr. [London], 9 (1903), No. 4, pp. 494–497*) —Limewater, water-glass solution, and cold storage are said to be the best methods of preserving eggs. Some of the author's general suggestions follow:

"Eggs for preservation should be treated as soon as possible after they are laid, but not until they have been cooled. Eggs should not be treated in a warm place, and where limewater or water-glass is used the preparation should be quite cold before the eggs are placed in the solution. Eggs from hens fed chiefly upon grain, and with full liberty, are likely to keep better than those laid by fowls in confined runs. The general experience has been that infertile eggs keep in good condition longer than those which contain a living germ. Probably this is less apparent when eggs are preserved at a low temperature. When eggs are preserved in water glass or limewater the containing vessels should be stored in a cool place, at a temperature not less than 33° F., or more than 45°. A cool, sweet cellar is excellent for this purpose. Exposure to a higher temperature even for a few hours will cause deterioration, in spite of the preservative. Preserved eggs should be carefully tested by light before they are sold. The best months for preserving are March, April, May, and June. It has been found in many cases that summer eggs do not keep nearly so well as those laid prior to the hot days.

"Preserved eggs should be sold under that designation, and not as 'newlaids,' or 'breakfast,' or 'fresh' eggs."

About eggs, G. BRADSHAW (*Agr. Gaz. New South Wales, 14 (1903), No. 2, pp. 127–133, pl. 1*).—The development of eggs, their composition, and related topics are spoken of, as well as the local egg industry.

A modern ostrich farm, E. H. RYDALL (*Reliable Poultry Journal, 10 (1903), No. 4, pp. 440, 441, figs. 3*).—Ostrich rearing, feeding, and related topics are discussed.

Fish food, R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 37, 38*).—Analyses are reported of a food for young trout and of beef liver, which is also used for the same purpose.

Two new textile fibers, G. SELLERGREN (*K. Landt. Akad. Handl. och Tidskr. 42 (1903), No. 1, pp. 35–41, pl. 1*).—A description of Aramina fiber from Brazil and of wool of the Swedish musk ox (*Ovibos moschatus*).—F. W. WOLL.

DAIRY FARMING—DAIRYING.

Vetch, cowpea, and soy bean hay as substitutes for wheat bran, J. F. DUGGAR (*Alabama College Sta. Bul. 123, pp. 51-72*).—In the first feeding experiment reported hairy-vetch hay was compared with wheat bran. The test was made with 2 lots of 3 Jersey cows each and lasted 8 weeks. The aim was to feed equal quantities of hay and bran in addition to a uniform basal ration. The results showed that 834.6

lbs. of hay was actually consumed in contrast to 890.4 lbs. of bran. The average waste in feeding vetch hay was 6 per cent, which was not included in calculating the results. At local prices for feeding stuffs, including wheat bran at $20 per ton and vetch hay at $10 per ton, the daily cost of the vetch ration per cow was 10.3 cts. and the bran ration 14 cts., making a difference of $1.11 per month in favor of the vetch ration. On the vetch ration the average yield per cow per day was 16 lbs. of milk and 1.03 lbs. of butter, and on the bran ration 15.8 lbs. of milk and 1.05 lbs. of butter, showing that the 2 rations were practically of equal value as regards milk and butter production. The estimated saving in cost of producing 1 lb. of butter on the vetch ration as compared with the bran ration was 3.4 cts., or 25 per cent.

In the second experiment, conducted on the same plan as the first, cowpea hay was substituted for wheat bran. As 16 per cent of the cowpea hay was rejected a greater amount was fed than that of bran. In 30 days 6 cows were fed 1,411 lbs. of cowpea hay, of which the quantity actually eaten was 1,176 lbs. Under the same conditions the bran eaten amounted to 1,097 lbs. On the cowpea ration the average daily yield per cow was 17.3 lbs. of milk and 1.13 lbs. of butter and on the bran ration 16 lbs. of milk and 1.02 lbs. of butter. With bran at $20 per ton and cowpea hay at $10 and including the waste in feeding cowpea hay the average cost of food for 1 lb. of butter was 12.3 cts. on the cowpea ration and 15.9 cts. on the bran ration, showing a difference of 23 per cent in cost. While the cowpea hay consumed was 7 per cent greater than that of bran, the yield of butter was increased 11 per cent. The waste in feeding cowpea hay was not decreased by running the hay through a feed cutter.

The 2 experiments showed that in rations containing 6 to 10 lbs. of concentrated feeds, vetch hay or cowpea was substituted for a part of the wheat bran with satisfactory results. The extent to which this substitution of leguminous hay may be carried is to be studied in future tests.

Two additional tests conducted for short periods are also reported. In one 6.8 lbs. of corn hearts, a by-product obtained in the manufacture of grits or hominy, was substituted for 7 lbs. of wheat bran, the results showing a difference of 7 per cent in milk production and 8 per cent in butter in favor of corn hearts. Soy bean hay was compared with cowpea, the waste in this test being, respectively, 32 and 22 per cent. On the basis of equal quantities actually consumed, soy beans produced 3.5 per cent more milk and 4.5 per cent more butter than cowpeas, the difference being fully counterbalanced, however, by the greater waste.

The digestible nutrients in the different rations fed in the experiments are given in tabular form.

From determinations made at different periods it was found that manure, including bedding, was produced by cows at the rate of 1,749 lbs. per month. Under conditions of continuous stabling 56.8 lbs., exclusive of bedding, was produced daily per cow. Practically one-half the manure was produced during a stabling period of 16 hours as compared with 8 hours out of doors.

Yield and fat content of milk from cows fed on mangels, J. Percival et al. (*Univ. Col. Reading Agr. Dept., Ann. Rpt. Field Trials and Expts. 1902, pp. 39, dgms. 8*).—An experiment was planned to compare the influence of 4 varieties of mangel-wurzels on the yield and quality of milk. The results were inconclusive so far as this object was concerned. They are, however, of interest in showing the yield and fat content of milk with intervals between milkings of 15 and 9 hours, respectively. Detailed data for 6 weeks are given for 8 cows milked at 6.30 a. m. and 3.30 p. m.

The percentage of fat in the milk was lowest in the morning or after the long interval. The milk of individual cows was below the legal standard of 3 per cent of fat on from 1 to 41 mornings out of 42, the average being about 26. On only 4 mornings did the mixed milk of the 8 cows contain 3 per cent or more of fat. The absolute yield of butter fat of 7 of the 8 cows, however, was greatest in the morning.

The yield of milk of individual cows was from 2 to 9 lbs. higher in the morning than in the evening.

Variation in the milk of a dairy herd during the winter months, T. S. DYMOND and B. W. BULL (*Essex Education Com., County Tech. Labs., 1903, Mar., pp. 19, dgm. 1*).—A detailed record is given of 4 Shorthorn cows from November 18 to February 28, together with weather conditions. The influence of food and weather upon variations in milk is discussed and the following conclusion is drawn: "Throughout this experiment the considerable variations in fat and solids have not been to any great extent due to alterations in food or alterations in weather, or to any external condition under which the cows were kept and which the dairy farmer could control. The important point is to recognize that these changes in quality are constantly taking place, but since they are not usually dependent on external conditions, but on the idiosyncratic variations of each cow, almost complete uniformity can be obtained by mixing the milk of a sufficient number of cows. In this experiment the mixing of the milk of 4 cows has been sufficient, but it would undoubtedly be desirable to mix the milk of a much larger number. How this can be carried out is a subject which must be left to practical men to discuss."

The covered pail a factor in sanitary milk production, W. A. STOCKING, JR. (*Connecticut Storrs Sta. Bul. 25, pp. 24, figs. 2*).—This is reprinted from the report of the station for 1901 (E. S. R., 10, p. 1007), with minor changes, including the addition of several diagrams.

Bacteria in milk and its products, H. W. CONN (*Philadelphia: P. Blakiston's Son & Co., 1903, pp. 306, figs. 43*).—This book, as stated in the subtitle, is designed for the use of students in dairying and for all others concerned in the handling of milk, butter, or cheese. Chapters are devoted to the nature of bacteria, sources of bacteria in milk, types of milk bacteria, growth of bacteria in milk, milk bacteria and health, protection of the consumer of milk products, bacteria in butter, bacteria in cheese, and the bacteriological analysis of milk. The great extent to which successful dairying is dependent upon bacteriology and the important relation of the milk supply to the dissemination of diseases make this thoroughly up-to-date work written in plain language exceedingly valuable. The book contains not only the results of recent progress along the lines discussed, but considerable new matter resulting from the author's own investigations. A bibliography of the more important recent literature, arranged topically, is appended.

Report of the professor of dairy husbandry, H. H. DEAN (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 56–68*).—Several lines of experiments in progress are reported upon.

Methods of handling milk for household purposes were compared, a scale of points being adopted for judging milk treated in different ways. In the first series of experiments the following was used: Smell 20, taste 25, acidity 30, depth of cream 15, appearance 10. In the second series the maximum for acidity was increased to 35 and that for appearance was reduced to 5. A vat of milk was divided into 6 lots, which were respectively clarified by running through a cream separator, pasteurized at 140° F., clarified at 140°, pasteurized at 160°, and clarified at 160°, one lot being kept for control. In the second series milk was also filtered. Pint samples of the different lots were placed in a refrigerator at 40° for 24 hours, and were then kept in a room at 70° for 3 hours, at the end of which period they were scored. After remaining at this temperature for 24 hours they were scored a second time. As regards depth of cream and appearance, normal and clarified samples led in both scorings. At the first scoring the highest average was obtained by milk pasteurized at 140° in the first series and 160° in the second series, and at the second scoring by milk pasteurized at 160° in both series. In these tests clarifying and filtering did not seem to have any advantage. "For customers who judge the value of the milk by the depth of cream and by its appearance, normal and clarified milk will suit best.

as the pasteurization of the milk prevents the cream from rising, and the bottle of milk does not present so pleasing an appearance. On the other hand, those who desire milk to remain sweet for 24 to 48 hours after delivery, especially if no refrigerator is convenient, and who wish to insure against disease germs in the milk, will find the pasteurized milk much better, especially that heated to 160°."

Measuring cream was compared with weighing. The measurements were made in inches in a pail 12 in. in diameter. Cream testing 15 to 20 per cent of fat was found to weigh 4.19 lbs. per inch; cream testing 20 to 25 per cent, 4.15 lbs.; cream testing 25 to 35 per cent, 4.10 lbs.; and cream testing 35 to 40 per cent, 4.07 lbs. The author recommends as a standard 4.1 lbs. per inch of cream, and that on the grounds of convenience in gathering for creameries cream should be measured instead of weighed. The use of the Babcock test is advised in preference to the oil test, which is reported as commonly used in cream gathering creameries in Ontario.

A vat of milk was divided into 4 portions, which were separated at temperatures of 85, 140, 160, and 180 to 185°. The different lots were ripened and churned separately and the butter was placed in cold storage and scored at the end of 1, 2, and 3 months. The experiment was repeated each month for 3 months. The butter from milk pasteurized at 180 to 185° stood first in quality, that from milk pasteurized at 160° second, and that from milk pasteurized at 140° third. The butter from unpasteurized cream was poorest. As the results of the present experiments in the pasteurization of milk for butter making confirm those previously obtained, it is intended to discontinue this line of work. The following conclusion is drawn: "Butter made from milk heated to 180 to 185° possesses undoubted keeping qualities not obtained by separating at ordinary temperatures, nor by heating to temperatures ranging from 140 to 160°. For export butter, pasteurization of the milk or cream at a temperature of from 180 to 185° is a decided advantage. Pasteurization is also advisable when making butter to place in cold storage."

In all, 44 experiments were made in ripening cream at temperatures from 55 to 80°. There was very little difference in the quality of the butter made from cream ripened at the different temperatures. In general, however, a temperature of 65° was found most satisfactory. In experiments made during the summer, lots of cream were divided into groups containing 0.4 to 0.5 per cent of acid, 0.5 to 0.6 per cent, 0.6 to 0.7 per cent, and 0.7 to 0.8 per cent. The butter made from each group was scored from 2 to 4 weeks after making and again a month later. "There was not much difference in the flavor of the butter in the different groups at the first scoring, but at the second scoring the samples made from cream with high acidity appeared to lose flavor more than those with low to medium acid, 0.4 to 0.6 per cent. It is altogether likely that the acid may vary considerably in cream without materially affecting the quality of the butter. For 'keeping butter' it is not advisable to have more than 0.6 to 0.7 per cent acid in cream testing 25 to 35 per cent fat."

The average results of 32 trials in making butter from cream containing different percentages of fat showed a score for flavor of 40.8 for cream testing 15 to 20 per cent of fat, 41 for cream testing 20 to 25 per cent, 40.9 for cream testing 25 to 30 per cent, 40.6 for cream testing 30 to 35 per cent, 41 for cream testing 35 to 40 per cent, and 40.5 for cream testing 40 to 45 per cent, the maximum score being 45. There was also very little difference in the keeping quality of the different lots of butter.

Data are given for experiments on the effect of churning, washing, draining, salting, and working butter upon the content of moisture and salt, from which conclusions are drawn varying in some respects from the results of earlier work along this line.

"There was little or no difference in the moisture and salt contents of the butters, whether churned to the size of wheat or of corn grains. In 1901 the samples churned to the size of corn grains contained the highest percentage of moisture and salt.

"The moisture and salt in the finished butter was very similar, whether washed with brine or with water. There was also little or no difference in the quality of the butter.

"The lots drained before salting at the rate of ¾ oz. salt per pound of fat in the cream, contained less moisture, and within one-half of 1 per cent the same amount of salt as lots not drained and salted 1 oz. per pound of fat in the cream.

"The unsalted samples contained an average of 13.239 per cent moisture. Those salted at the rate of ½ oz. salt per pound butter contained 12.996 per cent of moisture and 1.84 per cent salt. The lots salted 1 oz. per pound of butter contained an average of 13.562 per cent of moisture and 3.64 per cent of salt. In 1901, the unsalted butter contained the least moisture, in 1900 the most moisture, and this year it takes a medium position. The results indicate that the moisture content in unsalted butter is not necessarily higher than that in similar butter salted.

"Butter worked once, twice, and three times contained, respectively, 12.541, 12.246, and 11.759 per cent of moisture, and 3.65, 3.31, and 2.62 per cent of salt.

"Samples worked slightly before salting and then salted from one-half to three-quarters of an ounce per pound of butter had 13.791 per cent moisture and 3.41 per cent salt, while similar lots treated in the usual way and salted 1 oz. per pound of butter contained 13.995 per cent moisture and 4.06 per cent salt.

"The amount of moisture in the finished product is largely determined by the working which it receives. The salt depends upon the amount of salt added, the moisture in the butter at the time of adding the salt, and the amount of working given to the butter."

Experiments in ripening cheese are noted below from the report of the chemist.

Heating curds made from overripe milk to 110° instead of 98°, especially when combined with washing the curd after milling to remove the excess of acid, was found in preliminary experiments to give good results as regards the flavor and texture of the cheese.

Curds were washed after dipping in water at 98°, equal in quantity to the weight of the curd in one series of experiments and to twice the weight of the curd in another series. Similar experiments were made in washing curds after milling. From the results of the present and earlier work the following conclusion is drawn: "After 3 seasons of careful work, we find it no advantage to wash all curds, and it tends to cause loss of valuable cheese-making material. It also tends to produce 'open' cheese. Curds having a bad flavor or those having too much acid are benefited by washing, but to advise the washing of all curds we consider a mistake on the part of those advocating this method."

Determinations of the moisture in curd at the time of dipping and milling and in green and cured cheese are reported in tabular form. Several variations in the method of manufacture are noted. The work is noted as preliminary to further investigations along this line.

In continuation of experiments reported in 1901, 18 comparative tests were made of ripening cheese in well-lighted and dark rooms, the results for both years showing little difference in the quality of the cheese or loss in weight as regards light, so long as the temperature and moisture are favorable.

Cheeses were coated with paraffin as soon as taken from the press and after periods of 1, 2, and 3 weeks, and compared with uncoated cheese as regards quality and loss in weight. Two series of experiments are reported, from the results of which the following conclusion is drawn: "Dipping cheese in hot paraffin wax when about one week old prevents loss of moisture and adds somewhat to the appearance of the cheese, but does not prevent the growth of mold. The cheese ripened in an ordinary curing room and coated with the wax was poorer in quality in one series and better in the other. In cold storage the quality was slightly better as a result of paraffining. Whether or not it will pay to coat cheese with paraffin wax is a ques-

tion not settled yet. If paraffining is done, the best results are got by coating when cheeses are about one week old."

The average yearly production of the 20 cows in the dairy herd was 6,673 lbs. of milk and 250.87 lbs. of fat.

Water in butter, R. Harcourt (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 38, 39*).—A sample of butter sold in Toronto at the regular market price was found upon examination to contain 53.15 per cent of water, 41.21 per cent of fat, 1.50 per cent of curd, and 4.14 per cent of salt. The butter apparently contained no foreign fats. "The chief fault to be found with the butter was its abnormally high water content. No doubt it had been treated with one of the so-called nostrums, which have made it possible for the dealer to make a handsome profit in selling water at 20 and 22 cts. per pound."

Does the amount of nitrogenous matter in butter affect its keeping quality? R. Harcourt (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, p. 39*).—The percentages of nitrogen in a number of samples of butter made in different ways were determined for the purpose of obtaining data that would help to answer this question. The results, while not conclusive, are considered as indicating that the presence of more or less nitrogenous matter in butter does not necessarily affect its keeping quality.

Reports of experiments to determine the causes of the low percentage of volatile fatty acids in Netherland butter (*Verzamel. Verslag. Rijk Gesubsidiëerde Proefvelden, etc., 1901–2, pp. 1405–1543, dgms. 12*).—This consists of a series of reports by the directors of the different stations.

Report of K. H. M. van der Zande on the work in North Holland (pp. 1406–1426).—Experiments were made to determine the effect of early stabling to protect cows from unfavorable weather and also to determine the effect of changes in food. Four groups of cows were used, the first and second being stabled October 7, while the third and fourth remained on pasture. Of the 2 groups in the stable, the first was fed on freshly cut grass taken from a field precisely similar to that on which group 3 was pastured. Group 2 received the regular winter ration of hay and linseed meal. Groups 3 and 4 remained out of doors until December 14, group 3 having pasturage only, while group 4 received linseed meal in addition. Samples of milk were obtained each week, from which butter was made. Early stabling was found to be harmful and to lower the percentage of volatile fatty acids. The change of food, together with early stabling, was even more harmful than early stabling alone. The addition of linseed meal to the pasture feed also resulted in a decrease in the percentage of volatile fatty acids.

Report of M. H. M. van der Zande on the work in Friesland (pp. 1427–1473).—These experiments were carried on at 6 places in Friesland, at each of which 2 adjoining farms as nearly alike as possible were selected. At each place the cows on one of the farms were stabled early, on the other late. The food given after stabling was the ordinary ration. The results of all the tests show that the average decrease in the percentage of volatile fatty acids was as great for the cows stabled early as for those stabled late.

Report of B. Sjollema on the work in Groningen (pp. 1474–1514).—The experiments in this province were designed to determine if the method of ripening cream in butter making exerts any influence on the percentage of volatile fatty acids, the effect of adding a concentrated feed to pasturage and also the effect of sheltering cows at night during the fall, and the effect of feeding beet tops. It was found that the method of ripening the cream had no influence on the percentage of volatile fatty acids in the butter. In regard to the effect of stabling cows at night to protect them from the weather it was found that in case the decrease in volatile fatty acids was slight, such protection might check a further decrease, but that the effect was unimportant and unreliable. The character of the food was shown to have great

influence. Butter from cows fed on young fresh growth, as young clover, had a decidedly higher percentage of volatile fatty acids than butter from cows fed on rather worn-out grass land. The addition of linseed meal to pasturage had an injurious effect, but when all the cows were subsequently turned on young clover those that had been fed linseed meal showed a more marked improvement than the others. It was found that the time when the percentage of volatile fatty acids decreased corresponded with the time when the growth of the grass ceased. The individuality of each cow is believed also to be an important factor in determining the percentage of volatile fatty acids in butter. The experiments on the effect of feeding beet tops were made with 4 cows. Two of the cows on pasture were fed beet tops ad libitum and one week later beet tops were also given to the other 2 cows. The effect of the beet tops was apparent at once in an increase in the yield and fat content of the milk and in the percentage of volatile fatty acids in the butter. To determine what constituents in the beet tops caused the favorable results 6 cows were divided into 3 groups, group 1 being fed beet tops, group 2 sugar beets, and group 3 barley meal. After receiving beet tops for several days, group 1 was fed beet leaves alone for 1 week. The milk from this group showed at first a slight decline in the volatile fatty acids, followed by a sudden drop at the time when the cattle received only beet leaves. The results with group 2 showed a great increase in the percentage of volatile fatty acids, followed by a decrease as soon as the cows were again fed beet tops. The feeding of barley meal to group 3 resulted in a decrease in the volatile fatty acids, followed by an increase when the cows were fed beet tops. Two groups of cows were also fed molasses or unrefined sugar, the results showing a marked increase in the volatile fatty acids in the butter. The results of the tests as a whole indicate that the sugar in the beet was the cause of the increase in the volatile fatty acids.

Report of D. A. J. Swaving on the work in Zeeland (pp. 1515–1535).—The conclusions reached in these experiments were, that late pasturing decreases the amount of volatile fatty acids in the butter due largely to the poor condition of the pasture, that stabling alone will maintain the percentage of volatile fatty acids, that a change of feed at once affects the composition of the butter fat, and that by proper additional feed it is possible to maintain a satisfactory content of volatile fatty acids in butter even with late pasturing.

Report of J. J. L. van Rijn on work at Limburg and North Brabant (pp. 1535–1543).—The butter made in these provinces during the fall months has a higher percentage of volatile fatty acids than is found in the butter made in the northern provinces, and the author is convinced that this is due to differences in the methods of feeding. Information collected from a large number of factories as regards methods of feeding cows and handling the milk constitutes the main part of this report.—H. M. PIETERS.

Investigations regarding the ripening of cheese, R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 40, 41*).—Some of the results obtained in investigations of the chemical changes taking place in casein during the ripening of cheese at different temperatures are briefly reported. Once each month, from April to November 2, cheeses were made under uniform conditions from the same vat of milk, one of which was cured in cold storage at 38 to 40° F. and the other in the ordinary curing room at 65°. The percentage of casein soluble in water was determined at frequent intervals. Cheese made in June, July, and August ripened much more rapidly than cheese made in April and May. This was true not only in the case of cheese ripened in the curing room but also of cheese ripened in cold storage where the temperature remained uniform. Cheese kept in cold storage from the last of April to the middle of August ripened much more rapidly upon being transferred to the ordinary curing room. No corresponding check in the rate of ripening, however, was observed in the case of cheese transferred at the same time from the curing room to cold storage. The results so far obtained in the investigations in progress indicate that cheese will ripen about as much during 1 month in the ordinary curing

room as during 4 months in cold storage. A fuller report is promised upon the completion of the studies.

Annual reports of the dairymen's associations of the Province of Ontario, 1902 (*Ontario Dairymen's Assocs. Rpts., pp. 224*).—Among the large number of subjects discussed at the two meetings held, mention may be made of the following: Cheese Making, by G. G. Publow, G. H. Barr, and others; Injurious Flavors in Cheese, by F. C. Harrison; Organized Effort for the Promotion of the Dairy Industry in the United States, by H. E. Alvord; Cool Curing of Cheese, by J. A. Ruddick and R. M. Ballantyne; Rennet, Hot Iron, and Acidimeter Tests in Cheese Making, by H. H. Dean; Butter Making, by H. H. Dean, A. Smith, W. Waddell, J. W. Hart, and others; Work of the Experimental Farms, by W. Saunders; Bacteriology in Relation to Dairying, by W. T. Connell; Analysis of Cheese, by T. Macfarlane; Transportation of Dairy Products, by J. W. Robertson; Government Relations to the Dairy Industry in the United States, by H. E. Alvord; Ontario Agriculture, Past and Present, by C. C. James; and Water Content of Canadian Creamery Butter, by F. T. Shutt.

VETERINARY SCIENCE AND PRACTICE.

Experimental studies on bacterial antagonism, A. Lode (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 3, Orig., pp. 196–208, figs. 8*).—Attention is called to the evident antagonism between different bacteria, as thus far observed in cultures by various investigators. A similar antagonism was found to exist between the filtered metabolic products of these bacteria. The active principles in this antagonism may be utilized. Detailed notes are given on the behavior of antagonistic bacteria when cultivated close together on the same medium. Experiments were made on the animals to determine whether the metabolic products of bacteria could be utilized for curative or preventive purposes. These experiments were made on mice and gave entirely negative results, so that little is expected from this method.

Some observations on the protective bodies and on their relation to bacterial virulence, E. W. A. Walker (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 4, Orig., pp. 297–311*).—The author's experiments were chiefly confined to rabbits and the organism used was the typhoid bacillus. It was found that the amount of the complement present in the serum varies from hour to hour after the blood is shed and suddenly increases during the first few hours if the serum is left in contact with the blood clot. The complement does not belong so strictly to a given species of animal, but the deficiency may be made good by means of a complement from another species. The virulence of a bacillus was found to be increased by passage through bacteriolytic fluids in vitro.

The mechanism of agglutination, A. Joos (*Ztschr. Hyg. u. Infectionskrank., 40 (1902), No. 2, pp. 203–230*).—The results of investigations reported in this article may be summarized as follows: The agglutinable substance when mixed with the agglutinating substance combines with the latter without any macroscopic or microscopic alteration by which the operation can be detected. Micro-organisms which are modified in this way remain free and motile. Agglutination immediately results, however, if a trace of salt is added. The volume of the precipitate obtained stands in strict relation with the quantity of salt and serum added to the mixture. The function of the salt, therefore, is not a passive one; it actively assists in forming a combination between the agglutinable and agglutinating substances. A characteristic agglutination may be obtained in a fluid free from salt, provided that the bacteria contain salt. It was found during these experiments that the same results might be obtained from the use of a considerable variety of salts in addition to sodium chlorid.

Introduction to serum diagnosis, E. Marx (*Ztschr. Thiermed., 6 (1902), No. 5–6, pp. 388–418*).—A general account of the various bodies which have been obtained

from animal sera, and of the use of bactericidal immune sera, agglutinating sera, antitoxic and precipitating sera.

Organotherapy, E. Joest (*Ztschr. Thiermed., 7 (1903), No. 1, pp. 17-40*).—A general outline of the essential features of this method of treatment and of the results which have been obtained from its application in various diseases. The literature of the subject is critically discussed. Special attention is called to the use of extracts from the thyroid glands, reproductive organs, pancreas, and suprarenal bodies. The author believes that work thus far accomplished in this field of medicine has shown that there is an interdependence between the whole organism and different kinds of cellular tissue and that each kind of tissue performs a function which is of direct benefit to all other kinds of tissue. It has also been shown that certain functions may be much stimulated by the artificial introduction of extracts prepared from certain organs of the same or different species in the treatment of certain diseases.

The first Pan-Russian congress of veterinarians in St. Petersburg (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), No. 1, pp. 1-25*).—This congress held its meetings in St. Petersburg January 3-12, 1903. An organization committee had been working toward this end for the past year and succeeded in bringing together a considerable number of veterinarians, by whom a scientific and social programme was presented. The good wishes of the Czar were presented to the congress by Prince Constantinovich. The purpose of the meetings was outlined by the chairman of the organization committee, and a number of papers were read, among which the following may be mentioned: A Short Historical Account of Veterinary Work in Russia, by A. P. Otapenko; The Present Status of the Question of Tuberculosis, and the Relationship between Human and Bovine Tuberculosis, N. N. Mari; and The History of the Development of the Tubercle, Its Morphology and Biology, by K. Z. Kleptzov.

Reports of inspectors of stock for year ended March 31, 1902, T. A. Fraser et al. (*New Zealand Dept. Agr. Rpt. 1902, pp. 1-98, pls. 4*).—As usual in these reports of inspectors, detailed notes are given on the numbers of animals in the different parts of New Zealand, the condition of the pastures, and the prevalence of animal diseases. Brief accounts are also presented of the injuries to agriculture by birds and rabbits.

Report of the chief inspector of stock, J. R. Weir (*Jour. Dept. Agr. Victoria, 1 (1902), No. 8, pp. 774-784*).—Notes on the condition of stock and the prevalent diseases in various parts of Victoria. The diseases noted by the various inspectors include pleuro-pneumonia, tuberculosis, actinomycosis, anthrax, "yambuk disease," etc.

Report of the spaying expert, D. Wilson (*Jour. Dept. Agr. Victoria, 1 (1902), No. 8, pp. 819-821*).—In a total of 4,866 animals spayed by the author the loss amounted to 1 per cent. Spaying is recommended for good milch cows after they reach an age of 9 or 10 years. Notes are also given on caponizing of poultry and castration of other animals.

The occurrence of bacteria in the lungs and bronchial glands of live animals, U. Quensel (*Ztschr. Hyg. u. Infectionskrank., 40 (1902), No. 3, pp. 505-521*).—The author's observations were made on sheep, calves, horses, and hogs killed in abattoirs and passed as healthy after inspection. The lungs were examined from 16 calves, 15 sheep, 5 horses, and 6 hogs, and detailed notes are given on the organisms found in the lungs and bronchial glands. A considerable variety of bacteria were isolated from these organs and the author concludes that the majority of these organisms were present in the lungs during life and during a healthy condition of the animals. It is believed that these organisms are nearly if not quite always present, although in small numbers, in the lungs of healthy animals. Similar conclusions are drawn with regard to the bronchial glands, in which various organisms were found during a normally healthy condition of the animal.

Cryptogenetic sepsis in young animals, H. KABITZ (*Ztschr. Fleisch- u. Milchhyg., 13 (1902), Nos. 2, pp. 41–46; 3, pp. 80–82*).—A careful study of a number of forms of this disease was made and the conclusion was reached that cryptogenetic sepsis in the majority of cases is the result of infection through the umbilicus. The infection frequently takes the form of a gastric disease. Placentar infection is possible but has not been demonstrated. In some cases cryptogenetic sepsis is the sequela of septic pneumonia.

Husk, hoose or parasitic disease of the lungs of cattle, sheep, and pigs, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 22 (1903), No. 2, pp. 153–157*).—In Cape Colony the worm which causes this disease in sheep and goats is *Strongylus filaria;* pigs are affected with parasitic bronchitis due to the presence of *S. paradoxus;* while *S. micrurus* causes lung disease in calves. Notes are given on the symptoms, etiology, and treatment of this disease. Many remedies were tried in the treatment of the disease. It was found that kerosene oil produced good effects when given in doses of a teaspoonful to lambs and pigs and a tablespoonful to calves. Turpentine was also beneficial in similar doses. It should be mixed with milk or oil. Intratracheal injections were used with good results. One of these injections contained turpentine, chloroform, carbolic acid, and olive oil, and the other contained black poppy oil, oil of turpentine, carbolic acid, and purified cade oil.

Infectious epithelioses and epitheliomata, A. BORREL (*Ann. Inst. Pasteur, 17 (1903), No. 2, pp. 81–122, pls. 6*).—A number of related diseases were made the subject of the author's investigations, including sheep pox, cow pox, smallpox, acne, foot-and-mouth disease, cattle plague, and epitheliosis of mice. From a histological study of the lesions observed in sheep pox it is concluded that there is a characteristic and specific element in this disease, viz, a sheep pox cell with vacuolated nucleus having a pseudoparasitic content. When the localization of the sheep pox occurs the process appears to begin with the mesodermic lesion accompanied with a proliferated epithelial reaction and terminating, after a certain period, with cellular vacuolation. The process exhibits the same type in the skin, lung, liver, and kidney. There is a production of epithelial tumors developed at the expense of preexisting elements of the organ. In sheep pox lesions of the serous membranes there may be very minute granulations scattered in the edematous tissue. As a result of a critical comparison of the various epithelioses discussed by the author it is concluded that cancerous diseases do not constitute a pathological group absolutely different from and without analogy to infectious diseases. The author's study of epithelioses has convinced him that the virulent organism of this disease may pass through filters, and should therefore be classified with the smaller micro-organisms.

Human and bovine tuberculosis, N. RAW (*British Med. Jour., 1903, No. 2202, pp. 596–598*).—The author had under his observation more than 2,000 cases of pulmonary tuberculosis in man and witnessed more than 500 autopsies on cases of tuberculosis. From the clinical and pathological observations thus made he is inclined to believe that primary intestinal tuberculosis and other tuberculous infections of the serous membranes in children are probably cases of bovine tuberculosis produced by milk and are not related to human tuberculosis. The author discusses the symptoms of tabes mesenterica, scrofula, tuberculous meningitis, and post-nasal adenoids. The author believes that "human and bovine tuberculosis are separate and distinct diseases, as shown by Professor Koch, but that the human body is susceptible to both, and especially to bovine tuberculosis in the early periods of life." Since the 2 diseases are so rarely seen together, it appears in the opinion of the author to be reasonable to suppose that they are mutually antagonistic to each other and that bovine tuberculosis may perhaps confer immunity against human tuberculosis. As a preventive remedy against bovine tuberculosis the author recommends thorough pasteurization of all milk consumed by young children.

Recent evidence as to the identity of human and bovine tuberculosis (*Jour. Roy. Agr. Soc. England, 63 (1902), pp. 387–395*).—A brief critical review of some of the more important literature relating to this controversy. It is stated that in England the laws regarding the sale of tuberculous meat and milk have not been any less rigidly enforced since the publication of Koch's address. This statement is made on account of a contrary statement at the Berlin Conference to the effect that great laxity in this regard had been observed during the past year or two.

Tuberculosis of man and cattle, O. Stenström (*Ztschr. Thiermed., 6 (1902), No. 4, pp. 289–291*).—The author made a number of experiments in inoculating calves with the sputum of tuberculous patients. The results of these experiments are opposed to those of Koch, since in certain cases a true infection of tuberculosis with a tendency to become generalized was produced.

Professor Koch, and the danger from bovine tuberculosis, P. Garnault (*Le Professeur Koch, et le péril de la tuberculose bovine. Paris: Institut International de Bibliographie, 1902, pp. XXX + 1062, figs. 10*).—In this volume the author presents a brief account of an attempt which he made to inoculate himself in the arm with tubercle material of bovine origin. The greater part of the volume is of a highly controversial nature, in which the author argues against the proposition of the dual nature of tuberculosis, as proposed by Koch, and seeks to disparage the latter's scientific attainments, personality, and ethical principles. A bibliography of the literature relating to this controversy, and published since the delivery of Koch's address, is appended to the volume.

The specific nature of serum diagnosis of tuberculosis, P. Eisenberg and E. Keller (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 7, Orig., pp. 549–567*).—The literature of serum diagnosis in the investigation of tuberculosis is critically discussed, in connection with a bibliography of 88 titles. The observations made by the authors on human patients and numerous investigations on experimental animals indicate that serum reaction can not be depended upon in the diagnosis of tuberculosis. It was found that the serum reaction was negative in 30 per cent of active cases of tuberculosis.

Directions for making protective inoculation against tuberculosis in cattle, E. von Behring (*Ztschr. Thiermed., 6 (1902), No. 5–6, pp. 328–335*).—Notes are given on the best method for selecting cattle for the experiment, numbering the cattle, taking temperature, preparing and measuring the inoculation material, and the technique of inoculation and subsequent hygienic care of the cattle and stalls.

Jennerization as a means of combating bovine tuberculosis in agricultural practice, E. von Behring (*Ztschr. Thiermed., 6 (1902), No. 5–6, pp. 321–327*).—The author makes a further report upon the experiments already referred to (E. S. R., 14, pp. 393, 394). It is now considered as demonstrated that cattle vaccinated according to the method of the author are immune against infection with bovine tubercle virus of sufficient strength to produce fatal results in control cattle.

Histological changes after the injection of dead tubercle bacilli, G. Engelhardt (*Ztschr. Hyg. u. Infectionskrank., 41 (1902), No. 2, pp. 244–256*).—The present discussion deals with the controversy as to whether the injection of dead tubercle bacilli can produce typical tubercles with ultimate caseation of the interior. It is believed that the irritation produced by the dead tubercle bacilli is chiefly chemical rather than mechanical. The reasons for this belief, as stated by the author, are that a desquamative pneumonia is observed in the lungs of experimental animals after injection with dead tubercle bacilli and that this process closely resembles that which occurs in infection by living tubercle bacilli. Tubercles produced by dead tubercle bacilli were observed 80 days after the beginning of their formation, and a fibrinoid substance was not found in the center in any case, and no sign of caseation was observed.

Combating tuberculosis on the basis of herd records for over fifty-nine years, T. Hermann (*Ztschr. Thiermed., 6 (1902), No. 5–6, pp. 336–368*).—On an

estate near Bautzen 114 cases of tuberculosis occurred among cattle during the years 1842–1901. The relationship of heredity to the development of these cases was studied from the records kept concerning the herd. Among these various cases it was found that not a single one occurred which had not been subjected to one or another of the most important predisposing causes of tuberculosis.

In order to prevent the development of tuberculosis among herds of cattle the author considers it of chief importance to avoid the presence of these predisposing causes. The 4 chief causes of this sort as outlined by him are the use of the last of a large number of offspring by common parents, lack of ventilation, in-and-in breeding, and tuberculous parentage.

Tuberculosis in horses, H. MARKUS (*Ztschr. Thiermed., 6 (1902), No. 5–6, pp. 369–387*).—The author made a detailed study of this disease in 15 horses. It was found that the disease assumes a number of forms in the lungs of horses and that a distinction could readily be made between primary and secondary forms, or, in other words, between aspiratory and embolic tuberculosis. The author believes that the mode of infection is the only basis upon which the different forms of pulmonary tuberculosis can be classified.

Tuberculosis in cold-blooded vertebrates, L. TERRE (*Essai sur la tuberculose des vertébrés a sang froid. Dijon: Barbier-Marilier, 1902, pp. 128*).—The literature relating to tuberculosis in cold-blooded vertebrates is critically reviewed in connection with a bibliography of 168 titles. A bacillus was isolated from dermal tubercles in carp and this organism was studied with special regard to its relationship to the bacillus of Koch. The organism is called by the author the bacillus of carp. The diseases produced in carp by this organism resemble in all particulars the typical tubercular lesions caused by the bacillus of Koch in warm-blooded animals. The organism itself appeared to be identical with the bacillus of Koch in all of its morphological characters. When inoculated into fish, amphibia, or reptiles, the bacillus of carp caused typical tubercles which showed necrosis and caseation.

Experiments with tubercle bacilli from mammals and birds indicate that these organisms could be gradually transformed into the bacilli of carp by passing through cold-blooded vertebrates. This transformation constitutes, in the opinion of the author, a new argument in favor of the identity of the various forms of tuberculosis. When injected in moderate doses the bacillus of carp is not pathogenic for warm-blooded animals, but produces lesions of a regressive character. The soluble products and extracts from the bacillus of carp possess similar properties to those of the bacillus of Koch. The organism as obtained from fish was found to be susceptible to agglutination by the serum of tuberculous warm-blooded animals. It is believed by the author that the organism studied by him is identical with that found by Moeller in the blindworm.

Tuberculous ulcerations on the face of cats, G. PETIT (*Rec. Méd. Vét., 8. ser., 9 (1902), No. 22, pp. 651, 652, fig. 1*).—Notes on the symptoms and pathological anatomy of a tuberculous affection of the skin on the face of cats. The retropharyngeal and other lymphatic glands of the head were swollen and infected.

A new method for intensive staining of the tubercle bacillus, BIOT (*Ann. Acad. Macon, 3. ser., 6 (1901), pp. 85–91*).—In obtaining an intense coloration of tubercle bacilli the author found it desirable to use a mordant in connection with the staining method of Ehrlich or that of Ziehl. The preparations are immersed in a solution of formalin; they are then placed in a fuchsin bath slightly carbolized, to which a few drops of formalin have been added.

Actinomycosis of the tongue of cattle, together with alterations in the lymphatic glands of the head and lungs, H. HOHMANN (*Ztschr. Fleisch u. Milchhyg., 13 (1902), No. 1, pp. 14, 15, fig. 1*).—Notes on the pathological anatomy of cases of wooden tongue, and on the condition of the lymphatic glands in such cases.

Staining actinomyces in sections, S. CIECHANOWSKI (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 3, Orig., pp. 238, 239*).—Great difficulties have been experienced

in staining actinomyces in sections successfully. The author outlines a method which in his hands has given excellent results.

Anthrax, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 22* (*1903*), *No. 3, pp. 293–300*).—Brief notes on the nature, source of infection, symptoms, and treatment of this disease.

The diagnosis of anthrax, E. GOTTSTEIN (*Hyg. Rundschau, 12* (*1902*), *No. 23, pp. 1185–1193*).—Brief notes are given on the various means by which anthrax bacilli may be identified under the microscope or by means of inoculation experiments, and attention is called to the desirability of destroying all material which may contain anthrax bacilli and of disinfecting the premises after an outbreak of this disease.

Anthrax, F. C. HARRISON (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, p. 94*).—During the season of 1902 a number of reports were made of this disease and attention is called to the dangers which are incurred from not taking strict measures in the eradication of the disease and burning or burying of carcasses.

Treatment of anthrax with carbolic acid, A. MINDER (*Schweiz. Arch. Tierh., 44* (*1902*), *No. 6, pp. 267–271*).—The author administered a 0.5 per cent solution of carbolic acid in water in frequent doses so as to aggregate 40 to 50 liters during 24 hours. During the crisis of the disease doses of 1.5 liters were administered every 15 minutes. The condition of the affected cattle improved quite rapidly in all cases and recovery took place ultimately.

The antianthrax properties of rabbit and dog sera, O. BAIL (*Centbl. Bakt. u. Par., 1. Abt., 33* (*1903*), *No. 5, Orig., pp. 343–353*).—It was found during a long series of experiments that dog serum which had been shown to be perfectly inactive toward anthrax could be given very active properties toward anthrax by the addition of minute quantities of rabbit serum. The effect of rabbit serum was noticeable even when added in the proportion of 1 to 1,000. The author discusses at considerable length the theoretical bearing of this experiment. Other experiments showed that the serum of the sheep may be influenced in a similar manner by the addition of rabbit serum.

The destruction of carcasses of animals dead of anthrax, E. ZSCHOKKE (*Schweiz. Arch. Tierh., 44* (*1902*), *No. 6, pp. 283–292*).—Attention is called to the danger from the distribution of anthrax by means of carcasses of animals dead of the disease. It is urged that in all cases where the presence of spores on the outside of the carcass is possible, the whole carcass should be thoroughly incinerated.

An experiment in steam sterilization, C. EIJKMAN (*Centbl. Bakt. u. Par., 1. Abt., 33* (*1903*), *No. 7, Orig., pp. 567, 568*).—Live steam under low pressure was found to be much more effective in destroying *Bacillus pyocyaneus* and anthrax spores than was boiling water. The explanation of this difference in the effect of live steam and boiling water is believed to be found in the fact that the boiling point of water is increased by the presence of soluble materials, such as salt and sugar, while the steam is not thereby influenced.

Foot-and-mouth disease in New England, J. W. CONNAWAY (*Bul. Missouri State Bd. Agr., 2* (*1903*), *No. 11, pp. 44, figs. 7*).—The author was detailed by the Missouri State board of agriculture to investigate the extent of the outbreak of foot-and-mouth disease in New England and to advise the board as to the necessity of any quarantine action against cattle from New England. The results of the author's investigations indicate that the work of eradicating the disease is being vigorously prosecuted and that live stock in Missouri are in no apparent danger of infection. Notes are given on the symptoms, etiology, period of incubation, and rate of mortality and fatal consequences of this disease. In order to prevent unnecessary excitement among cattle owners attention is called to the differences between contagious foot-and-mouth disease on the one hand and ergotism and mycotic aphthous fever on the other. Both of the latter diseases occur from time to time in Missouri and neighboring States, and have occasionally been mistaken for foot-and-mouth

disease. The origin of the present infection in New England has not been definitely determined. The disease has been observed in 75 towns in Massachusetts and neighboring States, and the authorities have killed 1,848 cattle in order to check the spread of the disease. In this work the Bureau of Animal Industry of this Department and the board of cattle commissioners of Massachusetts have cooperated. Cattle are slaughtered and buried in deep trenches after being sprinkled with lime or other disinfectants, or in some instances have been burned. The indemnity paid for animals thus killed is 70 per cent of the appraised value.

Foot-and-mouth disease, C. W. Gay (*Iowa Agr., 2 (1903), No. 7, pp. 170–173*).—Notes on a recent outbreak of this disease in New England, with a brief statistical account of the animals slaughtered by this Department and the appraised valuations and compensation paid for slaughtered animals.

Foot-and-mouth disease, N. S. Mayo (*Industrialist, 29 (1903), No. 25, pp. 397, 398*).—Brief notes on the symptoms, pathological anatomy, and treatment of this disease.

The treatment of foot-and-mouth disease, F. Lieutaud (*Jour. Agr. Prat., n. ser., 5 (1903), No. 7, p. 218*).—In the author's experience cauterization and other antiseptic treatment of wounds and the use of protective serum were without results in the treatment of this disease.

Contagious pleuro-pneumonia of cattle, D. Hutcheon (*Agr. Jour. Cape Good Hope, 22 (1903), No. 3, pp. 319–322*).—The author recommends as the quickest and shortest method of eradicating this disease that all animals which have been directly exposed to infection should be slaughtered. It is suggested that in order to induce the natives to consent to the slaughter of their cattle, they might be granted permission to eat the meat after the internal organs had been removed and destroyed.

Parturient paresis, F. W. van Dulm (*Tijdschr. Veeartsenijk. Maandblad, 30 (1902), No. 3, pp. 111, 112*).—A test was made of the efficacy of the method of pumping air into the udder in cases of this disease. Good success was had and it was found that the greater the pressure produced inside the udder the more rapid was the recovery.

Treatment of parturient paresis with oxygen, Knüsel (*Schweiz. Arch. Tierh., 44 (1902), No. 6, pp. 261–267*).—In his veterinary practice the author had frequent occasion to treat cases of this disease. The treatment adopted at first was the injection of potassium iodid. Under the most favorable circumstances, however, about 40 per cent of the cases died after receiving this treatment. Better results were obtained from the use of air pumped into the udder under considerable pressure. Forty cases were treated in this way with complete success in every case. In explanation of the etiology of the disease the author suggests the possibility of ascribing the disease to the action of a toxin formed by some micro-organism. It might then appear that the free use of atmospheric air was unfavorable to the development of these organisms, which are assumed to be anaerobic.

Contagious mammitis of milch cows, E. Thierry (*Jour. Agr. Prat., n. ser., 5 (1903), No. 10, p. 318*).—Notes are given on an outbreak of this disease in a dairy herd. The symptoms and etiology of the disease are described and a short account is presented of preventive and curative treatment. The curative treatment recommended consists in intramammary injections of a tepid solution of boric acid in water.

A peculiar disease of cattle, M. Strebel (*Schweiz. Arch. Tierh., 44 (1902), Nos. 5, pp. 231–238; 6, p. 293*).—The author describes the symptoms which were observed in a number of outbreaks of disease among cows. The secretion of milk was greatly diminished, the movements and general behavior of the animal were nearly normal and the appetite was only slightly diminished. In one outbreak of the disease a number of animals were affected and some of them were submitted to emergency slaughter on account of their evidently impending death. It was discovered upon investigating these cases that the affected cows had been fed upon clover which was

grown on land treated with some artificial fertilizer, and the author suggests the possible connection between the fertilizer and the disease observed in the cows.

The discovery of the parasite of Texas fever and of carceag, V. BABES (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 6, Orig., pp. 449–458, figs. 4*).—A controversial article in which the author presents evidence for his priority in the discovery of the organism of Texas fever and of carceag or ictero-hematuria of sheep.

The cattle tick situation, H. A. MORGAN (*Proc. Soc. Prom. Agr. Sci. 1903, pp. 72–74*).—Notes are given on the life history of the cattle tick. The author suggests that if infested cattle be removed from their pastures and kept in feed lots or small pastures for a period of about 18 days the majority of the ticks would fall off and the cattle could then be taken back to other pastures which had been freed from ticks by rotation. The author believes that if some such plan were adopted in a cooperative way the cattle-tick nuisance could be readily eradicated.

The duration of active immunity to cattle plague, V. K. TVARYANOVICH (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), No. 1, pp. 25–27*).—In the experiments briefly reported by the author immunity to cattle plague in the calves, cows, and bulls upon which the author experimented was found to persist for a period varying from 4 to 6 months.

Petechial fever in cattle, A. MINDER (*Schweiz. Arch. Tierh., 44 (1902), No. 6, pp. 271–275*).—Detailed notes on the clinical symptoms and pathology of 3 cases of this disease.

Necrosis as a result of Bacillus necrophorus, H. A. VERMEULEN (*Tijdschr. Veeartsenijk. Maandblad, 30 (1902), No. 3, pp. 102–111*).—The author investigated a number of cases of necrosis of the liver, in cattle and from material obtained from these cases inoculation experiments were made with laboratory animals to determine the effect of *B. necrophorus*. It was found that the necrosis which is due to this organism may spread by means of embolism, by continuity, or contiguity.

Combating dysentery of calves with collargol, P. STAMPEL (*Ztschr. Thiermed., 6 (1902), No. 4, pp. 284–288*).—On the basis of the author's experiments with this disease it is concluded that dysentery of calves may be in the majority of cases prevented by repeated injections of collargol into the jugular vein during the first 3 days of the calf's life.

Infections of calves due to coli bacilli, BAER (*Schweiz. Arch. Tierh., 44 (1902), No. 5, pp. 223–228*).—Attention is called to the agency of coli bacilli in producing total cataract and icterus in calves. The number of infections produced by organisms of this group is known to be quite large and the diseases are of a variety of forms. Notes are given on the history of cases of total cataract and icterus produced by these organisms. It was found that in cases of total cataract organisms were isolated from the liver, kidneys, and viterous humor.

The beef measle worm in southern parts of Austria-Hungary, F. MUNIH (*Ztschr. Fleisch- u. Milchhyg., 13 (1902), No. 1, pp. 11–13*).—Brief notes on the extent of infestation by this worm, especially in the cities of Trieste, Fiume, and Pola. While the number of cattle found to be infested with this parasite is very small it is believed that figures obtained from the present examination do not represent the actual condition, since the masticatory muscles have not been thoroughly examined.

Experimental study of sheep pox, A. BORREL (*Ann. Inst. Pasteur, 17 (1903), No. 2, pp. 123–137, figs. 13*).—Investigations undertaken by the author were confined largely to filtration of the virus, vaccination, and serotherapy. It was found that when filtration was performed rapidly the virus did not pass through the filter. Notes are given on the most suitable means for obtaining virus in large quantities. In experiments to test the value of serotherapy in this disease the results obtained were quite encouraging. It was demonstrated that 20 cc. of serum obtained from a hyper-immunized animal was more than sufficient to prevent a serious mortality in a badly infested herd. Further experiments will be made to determine the minimum dose of serum required for effective prevention of the disease.

Sheep scab (*Bd. Agr.* [*London*], *Leaflet 61, pp. 6, figs. 3*).—A brief account of the symptoms, cause, and treatment of sheep scab. Notes are given on the life history of the scab mite and on certain preventive measures.

Sheep yards and dips (*Agr. Jour. Cape Good Hope, 22* (*1903*), *No. 2, pp. 157–159, pl. 1*).—Brief notes on a convenient arrangement and construction of sheep yards and dipping vats for use in treatment of sheep scab.

A preliminary report on the fringed tapeworm of sheep (Thysanosoma fimbriata), E. L. MOORE (*South Dakota Sta. Bul. 78, pp. 8, fig. 1*).—This worm is said to be generally distributed throughout the State. It was first observed in sheep upon the college farm. The largest number found in a single animal was 75, and the greatest mortality recorded in a given flock 25 per cent. Brief notes are given on the symptoms of the disease caused by infestation with this worm. The sheep appear to be unthrifty and gradually lose flesh; soft swellings appear under the throat. In preventing infestation with this worm it is recommended that a system of rotation of pastures be adopted and that water should be supplied in tanks raised above the ground so that it can not become contaminated. In treating the disease the best results were obtained from the use of Hutcheson's method with copper sulphate. Detailed directions are given for administering this remedy.

Maggots in sheep, G. T. BROWN (*Jour. Roy. Agr. Soc. England, 63* (*1902*), *pp. 416–420*).—Brief notes on the habits and life history of this insect. In order to prevent its attacks the author recommends the use of fine nettings on the windows of sheep houses and spraying sheep with some fluid possessing an objectionable odor.

The new method of treatment and prophylaxis of swine erysipelas, A. GRÉGOIRE (*L'Ing. Agr. Gembloux, 13* (*1903*), *No. 6, pp. 255–259*).—A brief account is given of the advantages and disadvantages of the Pasteur method of treatment in outbreaks of this disease. The chief disadvantage of this method in the author's opinion consists in the fact that it is merely preventive and has no curative effect. The recent method devised by Leclainche, who succeeded in producing a serum with both preventive and curative properties, is considered of much greater importance in veterinary practice.

The time required for the penetration of the bacilli of swine erysipelas and fowl cholera into the internal organs of mice after a hypodermic inoculation, T. TIEDE (*Ztschr. Thiermed., 7* (*1903*), *No. 1, pp. 41–67*).—The author critically reviews the work of other investigators who have attempted to determine this point with regard to anthrax, glanders, sheep pox, malignant edema, and other diseases. During the author's experiments it was found that in mice the organism of swine erysipelas could be found sparingly in the spleen and liver 15 hours after hypodermic injection; sparingly in the liver and lungs and quite abundantly in the spleen within 24 hours; and in large quantities in all organs within 48 hours. The bacillus of fowl cholera was found in mice after hypodermic inoculation within 15 minutes in the spleen, liver, lungs, and heart, and within 45 minutes in all organs, while after 1 to 3 hours the organisms were less abundant and of less uniform distribution; after 4 hours they were again found in large numbers, from which time until the death of the animal the numbers gradually increased.

Statistical notes on sarcosporidia, A. M. BERGMANN (*Ztschr. Thiermed., 6* (*1902*), *No. 5–6, pp. 462–468*).—During the performance of trichina inspection the author examined the carcasses of 27,751 hogs from the southern part of Sweden, with the result that 30.62 per cent were found infested with sarcosporidia, while in the northern parts of Sweden 27.59 per cent were found infested among 46,610 hogs. The sarcosporidia were distributed quite unequally, certain muscles being most extensively infested. The chief seat of the sarcosporidia was the lumbar portion of the diaphragm.

Diagnosis of glanders, C. TROESTER (*Ztschr. Veterinärk., 14 (1902), No. 8-9, pp. 372-374*).—In the author's experience the inoculation of male guinea pigs with material suspected of being glanderous does not furnish a sufficiently rapid and certain means for diagnosing glanders. The results are often uncertain on account of the frequent death of guinea pigs from septicemia and intermittent diseases. Whenever the results are unsatisfactory it becomes necessary to repeat the cultures of the suspected material, and much time is thus lost.

Serum inoculation against pneumonia in horses and its value from a practical standpoint, WALTHER (*Ztschr. Veterinärk., 14 (1902), No. 11, pp. 500-507*).—The author concludes from his own experiments and those of others that the best method of suppressing outbreaks of pneumonia among army horses is to subject all the horses of the squadron to serum inoculation. When carefully performed, this operation is usually successful and does not entail the loss of much time.

Contagious coryza of horses of the remount station, BECHER (*Ztschr. Veterinärk., 15 (1903), No. 1, pp. 11-13*).—Despite the best care and treatment which could be given to horses suffering from this disease, it was found that a large proportion of the patients suffered from a complication of chronic gastro-enteric catarrh after recovery from the symptoms of contagious coryza.

Fibro-epithelial neomorphs of the skin, liver, and lungs in horses, TETZNER (*Ztschr. Veterinärk., 14 (1902), No. 7, pp. 296-310, pls. 2*).—The present article is occupied with an account of the fibro-epithelial neomorphs in the lungs. The etiology and microscopic anatomy of these structures are described in detail.

The action of the poisonous principle of Equisetum, LUDEWIG (*Ztschr. Veterinärk., 14 (1902), Nos. 10, pp. 447-461; 11, pp. 483-493*).—During the author's numerous experiments with these plants it was found that *Equisetum limosum* was very dangerous to horses, while cattle and sheep could eat it without harm. The converse was true for *E. palustre*. It is believed that the contradictory results obtained in the investigation of these plants by various authors are to be explained by the assumption of a confusion of species. A chemical investigation showed the presence of an alkaloid in both species. Aconitic acid was also found in varying quantities. This substance occurred partly in insoluble combination with lime and partly in an easily soluble form of an alkaline salt.

Poisoning by Equisetum, WÜNSCH (*Ztschr. Veterinärk., 14 (1902), No. 10, pp. 461-467*).—Notes are given on a number of cases of poisoning from this plant which were observed among horses. Some of the horses were affected but slightly, while others died. The various lines of treatment, such as administration of calomel, arecolin, eserin, spirits of camphor, iodid of potash, strychnin, etc., were without apparent effect.

Sorghum poisoning, W. MAXWELL (*Queensland Agr. Jour., 12 (1903), No. 3, pp. 172, 173*).—A brief preliminary report upon investigations which are being conducted with various crops to determine the presence or nonpresence of certain poisonous bodies. As far as the work has been prosecuted it appears not to be safe to give cattle free access to sorghum until the seeds begin to develop. The younger stages appear to be more poisonous.

Some conditions of stock poisoning in Idaho, H. B. SLADE (*Idaho Sta. Bul. 37, pp. 157-190, pls. 2, figs. 3*).—A general discussion is presented on the nature of poisonous plants and the conditions under which poisoning occurs. The statements are largely based on European and American literature on this subject. From the replies to a circular letter distributed to stockmen it is estimated that the stock poisoned by plants during the past year in Idaho aggregated a value of $50,000. Most of the sheep lost in the State were poisoned by lupines. The author discusses the popular and scientific remedies which have been used or can be recommended in preventing fatal effects of plant poisoning. As a general remedy a mixture of potassium

permanganate and aluminum sulphate is recommended. Special notes are given on wild parsnip, death camas, species of larkspur, lupines, and *Veratrum californicum*.

Results of treating tetanus by inoculation with cerebral emulsion, J. Fiebiger (*Ztschr. Thiermed., 6 (1902), No. 3, pp. 161–170*).—The author found that the rate of mortality from tetanus could be much reduced by treatment with cerebral emulsion. The results of this treatment appeared to be quite as satisfactory as those of other known treatments. A treatment with cerebral emulsion is cheaper than serum therapy and the material is more easily obtained. The technique is not too complicated for the ordinary practicing veterinarian.

Fixation of tetanus toxin by the brain, Besredka (*Ann. Inst. Pasteur, 17 (1903), No. 2, pp. 138–147*).—The literature of this subject is critically discussed. The author made an emulsion of the brains of guinea pigs, in testing the effect of the brain upon the tetanus toxin. During these experiments it was shown that the cerebral substance is capable of fixing more tetanus toxin than it can neutralize. The fixative substance of the brain is, therefore, not the same as the antitoxic substance. The cerebral mass, when saturated with tetanus toxin, completely recovers its primitive integrity, after the addition of true antitoxin, whether obtained from an animal of the same or a different species. The combination of the brain substance and the toxin does not give a substance as stable as that obtained by a mixture of toxin and true antitoxin.

The power of the brain to neutralize tetanus toxin, E. Marx (*Ztschr. Hyg. u. Infectionskrank., 40 (1902), No. 2, pp. 231–238*).—A brain emulsion was prepared from guinea pigs and experiments were tried in testing the action of this emulsion upon tetanus virus in vitro. The results of these experiments may be stated as follows: The effect of the brain of guinea pigs is united with that of the antitoxin in neutralizing the tetanus toxin in vitro. It is believed, therefore, that the effects of the brain substance and of the antitoxin are functionally of about equal value.

Antitetanic properties of the central nervous system of immunized animals, K. Dmitrievski (*Ann. Inst. Pasteur, 17 (1903), No. 2, pp. 148–160*).—The author's experiments were made with the brains of immunized guinea pigs. Strict antiseptic conditions were observed in preparing emulsions of the cerebral hemispheres, the base of the brain, and the medulla oblongata, without separation of the latter from the upper portion of the spinal cord. Tetanus toxin was mixed with cerebral emulsions thus obtained from the guinea pigs which had received a single injection of tetanus toxin, those which had been immunized for 1 or 2 months, and others which possessed an immunity of 3 or 4 months' duration. The author concludes from his experiments that the brain of animals which have enjoyed an immunity of short duration, as well as their blood, does not possess any great antitetanic property and does not differ in this respect from the normal brain. The brain and the blood of animals which have been immunized for a long time contains a large quantity of antitoxin and is capable of neutralizing a larger quantity of tetanus toxin than the brain of normal animals. The difference, however, is not very great since all animals which were injected with a mixture of toxin and brain substance from immunized guinea pigs presented certain symptoms of tetanus. The blood of animals which have enjoyed a long immunity always contains more antitoxin than the brain.

The symptoms and prophylaxis of experimental rabies, D. Conradi (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 5, Orig., pp. 389–392*).—The purpose of the experiment reported in this paper was to determine the length of the incubation period of rabies under experimental conditions when the inoculation was made as nearly as possible in a natural manner. The virus was rubbed into abrasions of the skin, which were purposely made, so slight that no bleeding took place. The abrasions thus made and inoculated were washed with solutions of corrosive sublimate after the lapse of from 1 to 10 minutes. During the author's experiments 10 rabbits were treated in this manner, while 3 others were inoculated in the same manner

without treatment of the abraded surfaces with corrosive sublimate. The 3 control animals developed rabies after 174, 177, and 289 days, respectively, and all died, the course of the disease occupying 12, 40, and 24 days, respectively. None of the other 10 animals developed symptoms of rabies during the period of observation, which amounted to 582 days. The author believes that these experiments indicate the possibility of a longer incubation period for rabies than has usually been estimated.

Behavior of rabies virus in the central nervous system of susceptible, naturally immune, and immunized animals, R. Kraus et al. (*Ztschr. Hyg. u. Infectionskrank., 41 (1902), No. 3, pp. 486–526*).—The extensive experiments of these authors were undertaken for the purpose of obtaining information on the question whether rabies virus is propagated throughout the organism by way of the nervous system. The experiments were made on rabbits, pigeons, and hens. It was found that the different portions of the central nervous system, after a subdural infection with the virus of rabies, become infectious at different periods of time. The medulla was found to be infectious after 3 or 4 days when injection was made with laboratory virus, while from 6 to 10 days were required for the same process to take place after injection with virus from rabid animals just dead of the disease. The differences in the rapidity with which the 2 kinds of virus propagate themselves along the central nervous system is believed to be due to the difference in the active powers of multiplication of the different viruses in the nervous tissue. Further experiments of the authors indicate that the virus is not propagated in the dead brain of susceptible animals, but only in the brain of living animals. The authors believe that they have demonstrated that rabies virus is capable of propagating itself and that the negative results from transmission experiments with rabbits are due to the attenuation of the virus. Experiments with immunized rabbits showed that these animals are capable of resisting infection and that the virus of rabies is destroyed in the central nervous system. Immunity toward the disease is therefore believed to reside in the central nervous system, but the actual mechanism of this immunity is not understood.

The formation of substances immune toward rabies virus in naturally susceptible and insusceptible animals, R. Kraus and R. Maresch (*Ztschr. Hyg. u. Infectionskrank., 41 (1902), No. 3, pp. 527–539*).—The results of the authors' experiments may be briefly summarized as follows: Susceptible rabbits and dogs do not normally possess any substance antagonistic to rabies in their serum. Such substances are developed, however, in these animals after immunization with laboratory virus. In susceptible pigeons, only those which have been treated with laboratory virus develop any immune substance in the blood. Chickens, which are only slightly susceptible to rabies, normally have substances antagonistic to rabies in the serum, but do not produce any more of these antagonistic bodies after immunization with laboratory virus.

A bacillus found in animals and resembling that of influenza, A. Wolff (*Centbl. Bakt. u. Par., 1 Abt., 33 (1903), No. 6, Orig., pp. 407–411, fig. 1*).—In experiments undertaken for the purpose of securing a cholera toxin the author discovered an organism in rats which proved to be slightly pathogenic for these animals. The organism closely resembles the bacillus of influenza, and descriptive notes are given on its morphology and biology. The organism is only slightly pathogenic for rats, guinea pigs, and other experimental animals, as shown by inoculation experiments.

A new bacillus belonging to the influenza group, E. Freidberger (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 6, Orig., pp. 401–406, figs. 2*).—The author isolated from dogs an organism which he names *Bacillus hæmoglobinophilus canis* and which showed a striking resemblance to the bacillus of influenza. Notes are given on the behavior of this organism on various culture media. It proved to be slightly pathogenic for guinea pigs and other experimental animals.

Morphological characters and cultures of Bacterium pestis and the relationship of this organism to B. pseudotuberculosis rodentium, B. GALLI-VALERIO (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 5, Orig., pp. 321–330, pls. 2*).—A comparison was made between the morphological characters of these 2 organisms and their behavior upon various nutrient media. The organisms were compared also by means of inoculations of guinea pigs and other rodents. It was found that *B. pseudotuberculosis rodentium* was not pathogenic for rats but was pathogenic for guinea pigs, while *B. pestis* was pathogenic for rats and guinea pigs but did not produce tubercles so frequently as did the other organism.

The influence of passing plague bacilli through animals upon the virulence of these bacilli for different species of animals, R. OTTO (*Ztschr. Hyg. u. Infectionskrank., 41 (1902), No. 3, pp. 380–409*).—During the experiments recorded in this paper plague bacilli were inoculated into rabbits, guinea pigs, rats, and mice, for the purpose of determining the influence of these animals upon the virulence of the bacilli. It was found as a result of these experiments that plague bacilli could be subjected to repeated passages without causing any diminution of virulence for the species of animal in question. It appeared to be impossible to produce any permanent increase in the virulence of the bacilli by passage through animals, but in the case of rats a tendency was manifested toward localization in the lymphatic glands accompanied with an increase in the toxicity of the organism. No alteration in regard to the virulence of the bacilli for different species of animals was observed after subjecting the organisms to repeated passages through one species.

Short notes on a new chicken disease, H. STREIT (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 95–97, figs. 2*).—An apparently infectious disease broke out at Preston, Ont., and caused a great loss among chickens. The clinical symptoms are progressive anemia, sleepiness, paleness of the mucous membranes, and profuse diarrhea toward the termination of the disease, which results in death after from 2 weeks to 2 or more months. In some cases the bones were softened as in rickets, the spleen was usually enlarged to some extent, and the liver greatly enlarged. The liver also exhibited gray nodules, from which rod-like structures were isolated. From the blood of the liver numerous motile protozoa were obtained, and experiments were made to determine whether the disease could be directly transmitted by inoculation with these organisms. Diseased fowls were kept with healthy ones for several weeks without definite results; healthy fowls were fed with diseased organs, also without positive results. Quinin administered in doses of 2 to 6 gr. twice a day appeared to have no influence upon the progress of the disease. This disease is believed to be distinct from the entero-hepatitis in turkeys, as described by T. Smith.

Liver disease in poultry (*Bd. Agr. [London], Leaflet 78, pp. 4*).—Notes on the external symptoms, pathological anatomy, cause, prevention, and treatment of this disease.

The identity of human and avian diphtheria, F. C. HARRISON (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 98–104*).—The author discusses the literature of this subject, with a bibliography of 48 titles. During the author's investigations 300 fowls have been under observation or have been inoculated. A number of fowls were inoculated with fresh serum obtained from vaccine manufacturers, and other birds were treated with fresh horse serum. These experiments showed that diphtheria antitoxin produced no effect when inoculated in chickens suffering from fowl diphtheria. Some positive results were to have been expected if the bacteria of human and avian diphtheria were the same. Ordinary horse serum gave better results than antidiphtheritic serum but was not a specific for fowl diphtheria. Inoculation experiments indicated that the bacillus of human diphtheria was not pathogenic for hens. Cultures were obtained from over 200 fowls which had died of fowl diphtheria or were killed in some stage of the disease, and no trace of bacilli

of human diphtheria was found in any of them. Roup, or fowl diphtheria, according to the author, is produced by *Bacillus cacosmus*. It was also found that roup with its various symptoms could be produced by inoculation with *B. pyocyaneus*.

AGRICULTURAL ENGINEERING.

Report of irrigation investigations in Utah (*U. S. Dept. Agr., Office of Experiment Stations, Bul. 124, pp. 316, pls. 19, figs. 2*).—This is a report of investigations made during 1901 and 1902 under the direction of Elwood Mead, chief of irrigation investigations of this Office, assisted by R. P. Teele, A. P. Stover, A. F. Doremus, J. D. Stannard, Frank Adams, and G. L. Swendsen. The report contains the following papers: General Discussion of Irrigation in Utah and Irrigation from Jordan River, by R. P. Teele; Irrigation in Utah Lake Drainage System, by A. P. Stover; The Spanish Fork River Irrigation System, by A. F. Doremus; Irrigation in the Weber Valley, by J. D. Stannard; Agriculture Under Irrigation in the Basin of Virgin River and Court Adjudications of Water Rights on Sevier River, by Frank Adams; and Appropriation of Water from Logan River, by G. L. Swendsen.

The bulletin is the second of a series of reports on irrigation laws and institutions of individual arid States, the first being devoted to California conditions (E. S. R., 13, p. 794). It also deals with the methods and results of irrigation, duty of water, crop values, cost of water, and improvement of methods and practices.

The plan followed in the investigations reported was to select typical streams in various parts of the State, and describe the actual conditions created by the appropriation and use of their waters. Thus, the Virgin and Sevier rivers were selected in the southern part of the State, the Weber and Logan in the northern part, and the Jordan and its tributaries in Central Utah. In this way practically every feature of the State's irrigation system is described.

The distinctive features of the Utah irrigation system, as brought out in this report, are cooperation in the organization and operation of canals and the time method of distributing water to users. The principal weakness of the system is that rights are not defined until they come into controversy. In 1903 the State legislature enacted a law which was drawn for the purpose of defining all existing rights, and of providing for the control of the acquirement of rights in the future, thus making all rights a matter of record, giving those charged with the distribution of water a definite basis for its division, and giving notice of the extent of existing rights to those desiring to obtain rights to divert water.

The duty of water as measured under 11 canals varied from 8.15 to 106 acres per cubic foot per second of water. The value of crops, as recorded for 20 localities, varied from \$10.93 to \$39.40 per acre. The annual cost of water per acre as recorded for 25 canals and ditches varied from 40 cents to \$3.

The utilization of Utah Lake as a reservoir, W. P. HARDESTY (*Engineer. News, 49 (1903), No. 21, pp. 442–445, figs. 5*).—A description of the dams regulating the outflow of Utah Lake and of the pumping plant raising the water of the lake into the Jordan River and thus maintaining the flow in the latter in seasons of low water.

Preliminary report on artesian basins in southwestern Idaho and southeastern Oregon, I. C. RUSSELL (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 78, pp. 53, pls. 2, figs. 3*).—This report is based on investigations made in 1901 and 1902, "and contains a description of the geologic structure of southwestern Idaho and southeastern Oregon, with special reference to the occurrence of underground waters. The artesian basins are described as far as these are known, and facts are assembled as to the probabilities of obtaining deep or flowing wells." The four principal areas in southwest Idaho and southeast Oregon in which artesian water has already been discovered, or in which convincing evidence is found that it

may be obtained, are described. These are the Lewis basin, on the Snake River, between Glenns Ferry and Weiser; the Otis basin, in the extreme northeastern part of Harney County, Oreg.; the Harney basin, included in the inland basin draining into Malheur and Harney lakes, and the Whitehorse basin, in the southern part of Whitehorse Valley.

The legal restrictions which should control the construction and use of artesian wells are pointed out and the text of the Washington law relating to this subject is given.

Duty of water in Montana, S. FORTIER (*Montana Sta. Bul. 43, pp. 55, figs. 56*).—This is the second of a series of farmers' bulletins on irrigation and includes a summary of results of studies made in cooperation with the irrigation investigations of this Office. The bulletin defines "duty of water," discusses methods of measuring duty of water, and conditions affecting it, viz, losses in conveyance, climatic conditions, system of fixing time rotation, manner of paying for water, judicial decrees for excessive amounts, cultivation and grading, kind of crops, manner of irrigating, character of soil and subsoil, ground-water level, and configuration of the surface of the land; and gives tabular statements accompanied by diagrams showing the observed duty of water under laterals in 46 different cases and under canals in 8 different cases. The average duty under laterals was 142 acres for each cubic foot-second of water, or 3.7 acres per miner's inch. The duty under canals was considerably less, about 2.5 acres, due to losses in conveyance.

Water resources of Molokai, Hawaiian Islands, W. LINDGREN (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 77, pp. 62, pls. 4*).—This report is based on observations made in 1900 and deals with the water supply in its relation to the decrease of the forested area, grazing, and other conditions. The problems of water conservation and utilization are discussed and it is shown that they are "rather difficult and involved, but are similar in many respects to those of the arid West, the solution being found in combined systems of storage, water-power development, use of the power in pumping, the construction of wells, collecting tunnels, and the economical employment of various devices for lifting water." The topography, geology, soils, climate, vegetation, agricultural possibilities, etc., of the island are also briefly discussed.

"The soils of Molokai are similar to those of the other islands of the Hawaiian group and are usually of great fertility. They may be divided into residual and sedimentary soils.

"The residual soils result from the gradual decomposition of the basaltic lavas and are usually deep red, very rich in iron and in substances necessary for plant growth.

"The sedimentary soils are partly of a deep-red color, partly dark brown, and not very different in character from the residual soils; they consist, in fact, of the same substance merely transported and redeposited. In a few places along the immediate coast line are small areas covered by coral sand, consisting largely of carbonate of lime, usually more or less mixed with detritus from the hills.

"The west end of the island contains a very great amount of good, smooth land, with excellent soil. . . .

"The finest body of agricultural land on the island is situated in the great gap, and has an area of about 14,000 acres. The principal problem of the water supply of the island is how to bring the water from that part which receives an abundant precipitation to this arid portion containing the rich soils."

The rainfall on the northeasterly portion of the island and at all points over 2,500 ft. high is abundant, reaching 100 ins.; the west end and south coast are dry.

The sources of water supply which are discussed include springs, running streams, and wells. Estimates of the total amount of water available are given.

Preliminary plans and estimates for drainage of Fresno district, California, C. G. Elliott (*U. S. Dept. Agr., Office of Experiment Stations Circ. 50, pp. 9*).

Practical irrigation in humid areas, B. Adams (*Forestry and Irrig., 9 (1903), Nos. 6, pp. 285–288, figs. 3; 7, pp. 346–353, figs. 4*).—This article gives somewhat detailed descriptions of various irrigation plants used in Massachusetts, New Jersey, Florida, Texas, Kansas, and Wisconsin.

The management of water in Java, F. Bernard (*Aménagement des eaux à Java. Paris: Librairie Polytechnique, 1903, pp. 80, pls. 16, figs. 75*).—A study of the Javan system with reference to applicability to Indo-China. Since the Javanese so largely subsist on rice the report is substantially a treatise on rice irrigation. In the first part the development of agricultural industries since 1602 is briefly traced and the topography and other features of different parts of Java, the drainage basins, dams, canals, ditches, etc., are described. Maps show the irrigation system in detail and the nature and extent of the area irrigated. The second part deals with technical hydraulic and engineering details of construction and management of dams of various kinds, canals, aqueducts, siphons, weirs, etc. The third part is devoted to the actual distribution of water in rice culture.

Government control is briefly discussed. The water is distributed gratuitously, the government being reimbursed by the tax on the crop. When works now in progress are completed the government will be able to irrigate 775,000 hectares (1,914,250 acres) of land. This has been done at an expense of 300 to 400 francs per hectare ($24 to $32 per acre).

The restoration of the ancient irrigation works on the Tigris or the recreation of Chaldea, W. Willcocks (*Cairo: National Printing Dept., 1903, pp. 71, pls. 10*).—The author describes these works, especially the Nahrwan Canal, and discusses their restoration. Appendixes give monthly summaries of observations on temperature, pressure, rainfall, and wind movement at Bagdad during 1888, 1894, 1899–1902, and an address on Egypt 50 years hence.

The new directorate of agricultural hydraulics and improvement, L. Mougeot (*Jour. Agr. Prat., n. ser., 5 (1903), No. 6, pp. 183–187*).—The report, decrees, and regulations regarding the establishment of this directorate are given in full.

Notes on the floods of February 28 to March 5, 1902; effect of proposed drainage works on Passaic floods, C. C. Vermeule (*Geol. Survey New Jersey Rpt. 1902, pp. 27–57, pls. 7*).—A study of the causes and conditions of these floods, with a discussion of means of controlling such floods by means of storage reservoirs, drainage, etc.

First annual report of the State board of public roads of Rhode Island (*Providence, R. I.: E. L. Freeman & Sons, 1903, pp. 32, map 1*).—This is the first report of the board appointed under authority of an act of the State legislature passed in January, 1902, and deals with present conditions, needs, etc., of Rhode Island highways, and presents a classification of the "main or principal highways of the State" with recommendations of the sections to be first constructed. "The length of these particular sections makes a total of 20 miles, and the estimated cost for the proper improvement of the same amounts to $100,000, an average of $5,000 per mile. The estimate in each case provides for the construction of a macadam road of a standard width of 14 ft., exclusive of shoulders and gutters, with a varying thickness of crushed stone from 6 to 9 in., according to the location of the road, the nature of the soil, the amount and weight of traffic, and includes drainage and grading. . . . For the present year the board recommends an appropriation of $100,000, to be followed by an annual increased appropriation of $25,000 for 3 years; and for the fifth and sixth year an appropriation equal to that made for the fourth year. By this plan of graded appropriations the whole work could be completed within a period of 6 years."

On the cause of the cementing value of rock powders and the plasticity of clays, A. S. Cushman (*Jour. Amer. Chem. Soc., 25 (1903), No. 5, pp. 451–468, figs. 3*).—A series of comparative studies are reported which lead to the conclusions "(1) that the cementing power of rock powders is a property similar to the plasticity of clays; (2) that all rock powders that have cementing power show the same peculiar relation to water that is shown by substances that possess an amorphous colloid structure, i. e., they can be dehydrated and rehydrated, until, by prolonged high heating, the structure is destroyed." Page's method of testing the cementing value of rock powders, which was used in the experiments reported, is in brief as follows: "The stone or other material is ground in a ball mill until it passes a screen with 40 meshes per centimeter (100 per inch). This sifted powder is then mixed with sufficient water to make a stiff 'dough.' After standing 24 hours, cylindrical briquettes are made of standard size (25 mm. by 25 mm.) at a standard pressure of 100 kg. per square centimeter. This is done in a specially designed hydraulic press. The briquettes are then dried in an air bath at 100° and tested in an impact machine which delivers a standard blow of 1 kg., falling 1 cm. The cementing value is measured in this laboratory by the average number of standard blows that a series of briquettes made from a rock powder will stand."

Machines at the general agricultural congress at Paris, M. Ringelmann (*Jour. Agr. Prat., n. ser., 5 (1903), Nos. 13, pp. 404–411, figs. 14; 14, pp. 437–440, figs. 8; 15, pp. 470–475, figs. 12*).—This includes a general account of the exhibit of agricultural machinery at this congress, and describes special forms of machines of the following classes: Machinery and implements for (1) preparing the soil, (2) for seeding and subsequent culture, (3) for harvesting the crop, (4) for preparing the crops for use, and (5) for miscellaneous purposes.

Fertilizer machinery (*Amer. Fert., 18 (1903), No. 6, pp. 5–19, figs. 19*).—Various machines used in the preparation of fertilizers on a commercial scale are described.

Tests of machines for the decortication of rice in Madagascar, M. Ringelmann (*Agr. Prat. Pays Chauds, 2 (1903), No. 12, pp. 697–702, figs. 3*).—Tests of 4 machines for this purpose are reported.

Cold-storage building, J. B. Reynolds (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 6–9, figs. 6*).—An account is given of the construction of a cold-storage building using mechanical refrigeration, with a summary of results of experiments with it, which have been reported elsewhere. (E. S. R., 14, p. 866.)

Cooperative granaries and structures for drying grain, M. Ringelmann (*Jour. Agr. Prat., 3. ser., 5 (1903), No. 19, pp. 600–603*).—Previous articles on this and related subjects are noted and a number of structures in actual use are described.

Notes on stable ventilation, Noack (*Deut. Landw. Presse, 30 (1903), No. 34, p. 289*).—Brief remarks on the importance of adequate ventilation even for piggeries, and on means of securing it.

Whitewash and lime paints for farm buildings, M. Ringelmann (*Jour. Agr. Prat., n. ser., 5 (1903), No. 16, pp. 501, 502*).—Various formulas are given.

MISCELLANEOUS.

Fifteenth Annual Report of Louisiana Stations, 1902 (*Louisiana Stas. Rpt. 1902, pp. 24*).—This contains a summary of the work of the Sugar Station at Audubon Park, the State Station at Baton Rouge, and the North Louisiana Station at Calhoun, an outline of the work of the State geological survey, a list of publications issued by the stations, organization lists, and a financial statement for the fiscal year ended June 30, 1902. Results in 1901 and 1902 of comparative tests of sugar-cane seedlings are brifly reported.

Eighteenth Annual Report of Maine Station, 1902 (*Maine Sta. Rpt. 1902, pp. 226*).—This is made of reprints of Bulletins 79–88 of the station on the following

subjects: Poultry experiments in 1900-1901 (E. S. R., 13, p. 981); feeding stuff inspection (E. S. R., 13, p. 1075); fertilizer inspection (E. S. R., 13, p. 1031); orchard notes (E. S. R., 14, p. 42); grass thrips (E. S. R., 14, p. 373); cereal breakfast foods (E. S. R., 14, p. 376); fertilizer inspection (E. S. R., 14, p. 649); variations in *Trillium grandiflorum* (E. S. R., 14, p. 634); oat smut and its prevention (E. S. R., 14, p. 877); potato insecticides and fungicides in 1902 (E. S. R., 14, p. 886); finances, meteorology, index (noted below).

Fifteenth Annual Report of Michigan Station, 1902 (*Michigan Sta. Rpt. 1902, pp. 67–325*).—This includes a financial statement for the fiscal year ended June 30, 1902, reports of the director and heads of departments on the work of the station during the year, meteorological observations noted elsewhere, and reprints of Bulletins 193–202 and Special Bulletin 16 of the station on the following subjects: Some experiments with beet pulp as a stock food (E. S. R., 14, p. 179), feeding experiments with dairy cows (E. S. R., 14, p. 182), report of the South Haven Substation for 1901 (E. S. R., 14, p. 143), strawberry notes for 1901 (E. S. R., 14, p. 147), notes on vegetables (E. S. R., 14, p. 143), sugar-beet experiments in 1901 (E. S. R., 14, p. 244), sand lucern (E. S. R., 14, p. 243), cowpeas, soy beans, and winter vetch (E. S. R., 14, p. 239), some insects of the year 1901 (E. S. R., 14, p. 267), aeration of milk (E. S. R., 14, pp. 387, 388), and analysis of commercial fertilizers (E. S. R., 14, p. 343).

Fourteenth Annual Report of Texas Station, 1902 (*Texas Sta. Rpt. 1902, pp. 139–146*).—This consists of a report of the director on the work of the station and substations during the year and a financial statement for the fiscal year ended June 30, 1902.

Finances, meteorology, index (*Maine Sta. Bul. 88, pp. 211–226+8*).—This includes reprints of 6 newspaper bulletins dealing with fresh fish as manure, the Angora goat, management of raspberries and blackberries, apples and plums for central Maine, experiments with clover and low grade cotton-seed meal; meteorological observations noted elsewhere, a financial statement for the fiscal year ended June 30, 1902, an index to the bulletins of the station issued during the year, and announcements relative to the work of the station.

Proceedings of the twenty-fourth annual meeting of the Society for the Promotion of Agricultural Science held at Washington, D. C., December 29, 1902 (*Proc. Soc. Prom. Agr. Sci. 1902, pp. 113, pls. 2*).—The papers which were read at the meeting were noted in the article in E. S. R., 14, p. 523. The president's address was given in full in E. S. R., 14, p. 625. The other papers which have been included in the proceedings are noted elsewhere in this issue.

History of the Örebro Royal Agricultural Society from 1803–1902, J. V. JONSSON (*Örebro Läns Kongl. Hushållnings-Sällskaps, historia 1803–1902. Örebro: Örebro Dagblads, 1902, vols. 1, pp. 430, pls. 14; 2, pp. 307, pl. 1*).—In these 2 volumes the author has brought together an elaborate historical account of the development of agricultural industries in the district of Örebro from the earliest historical times until the present. Particular attention, however, is given to the development of agriculture during the nineteenth century. The various subjects which are discussed include an historical review of Swedish agriculture before the year 1800, historical notes on the development of the above society during the nineteenth century, notes on the agricultural school of the district and other related schools, notes on the lakes and marshes of the Örebro region, and general accounts of cattle raising, dairying, horse breeding, forestry, fruit raising, domestic science, and fish culture.

The agricultural development of the Philippines, M. L. TORNOW (*Berlin: Hermann Patel, 1901, pp. 53, figs. 10, map 1*).

Experiment station work, XXII (*U. S. Dept. Agr., Farmers' Bul. 169, pp. 32, figs. 6*).—This number contains articles on the following subjects: Pure water for

cows; when to cut forage crops; lippia or fog fruit; pithiness in celery; irrigation of strawberries; farmers' fruit garden; management of orchards; tropical and subtropical fruits; China asters; preserving sweet potatoes; food value of beans; tankage for pigs, and remedies for fleas.

The farmer's business handbook, I. P. ROBERTS (*New York and London: The Macmillan Company, 1903, pp. XIII+300*).—The object of this book (one of the Rural Science Series) is to encourage the average farmer to adopt more business-like methods. It treats of the simpler forms of farm accounts, and the commoner and more usual aspects of law as applied to rural matters. It also contains agricultural inventories from the Twelfth U. S. Census.

Destruction by lightning in Ontario, 1902, J. B. REYNOLDS (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 9–11*).—Statistics are given of damage to buildings, trees, stock, and persons.

NOTES.

Alabama College and Station.—J. F. Duggar has been elected director of the station. The chemical work of the station has been divided; hereafter Prof. B. B. Ross will have charge of the analysis of fertilizers and feeding stuffs and Dr. J. T. Anderson, now promoted to the position of chemist, will have charge of the analysis of soils and crops. J. C. Phelps, assistant chemist, has resigned to engage in teaching agriculture and chemistry in the district agricultural school at Evergreen, Ala.

Arkansas Station.—W. G. Vincenheller has been elected director to succeed R. L. Bennett, resigned. The substation at Newport has been closed and the property there will be disposed of.

California Station.—The last legislature appropriated $5,000 to the station as a deficiency fund for the publication of delayed bulletins and reports, and $6,000 annually for two years for university printing, a portion of which will be available for publications of the station. Henry J. Quayle of Illinois has been appointed assistant in entomology, and George Roberts, formerly of the Kentucky Station, assistant chemist in charge of the fertilizer control. M. E. Jaffa, who has been on a year's leave of absence, has returned. Professor Jaffa spent a portion of the time with Prof. W. O. Atwater at Middletown, Conn., studying methods of food investigation, and about four months traveling in Europe studying agricultural institutions of various kinds.

Connecticut College and Station.—W. E. Simonds, former vice-president of the board of trustees, is dead.

Delaware College.—W. H. Bishop, professor of agriculture and biology, has resigned to engage in dairy farming and stock breeding at Scarsdale, N. Y. He is succeeded by James A. Foord, formerly of Cornell University and Station.

Georgia Station.—The station is overhauling its waterworks system, putting in a new pump and gasoline engine, and constructing a 20,000-gallon reservoir to be filled with spring water. The pump will be used as a means for irrigating small areas near by.

Hawaii Station.—The legislature of Hawaii has appropriated for the biennial period ending June 30, 1905, $111,650 for the board of agriculture, horticulture, and forestry. This includes $16,800 for the federal experiment station as follows: Maintenance $10,000, salary of chemist $2,000, laboratory and office building $3,000, residence for chemist $1,500, stenographer $600, and farmers' institutes $300.

Indiana Station.—The station cattle barn was struck by lightning and entirely destroyed on July 10, the loss, including contents, being over $4,800, with insurance amounting to $2,500. No stock was lost. The building will be replaced by a temporary structure costing between $1,500 and $2,000, with the intention of erecting next year a more substantial barn at a cost of about $15,000.

Iowa College and Station.—Rev. A. B. Storms of Des Moines has been elected president of the college and will take up his duties with the beginning of the new college year. G. E. Stayner has been appointed assistant in agronomy at the station.

Kansas College and Station.—D. H. Otis, in charge of animal husbandry in the college and station, has resigned to become superintendent of a large farm in Labette County, Kans. He entered upon his new duties about September 1.

Maine University.—The last legislature appropriated $2,500 a year for a department of forestry, and the trustees have now authorized the appointment of a professor of forestry.

Massachusetts Station.—W. E. Tottingham has been appointed assistant in the chemical laboratory, department of foods and feeding.

Michigan College and Station.—Hon. Franklin Wells, for thirty years a member of the State board of agriculture, which has charge of the college and station, and for nearly twenty years president of that board, died suddenly July 3, at Constantine, Mich. He is succeeded by Charles F. Moore, of St. Clair.

Missouri University and Station.—The station has established what is thought to be the first laboratory for animal breeding in the United States. It is intended to investigate some of the applications of Mendel's law to animal breeding, and to observe accurately the results from various methods of breeding. Observations will be made on the factors which determine the birthweight of animals. This laboratory is in charge of Prof. F. B. Mumford. E. B. Forbes, B. S., of the University of Illinois, has been elected assistant professor of animal husbandry.

Nebraska University and Station.—The contracts have been let for a dairy barn and stock-judging pavilion and machine shops, provided for by the last legislature. The cost of these two buildings will be about $20,000. The barn will be 164 ft. long, the main part being 80 ft. wide and the wings 40 ft. and 64 ft., respectively. It will cost about $10,000 when finished. It will contain a stable for cattle, 60 by 64 ft., and accommodate 50 dairy cows and about 20 or 30 young cattle. It will contain a bedroom, bathroom, and closets for farm men; and will also have accommodations for hay and grain storage, with several box stalls for hospital purposes and for stock bulls. A live-stock judging pavilion, 40 by 60 ft., will form one wing to the barn. This, together with the offices, will be heated with steam. The shop building will include a farm-machinery room for instruction in the handling of ordinary farm machinery, a carpenter shop for elementary work, and a blacksmith shop for forge work. The main part of this building is 42 by 72 ft., two stories high, with a wing for the blacksmith shop, 40 by 60 ft., one story high. The contract is also about to be let for the construction of a greenhouse and horticultural laboratory for students' use, the greenhouse space to be 40 by 60 ft. and the horticultural workroom about 40 ft. square, the cost of this building to be about $6,000. A class of 45 teachers from different parts of the State took a course in agriculture at the summer school. The chemical department of the station has been making analyses of samples of sorghum, taken daily during a recent dry spell, to ascertain the relation, if any, between dry weather and the presence of prussic acid, as has been claimed.

Nevada College and Station.—J. E. Stubbs, president and director, is traveling in Japan for his health, which he has not fully recovered since his recent severe illness. N. E. Wilson, chemist, has been appointed vice-director of the station. S. B. Doten, entomologist, has been making quite extensive experiments in the field in destroying locusts and crickets, which are proving a great plague in the eastern counties of the State.

New Hampshire Station.—Lucian A. Hill, assistant chemist, has resigned to become assistant chemist in the research laboratory of the McLean Insane Asylum at Waverly, Mass. H. H. Scudder, formerly of this Department, and W. E. Hayes have been appointed assistant chemists in the station. W. D. Gibbs, of the Texas College and Station, has been elected president of the college and director of the station, and will enter upon his new duties September 1.

New Jersey Station.—The board of managers has awarded the contract for rebuilding the laboratory building, which was partially destroyed by fire in April. It is expected that the building will be ready for occupancy in September.

Cornell University and Station.—I. P. Roberts retired from active duties in the college and station July 1. He is succeeded by L. H. Bailey, who is director of the college of agriculture, dean of the faculty, and professor of rural economy. H. H. Wing, who has heretofore had charge of animal industry and dairying, has been relieved of the latter subject, which is now in charge of R. A. Pearson, formerly assistant in the dairy division of this Department. Samuel Fraser, formerly of the Briarcliff School, has been elected instructor in agronomy, and J. A. Bonsteel, of the Bureau of Soils of this Department, has been elected to the chair of soil investigation. G. W. Cavanaugh has become assistant professor of chemistry in its relations with agriculture, and J. A. Bizzell has been appointed assistant chemist to the experiment stations. John Craig, formerly in charge of extension work, is now professor of horticulture, with R. S. Northup of North Dakota as assistant. The university has recently purchased three farms lying contiguous to the old farms, which will be used in connection with the station and college work in agriculture.

North Carolina College.—The summer school for teachers during the month of July was attended by 361 teachers, about 140 of whom took agriculture and nature study. The school was a great success and aroused much enthusiasm. A farmers' convention covering 3 days was held at the close of the school, which was attended by between 250 and 300 persons. A permanent organization was effected and a much larger meeting is planned for next year.

Ohio Station.—George M. Lummis has been appointed assistant botanist.

Oklahoma College and Station.—Material changes have been made in the courses of study in the college. The preparatory department has been discontinued and in its stead a school of agriculture and domestic economy has been established. The course in the school covers 2 years of 20 weeks each, beginning October 15 and closing March 15 in each year. Students proficient in common school studies may take all of the agricultural work of the school in 1 year of 20 weeks. The college course has been extended to 5 years, and graduates of the common schools are admitted to the subfreshman class without examination. The college course in agriculture has been modified so that in addition to full work in agriculture and allied subjects, the student will elect from botany, veterinary science, and chemistry, 4 terms work in one and 3 terms work in another, in addition to the required work earlier in the course. The 8 weeks short course will be continued. W. C. Theile has been appointed clerk and stenographer of the station, vice C. O. Pearcy, resigned. F. O. Foster, a graduate of the Michigan Agricultural College, has been appointed assistant in agriculture in the station and assistant in dairying in the college.

Rhode Island College and Station.—Ex-Governor Charles Dean Kimball, of Providence, has been appointed on the board of managers, vice Benjamin A. Jackson, term expired, and was elected president of the board at the July meeting. The temporary appointment of W. D. Hurd, B. S., to act as agricultural demonstrator marks a new epoch in Rhode Island. He is paid from a special State appropriation and is giving demonstrations around the State in soil testing, spraying, and other agricultural lines, thus carrying directly to the farmers the results of the investigations of this and other stations. This work seems to meet with general favor.

South Dakota College.—J. W. Heston has resigned from the presidency of the college and has been succeeded by Rev. James Chalmers.

Wisconsin University and Station.—George C. Humphrey, instructor in animal husbandry at the Michigan Agricultural College, succeeds W. L. Carlyle, who, as previously noted, has resigned to accept a similar position in the Colorado College

and Station. W. B. Richards has been appointed assistant in animal husbandry. Dr. A. S. Alexander, lecturer in the Chicago Veterinary College, has been appointed instructor in veterinary science and will also give lectures and demonstrations on the horse. The last legislature appropriated $25,000 for furnishing and equipping the new agricultural building and $15,000 for a farm engineering building. It also gave $10,000 for the purchase of improved live stock, $10,000 for the purchase of additional farm lands, $1,500 annually for 2 years for tobacco investigations, and $2,500 annually for 2 years for cranberry investigations.

Wyoming University and Station.—E. E. Smiley, president of the university, has resigned, the resignation to take effect September 1. Wilbur C. Knight, professor of geology and mining engineering in the university and geologist of the station, died July 28. The State board of charities has turned over to the university and station the penitentiary buildings and farm in Laramie, the last of the prisoners having been transferred to the new penitentiary at Rawlins. The buildings connected with the penitentiary belonging to former contractors were purchased for the station from State funds. There is thus added to the college and station equipment a farm of 320 acres, situated on the Laramie River, where an abundance of good water is at hand, and buildings which cost originally approximately $100,000. The final purchase of the old experiment station farm, consisting of 120 acres, has been authorized. The station is to take up work with live stock, and it is expected that some breeding stock of cattle, horses, and swine will be added during the year. It already has the promise of a few brood mares with which to begin its work in horse breeding.

Convention of Farmers' Institute Workers.—The eighth annual meeting of the American Association of Farmers' Institute Workers was held in the Parliament Buildings, Toronto, Canada, June 23–26. Seventeen of the States of the Union and four of the Provinces of the Dominion of Canada were represented by their institute officials.

The association was welcomed to Canada by the Honorable G. W. Ross, Premier of Ontario, who spoke of the remarkable progress which agriculture had made in recent years, both in the United States and in the Dominion of Canada, and of the friendly competition that exists between the two countries.

The president, W. C. Latta, in his annual address, reviewed the scope and growing importance of the farmers' institute work, dealing particularly with the means of making it more effective for good. Referring to the training of the institute worker he said that this should be special and "should include a boyhood spent on the farm, a common and high school education, a thorough technical training at an agricultural college, and, after graduation, several years of experience in some line of practical agriculture." The qualifications of the workers and the organization of farmers' institutes was discussed at length.

The programme included the following papers, most of which were quite freely discussed: Training for Institute Work; Prime Qualifications; Should the Worker have Special Training? How may it be Secured? Franklin Dye, Trenton, N. J. Organization for Institute Work—Should it be a Permanent Organization or should we work through other Farmers' Organizations? L. R. Taft, Agricultural College, Michigan. Accessories in Institute Work—Demonstrations, Judging Contests, Field Experiments, F. H. Rankin, Urbana, Ill. How far is it Practicable to Conduct a Season's Campaign in some Agricultural Interest? What Interests may be Appropriately and Successfully Advanced, such as Roads, Homes, Reforesting, Agriculture in High Schools, or Agricultural Education? F. E. Dawley, Fayetteville, N. Y. How to Advertise Institute Meetings, Geo. McKerrow, Madison, Wis. The Evening Session—How to make it Interesting and Instructive: (a) The Romance of Agriculture, C. C. James, Toronto, Canada; and (b) Local Help, Wesley Webb, Dover, Del.

Some Essentials to the Permanency of Farmers' Institutes, E. B. Voorhees, New Brunswick, N. J. How the Farmers' Institutes and the Agricultural Colleges may be mutually helped, Dr. James Mills, Guelph, Canada. How the National Department of Agriculture may through its Institute Office Assist the State Institute Meetings, John Hamilton, Washington, D. C. Women's Institutes, Miss Laura Rose, Guelph, Canada, and Miss Agnes Smith, Hamilton, Canada. How the Institutes can Bring the Most Good to Our Girls, Miss Blanche Maddock, Guelph, Canada. How to Enlist the Interest of Our Boys in Agriculture, Hon. John Dryden, Toronto, Canada.

There was a discussion of problems and methods in institute work, participated in by delegates selected from different sections of the country; and the institute work from the standpoint of the worker was discussed by D. C. Anderson, Andrew Elliott, and Henry Glendinning, of Ontario.

The reports of the directors giving account of the institute work in the several States all indicated that progress had been made during the year, and that appreciation of the work is becoming more general as the public becomes better acquainted with what is being done for the benefit of agriculture through this method of instruction, and with what is possible to be accomplished.

Expressions with regard to the quality of the work required showed that the people were not satisfied with anything but the best. The problem now confronting the institute directors is that of securing a sufficient number of capable instructors to meet this need. Two of the State directors reported that they were about to introduce into their system a normal school plan for training lecturers, the instructors in these schools to be selected from the forces of the agricultural college and experiment station, and the school to continue from one to two or three weeks as the necessities in each case seem to justify.

On Thursday the members of the association and their friends were given a complimentary trip to the Ontario Agricultural College at Guelph, where luncheon was served and the visitors were escorted over the grounds and through the buildings by the members of the faculty. The president, Dr. James Mills, in a short address, explained to the association the work and purpose of the college. He called attention to its appreciation on the part of the citizens of Ontario by stating that during the month of June, last year, over 30,000 farmers had visited the college and inspected its work, and that this year that number would probably be exceeded. On the day that the association was at the college there were over 1,200 visiting farmers present. This movement was begun, and has been developed to its present proportions, through the instrumentality of the farmers' institutes of the Province.

At a business meeting on Wednesday several amendments to the constitution, proposed at the last annual meeting, were considered and adopted. Among them was one providing for representation of this Department in the association by two delegates, one from the Department at large and one from the Office of Experiment Stations. Resolutions were passed expressing appreciation of the interest manifested by the Department and the Office in the institute work and in the meetings of the association, and approving the step which has been taken in establishing an agency in the Department for its promotion and aid.

On Friday morning such of the members as remained over were taken around the city in a tallyho coach, and given opportunity to see its principal streets, public buildings, and other objects of interest; after which they were driven to the Dentonia Stock Farm, now owned by Mrs. W. H. Massey, of Toronto. The visitors were shown over the dairy, and the various barns and other buildings connected with this farm, all of which are complete in their appointments, and admirably arranged for their purposes.

St. Louis was selected as the place of the next meeting, the date being left for the executive committee to fix. The officers elected for the ensuing year were: Presi-

dent, B. W. Kilgore, of North Carolina; vice-president, E. E. Kauffman, of North Dakota; secretary-treasurer, G. C. Creelman, of Toronto, Canada; executive committee, Geo. McKerrow, of Wisconsin; H. G. Easterly, of Illinois; and J. C. Hardy, of Mississippi, in addition to the president and the secretary-treasurer, ex officio.

American Chemical Society.—The twenty-eighth general meeting of the American Chemical Society was held at Cleveland, Ohio, June 29 and 30. About 100 members were present. A brief address of welcome was delivered by Prof. E. W. Morley, of Western Reserve University, to which the president of the Society, Dr. J. H. Long of Northwestern University responded. While the programme was of the usual length for the summer meetings, few papers of direct agricultural interest were presented. A paper by G. B. Frankforter, of the University of Nebraska, showing that 42 per cent of pitch, containing 21 per cent of turpentine, besides a large amount of good charcoal, can be obtained from the butts of the Douglass fir which are now discarded by lumbermen, was of especial interest as pointing a way to a better utilization of our forest products. Dr. F. K. Cameron of this Department discussed the toxic limits of various acids and salts, singly and combined, for seedlings of corn, wheat, and clover, showing the acids to be, as a rule, more toxic than the salts and single salts more so than mixtures. The results, however, are not uniform with the different plants and do not always bear out the dissociation theory. The possibility of breeding plants of high resistant power was referred to.

In a paper on cereal foods, by E. Gudeman, it was shown that as a rule these differ very slightly in composition from the grains from which they are prepared. The carbohydrates have probably been rendered somewhat more digestible by the cooking processes through which the cereal foods have gone.

A. A. Noyes and R. B. Arnold discussed the rate and conditions of hydrolysis of starch, and the precautions to be observed in determining this substance by means of Fehling's solution. It was shown that the acid solution should not be completely neutralized before the Fehling's solution is added.

A paper by A. P. Sanders on the analysis of sea water from Woods Hole led to a discussion of the possibility of sympathetically preparing sea water in which marine flora and fauna would thrive. Dr. J. S. Chamberlain of this Department, pointed out that this had been successfully done in some experiments conducted in the Department.

The afternoon of each day was devoted to excursions through the city and to the chief industrial centers and manufacturing plants of Cleveland. The city contains an unusual number of establishments of this sort in which chemistry finds important application.

New Hydrographic Committee in Russia.—The past spring a law was promulgated for the establishment, in the Russian ministry of agriculture and imperial estates, of a hydrographic committee to deal with scientific, technical, and legal questions relating to the conservation and regulation of the water supply of the country. The committee is to be composed of representatives from the different branches of the government, especially from the ministry of agriculture and imperial estates, and from the Imperial Academy of Sciences, as well as experts in hydraulics, geology, agriculture and water rights. The subjects under the jurisdiction of the committee are measures relating to the conservation, increase, and regulation of the water supply and the laws relating thereto; a survey of the data available with reference to drafting a general water law; questions relating to the management of water by private parties; technical questions involving the interests of landed properties of the state, town, or private persons; and the settlement of disputes arising under the law relating to the construction of irrigation and drainage ditches through a neighbor's land.

Miscellaneous.—Dr. Wilhelm Rimpau, the distinguished agriculturist of Schlanstadt, Germany, died May 20, 1903, in his sixty-first year. Rimpau is best known in this country through his plant breeding work with cereals. He was one of the first to point out the almost universal self-fertilization of wheat, and maintained that different varieties of wheat could be grown in adjoining rows with little or no probability of crossing. Acting upon this belief he was able to establish his crossbred cereals and to conduct extensive experiments upon a limited area of ground. He devoted much attention to potato and sugar beet breeding, and was formerly prominent in the investigation on reclamation and cultivation of moor soils. He is said to have been one of the four founders of the *Deutsche landwirthschaftliche Gesellschaft.*

Prof. G. E. Day of the Ontario Agricultural College, has declined a tempting offer to go to South Africa as secretary of agriculture for the Orange River Colony. A strong stand for his retention at Guelph was made by representatives of the live stock interests, who paid a high tribute to his sterling qualities and excellent work, in an interview with the premier and the minister of agriculture for Ontario.

W. A. Noyes of the Rose Polytechnic Institute, and H. N. Stokes of the U. S. Geological Survey, have been appointed chemists in the Bureau of Standards in this city.

We note from *Science* that the professorship of forestry at the Royal Agricultural College at Cirencester, which has been vacant since the death of the late Sir Henry Gilbert, has now been filled by the appointment of Dr. W. Schlich, late inspector general of forests for the government of India and principal professor of forestry, Coopers Hill.

A canvass has been made with reference to the organization of a society for horticultural science, which would meet in connection with kindred societies such as the American Association for the advancement of Science and the American Pomological Society. The matter has been promoted by Prof. S. A. Beach of the New York Geneva Station. It will be considered in conjunction with the meeting of the American Pomological Society at Boston, September 10–12, and if sufficient interest is manifested a permanent organization will be formed.

A call has been issued for the convention of the Association of American Agricultural Colleges and Experiment Stations, to be held in this city beginning Tuesday, November 17, 1903.

Notice has been received of an international dairy congress to be held at Brussels, September 8, 9, and 10. Among the subjects to receive consideration special mention is made of (1) an international agreement for the repression of adulteration of dairy products, (2) the hygiene of milk and its products, and (3) the formation of an international dairy association. The congress will also be open to the presentation of papers and discussion on all subjects pertaining to dairy science and technics.

The American Grape Acid Association, 318 Front St., San Francisco, Cal., offers a bonus of $25,000 to the person who can devise a process for the use of grapes for grape acid. The association desires the best formula, and the right to use the same, by which grapes containing 20 per cent saccharine material may be turned into tartaric acid at a price that will admit of placing the product upon the market. This offer closes December 1, 1904, when all papers are referred to the following jury: Percy T. Morgan, president of the California Wine Association; Andrea Sbarboro, president of the Manufacturers' and Producers' Association of California; E. W. Hilgard, director California Agricultural Experiment Station; C. de Guigne, president of the American Cream Tartar Co., and A. Schilling, of the firm of A. Schilling & Co., the decision of 3 out of the 5 being final. The association invites correspondence regarding this matter.

O

EXPERIMENT STATION RECORD.

Vol. XV. October, 1903. No. 2.

Among the important scientific meetings held during the past summer and early fall were several whose fields border on agriculture and horticulture, and which were this year of rather special importance. This was the case despite the tendency on the part of a considerable number of societies to change the time of their principal meetings from the summer to the winter season. The month of September was especially rich in such meetings, and short accounts of several of them are given in the present issue.

By far the largest meeting of this kind was the Eleventh National Irrigation Congress, held at Ogden, Utah, September 15–18. This was attended by nearly 1,500 delegates and visitors, the largest attendance in the history of the congress, and attracted specialists from the agricultural colleges and experiment stations throughout the irrigated region.

The Secretary of Agriculture was present as a guest of the congress and presented a paper setting forth quite fully the work of his Department in relation to irrigation and the needs of that region. This paper was received with much interest and appreciation, and a resolution indorsing the work of the Department was unanimously adopted in open session.

An extended programme of general and technical papers was provided, but so much time was taken up in general addresses and debates that the majority of the special papers were presented only by title. The interest of the congress was largely centered in the plans and projects of the reclamation service under the national irrigation law, and the repeal of certain land laws. The lengthy debate on the policy of repealing the desert land act, the timber and stone act, and the commutation clause of the homestead act was concluded by a compromise resolution asking Congress to amend the laws so as to prevent fraud.

A novel and interesting feature of the congress was a very fine display of the products of irrigation, exhibited in competition for prizes. The prizes consisted of four silver cups, valued at $500 each,

donated by private parties, and were for the finest fruit (won by Idaho), the best display of barley (won by a Montana malting company), the finest hops (won by North Yakima, Wash.), and the best sugar-beet exhibit (won by a farmer of Garland, Utah). In addition, the Utah Station had an interesting exhibit illustrating some very striking results of irrigation experiments on wheat, rye, and sugar beets, and the Wyoming Station made a fine showing of barley.

The meeting of the American Veterinary Medical Association at Ottawa developed a unanimity of opinion regarding the desirability of further improving veterinary instruction at some of the less thorough institutions. This is made necessary by the rapid progress in veterinary medicine, as a result of the extensive scientific investigation which is being carried on throughout the world, and by the increased demands upon veterinarians in public positions and in private practice for thorough equipment and preparation in their profession. A proposition for systematic supervision of veterinary instruction throughout the United States and Canada by the association, with a view to improving the standard of such instruction, met with very general approval.

Perhaps the most important scientific event of the meeting was the discussion on the subject of tuberculosis. On the one hand, it was shown conclusively that human and bovine tuberculosis may be intertransmissible, and in view of the evidence presented this conclusion was generally accepted by the members of the association. On the other hand, the successful experiments of Hon. W. C. Edwards, of Rockland, Ontario, in the application of the Bang method, the results of which were inspected by the members of the association, demonstrated the practicability of this method on a large scale and showed that it is comparatively easy for the stock raiser to eradicate tuberculosis from a herd without sacrificing valuable animals.

It is interesting to note that some of the results relative to tuberculosis announced at this meeting received strong corroboration at the International Congress of Hygiene and Demography, held at Brussels September 2–8. This congress was largely attended by physicians and veterinarians from European countries and America.

The announcement of the results arrived at by the German Imperial commission precipitated a long and rather heated discussion relative to the duality of tuberculosis, during which the adherents of the Koch theory were compelled to admit the possibility of transmitting the disease between man and animals. The sense of the congress was expressed in a resolution recognizing the possibility of the intertransmission of tuberculosis, and urging that the usual sanitary precautions for the prevention of such intertransmission should be continued in force without abatement.

Another important announcement made at this international congress was a report by Arloing to the effect that he had succeeded in immunizing cattle against tuberculosis by inoculation with attenuated cultures of tubercle bacilli. The results obtained by von Behring, McFadyean, Pearson, and others, previously noted,[a] are thus substantially corroborated.

It will be remembered that von Behring's method consisted in producing a mild form of tuberculosis in cattle by inoculation with an attenuated culture of the bacilli. The best results were obtained from the use of bacilli of human origin which had been cultivated on artificial nutrient media for a number of years. It was found preferable to apply this method of immunization to young cattle from five to seven months old, which received intravenously one milligram of a serum culture and four weeks later twenty-five milligrams of the same culture. The first inoculation usually produced a slight elevation of temperature, some loss in weight, and a susceptibility to tuberculin. The symptoms soon disappeared, however, and the animals were then found to be highly resistant to inoculation with large quantities of virulent tubercle bacilli.

Various modifications of this method have been employed by von Behring and other investigators, but the results obtained in Germany, the United States, and France agree in indicating that a high resisting power or practical immunity may be produced in cattle by this method.

The biennial meeting of the American Pomological Society at Boston was the occasion of the formation of a new scientific organization by the horticulturists in attendance, and within the society several new matters of general importance were considered. Among these were the packing of fruit under Government supervision, such as is exercised in Canada; the scoring of fruit according to a definite scale of points, for which no satisfactory basis has yet been devised; and the nomenclature of new varieties.

Two important steps have recently been taken by the society which should tend to simplify the nomenclature of fruits by preventing the further duplication of names and the renaming of old varieties. These are the establishment of an ad interim committee on the examination of new fruits, and the adoption of a new code to govern the naming of fruits, the latter provided by a special committee on the revision of the rules of nomenclature which was appointed four years ago. While this action will not prevent confusion and fraud in variety names on the part of unscrupulous persons, it will guard against unintentional mistakes by providing a practical means for entering supposedly new varieties.

[a] E. S. R., 14, pp. 393, 495, 609.

The usual number of papers on the practical and technical phases of pomology were presented, which are noted quite fully in the account of the meeting given elsewhere (p. 204).

The new Society of Horticultural Science has at present no connection with the Pomological Society, and was organized by independent action. Its purpose is to foster the development of the scientific aspect of horticulture as distinct from its popular side; and it is expected to occupy a place not now filled by any other organization. For a long time American horticulturists engaged in research work or in teaching horticulture, particularly station and agricultural college men, have felt the need of an organization where they might discuss the technical features of their work. Previous to this time no place has been open to them. The numerous horticultural and pomological societies now in existence are organized along popular and commercial lines, and deal more particularly with the practice of horticulture.

The new organization proposes to concern itself primarily with the principles underlying horticultural practice, and the purely scientific and technical features of that art. Membership is to be open under certain restrictions to persons engaged in horticultural teaching and investigations. It will include for the most part the horticulturists of the experiment stations and agricultural colleges, and such other scientific men and investigators in different sections of the world as are engaged in work bordering on horticultural lines.

With reference to the matter of affiliation, there was a feeling shared by many that if the society affiliated with any other organization it should be with some scientific society from which it might derive inspiration for a higher order of work, rather than with a society organized along popular lines. This matter was finally left in the hands of a special committee, to be reported upon at the next meeting, as was also the question of issuing a periodical publication.

It is believed that the organization of this new society will prove of special value to experiment station horticulturists. It should have a tendency to systematize horticultural work and to stimulate it along investigational lines, besides serving as a rallying place for consultation and discussion. An examination of the literature of the experiment stations shows a considerable amount of research work bearing on horticulture, but this is not systematized or correlated to the extent that it is in some other branches of agriculture. Much of the work is disjointed, many problems are untouched, and still others need rounding out.

Provision is made by the society for the assignment of special subjects to referees and alternates for investigation, and several such assignments were made at the first meeting. It is intended to make these investigations systematic and comprehensive, including the chemistry, soil physics, physiological botany, etc., of the problems in ques-

tion. With an active programme committee attention can be focused upon the extent and limitations of knowledge relating to different horticultural problems, and investigation thus stimulated in the direction where it is most needed.

Elwood Mead, chief of the irrigation investigations of this Office, returned in September from Europe, where he spent the summer in studying irrigation. Germany, Switzerland, Italy, and France were visited, but the greater part of his time was spent in Italy investigating the laws and practice of that country. Some of his observations are of special interest as showing the conditions under which irrigation has been developed and is managed in that humid country, and the manner in which some of its problems have been disposed of.

The reason for paying special attention to the valley of the Po was the similarity of its conditions to those of many sections in the eastern part of the United States. The rainfall of this part of Italy is about 40 inches a year, which is above that of Omaha, Kansas City, or Cincinnati. Farmers do not irrigate because they have to, but because it pays. In the greater part of the country the staple crops are the same as those of the northern part of the United States, corn, wheat, and clover being the leading products. The fields in which these are grown are also frequently planted with mulberry trees, which furnish food for the silkworms. Irrigation increases the yield of mulberry leaves about one-third. It enables a crop of corn to be grown after the wheat crop has been harvested, and doubles the yield of alfalfa and clover.

Rice and "marcite," two important crops, could not be grown without the aid of irrigation, and these can not be grown everywhere in the irrigated districts. The most profitable crop is marcite. The marcite fields are water meadows which are kept green the year through by running water over the land for a short time every day. In winter the water for this kind of irrigation comes principally from springs and is warm enough to keep the grass growing in the coldest weather. The grass is cut when it reaches a height of about 15 inches. It is chiefly used for feeding dairy cattle; and in the vicinity of large cities like Milan, where there is a local demand for milk and butter, the annual value of this crop is surprising, the product from some of the fields last year having sold for $300 an acre.

Land and water rights in the best marcite districts surpass in price the fruit lands of southern California, some of the farms near Milan being held at over $3,000 an acre, and rights in the canal selling for over $1,200 an acre. These are maximum prices and are far higher than the prices for lands and water rights where only wheat and corn can be grown. The minimum prices for lands with rights in the ditches in the districts recently brought under irrigation range from $160 to $180 an acre. Unirrigated land in the same neighborhood sells

for about $100 an acre. The appearance of the crops on the unirrigated lands in July and August was very like those of Kentucky, Indiana, or Missouri. The grass along the roadside was green and there were no sharply defined lines between the irrigated and unirrigated lands, as is true in the arid part of the United States. The same crops grow above ditches as below them, but there was a luxuriance and perfection in the irrigated farms not seen where they depended on rain.

The oldest canal inspected in Lombardy was constructed in 1150. This was built by the monks and was small and crooked, as were nearly all the canals built during the next five hundred years. The land could be farmed without irrigation and the building of canals meant increased expenditure, more people to cultivate the land, more houses for them to live in, and more barns in which to store the products. The large outlay in other directions, besides the cost of ditches, retarded this change, but in recent years progress has been rapid because of the need of finding employment and support for the dense population, there being about 380 people to the square mile in the province of Milan. There are several important ancient canals which are used for navigation, but many of the large irrigation canals have been built within the past fifty years. Among those visited, the last to be completed cost about $1,200,000 and has been finished about five years.

One of the instructive features of Italy's irrigation system is the way in which farmers have united in cooperative societies to build and operate canals or to distribute water from laterals. The largest of these societies is the Irrigation Association at Vercellesi. It has 14,000 members and controls the irrigation of 123,500 acres. It supervises the operation of over 7,000 miles of canals and ditches, with 40 water masters, and has about 150 miles of telephone lines. It buys water at wholesale and pays on an average $170,000 a year for the quantity purchased. The main society is divided into 40 subordinate societies, each of which elects a member to a general assembly which directs the policy of the association. This society transacts a business of about $600,000 a year.

One of the effects of these cooperative societies is the absence of friction and controversy between neighbors and neighborhoods, so often manifest in the United States. In the society above referred to there has never been an appeal from the decision of the manager, nor a single instance of a member's failing to pay his water rentals. In traveling through a region in which 27,000 cubic feet of water per second was being distributed every day there was not a single complaint of injustice or extortion, nor a fear expressed by any farmer that he would not receive his share of water when his turn came.

Much of the land is farmed by tenants, and as the area each cultivates is small, the general practice is to rotate the use of water along

laterals. These rotations are worked out with a system not approached anywhere in the United States outside of Utah, and a few ditches in southern California. In one instance the turn of a farmer was only one hour each week. It began at 7 o'clock Monday morning and ended at 8 o'clock. That was his single "rain" in seven days which could be absolutely relied upon. The farmer paid about $6 a year for the watering of each acre. In looking over the accounts of one association the largest annual payment by any farmer for water was found to be about $1,200 and the smallest 4 cents.

The Government exercises absolute control over the public streams and regulates the amounts each canal may divert. Parties wishing to build new canals must obtain the Government's consent. No perpetual rights to water are now granted. Appropriations are treated as franchises and their life is limited to thirty years. On the other hand, the Government is liberal in its treatment of meritorious projects, frequently extending aid by paying the interest on bonds issued to secure funds to build canals, the usual plan being to pay 3 per cent for the first ten years, 2 per cent for the second ten years, and 1 per cent for the third ten years, so that the interest payments by the Government end with the expiration of the water right. When the right expires it may be renewed just as franchises are renewed in this country.

In many sections of Italy canal companies have experienced the same losses and farmers suffered the same injury from seepage as are met with in this country. In some instances canals have had to be cemented for their entire length. Drainage has also had to follow canal building, as the seepage water fills the farmers' fields and the cellars of houses in towns. In recent years the granting of rights to build canals is frequently conditioned on the canal company constructing, along with its irrigation works, a complete system of drains to carry off the surplus water. In some districts drainage works have been built under an agreement whereby the canal company pays 60 per cent of the cost of drains and receives the water they collect, the farmers pay 20 per cent, and the municipality the remaining 20 per cent.

Mr. Mead believes that irrigation is certain to be a large factor in increasing the production of farms in the humid parts of the United States, especially in those sections of the country where streams have fall enough to permit water to be distributed by gravity, and in the Southern States where the long hot seasons will make the ability to supply water when needed of great value to farmers. Irrigation is not for the arid West alone. The conditions which make it pay in Europe exist here in equal measure, and with increasing population and higher land values canal building will become as important along both slopes of the Alleghenies as it now is along the southern and western slopes of the Alps.

ANNUAL MEETING OF THE AMERICAN VETERINARY MEDICAL ASSOCIATION.

E. V. Wilcox, Ph. D.,
Office of Experiment Stations.

The fortieth annual meeting of this association was held in the council chamber of the city hall at Ottawa, Canada, September 1–4, 1903. An unusually large number of members and visitors were in attendance, and the meeting as a whole was considered to be one of the most important and instructive in the history of the association.

The usual order of business was observed on the first day, beginning with the address of welcome by Hon. Frederick Cook, mayor of Ottawa, followed by a response by Dr. D. E. Salmon of this Department; reports of committees and outgoing officers, as well as of State secretaries, and closing with the election of the following officers for 1903–4: President, R. R. Bell; vice-presidents, M. E. Knowles, J. G. Rutherford, C. J. Marshall, W. H. Dalrymple, J. E. Ryder; secretary, J. J. Repp; treasurer, W. H. Lowe.

The president, S. Stewart, in his annual address, called attention to the necessity of improving veterinary education by raising the standard of entrance requirements and the courses of study in certain veterinary colleges. He recommended that the association make a special investigation of the courses of study in all institutions which give veterinary instructions, in order that the status of veterinary courses may be made known to the profession, and especially to the association. He spoke in an optimistic manner regarding the prospects for young graduates from veterinary schools and the demands for qualified veterinarians in various parts of the country. Brief mention was also made of recent veterinary legislation in various States; and the subject of clinics in connection with meetings of the association was discussed and highly recommended.

The committee on intelligence and education made a report on literature which may be obtained by members of the association. This literature includes public documents, State publications, and various other books and pamphlets. The committee on army legislation reported that no further efforts had been made in that direction, but expressed the hope that conditions might soon become more favorable for legislation looking toward a more elaborate organization of the army veterinary staff.

The following resident State secretaries made brief reports: B. D. Pierce, of Massachusetts, briefly outlined the recent outbreak of foot-and-mouth disease in that State, called attention to the presence of mange in horses, and discussed the status of tuberculosis in cattle. Glanders was said to be on the increase. M. E. Knowles, of Montana, reported veterinary conditions as favorable. Tuberculosis was found in a considerable percentage of dairy cows, but not in range cattle. An efficient and satisfactory meat inspection service has been established in Montana. The position of inspector in the different cities, however, has been filled by physicians on account of the lack of qualified veterinarians.

C. J. Marshall, of Pennsylvania, stated that four large veterinary associations have been formed in Pennsylvania, and that veterinary affairs in general are in a flourishing condition. A movement is on foot for the establishment of meat and milk inspection in Philadelphia. Legislation is in force regarding the control of tuberculosis, the utilization of tuberculous meat, the regulation of rabies, and the quarantine of dogs. Brief notes were presented on veterinary instruction in the University of Pennsylvania, and on glanders, anthrax, and hemorrhagic septicemia, influenza of horses, canine distemper, and forage poisoning. Attention was called to the urgent demand for a reliable serum treatment for influenza in horses and distemper in dogs. The experiments for perfecting a method of immunizing cattle against tuberculosis are not yet concluded, but the belief was expressed that the method will prove practical. The application of the tuberculin test by laymen was condemned, and retesting was urged at least once in six months. C. H. Higgins, of Ottawa, gave a brief account of the control of glanders by the Dominion government, and presented notes on anthrax, blackleg, and tuberculosis in Canada. The conditions for veterinarians were considered favorable, but the usual fees too small. T. E. Robinson, of Rhode Island, stated that the veterinary profession in his State was in better condition than ever before. A State veterinary association has been formed, but thus far no success has been had in securing veterinary legislation. G. W. Dunphy, of Michigan, reported that veterinary practice in his State had increased greatly during the past year, especially in country districts. This was attributed to an increase in the value of live stock. Rabies was said to have prevailed extensively throughout the State. Cases of tuberculosis, hog cholera, and glanders were observed.

The committee on pharmacopœia requested further instructions regarding its work, and this gave rise to considerable discussion of the character of the prospective volume and the place of its publication, but no definite action was taken.

M. E. Knowles presented a paper on Meat and Milk Inspection, in which attention was called to the importance of State control of meat

and milk inspection. Montana was the first State to pass a law regulating all the details of this inspection. A bill was introduced into the State legislature in 1897 and another somewhat different bill in 1901. Both of these failed. In 1903, however, a bill was enacted containing wise and stringent measures concerning this matter. At present there are 8 inspectors in service in the State. Dairymen began to fight the measure from the first for the purpose of testing its constitutionality. Some litigation of this sort is still pending, but decisions thus far obtained are favorable to the constitutionality of the law. The sanitary condition of the milk and meat supply has been much improved by the action of this law. The percentage of tuberculosis in the dairy herds thus far examined has varied from 18 to 30 per cent. D. E. Salmon, in discussing this paper, called attention to the present demand for milk and meat inspectors, the special requirements in regard to the qualifications of such experts, and the difficulties of obtaining enough qualified men. He argued that veterinary courses are defective in respect to instruction on the subject of meat inspection, and that in his opinion all inspectors should be veterinarians. J. Law agreed that veterinary instruction in most colleges is still defective with regard to the subject of meat inspection, and suggested that more attention might be paid to this subject if the salaries of meat inspectors were higher.

Hon. Sidney Fisher, Minister of Agriculture, addressed the association on the subject of the importance of veterinary science to agriculture. Attention was called to the cosmopolitan nature of veterinary science, due to the general spread of infectious diseases and the similarity of conditions throughout the civilized world. The veterinary conditions of the United States and Canada were considered as being practically the same, and the results obtained in either country were mutually useful. The prominence of the live-stock industry in both countries indicates the importance of veterinary science to their agriculture. An account was given of the veterinary service of Canada and the close association between veterinary work and agricultural science in that country. A very optimistic opinion was expressed concerning the value of this international meeting and the prestige which would result to the association from it.

On the second day of the meeting the association was entertained at the Pine Grove Stock Farm of Hon. W. C. Edwards, Rockland, Ontario. The sessions of this day were devoted entirely to a discussion of the subject of tuberculosis. The first paper was by Hon. W. C. Edwards, and related to the results of his experiments with the Bang system among his own herds, the reacting and nonreacting herds being presented for the inspection of the members. This system of eradicating tuberculosis was introduced by Senator Edwards on his farm in 1898. A certain percentage of the herd was found to be

somewhat tuberculous, and the tuberculin test was made with all the animals. The healthy cows were then separated from the tuberculous cows and mainta ned in separate pastures. The healthy and tuberculous animals were never allowed to come in contact by any means either direct or indirect. It was found possible to raise the calves from tuberculous cows on sterilized milk, but this method proved too troublesome and healthy nurse cows were employed. Under these conditions it was found possible to raise at least 98 per cent of healthy calves where both the dams and sires were tuberculous. During an extensive application of the tuberculin test no harm whatever was observed as resulting from the use of this remedy, no case of abortion occurred, and no other bad effects of tuberculin could be determined. Senator Edwards believes as a result of his experiments that the only practical method at present is that devised by Bang. He argued against the stringent use of the tuberculin test in preventing the importation of infected animals, since ultimately each stock grower must apply the Bang method to his herd in order to keep it free from tuberculosis. Scrub cattle which react should be killed, but valuable animals should never be destroyed but rather used as breeders. Attention was called to the great importance of proper sanitary conditions in the control of tuberculosis. After an outbreak of tuberculosis his method consisted in cleaning the buildings with brooms, fumigating for 24 hours with brimstone, then with live steam for another 12 hours, and then treating with carbolized whitewash. Upon making a retest of the reacting animals a number of animals did not react, but they were nevertheless considered to be tuberculous and were kept separate. Spring was considered the best time for making the test. The King system of ventilation had been tried but found unsatisfactory for so cold a climate. It was recommended for southern regions.

Dr. D. E. Salmon presented a paper on Bovine and Human Tuberculosis. Attention was called to the relationship between human and bovine forms of this disease, and to the great differences of opinion which have prevailed with regard to the unity or duality of tuberculosis. In the laboratories of the Bureau of Animal Industry a number of differences have been noted in the morphology and virulence of types of tubercle bacilli of different origin. Dr. Salmon discussed Koch's work with special reference to variations observed in the virulence of bacilli from different human beings. The results obtained by various investigations since Koch's London address were critically discussed. It was stated that bovine and human tubercle bacilli have been compared as to their morphology and virulence. Positive results were obtained from inoculations of various animals with tubercle bacilli of human origin. Cultures of tubercle bacilli were obtained from

human lymphatic glands and human sputum which proved to be exceedingly virulent for cattle, goats, rabbits, and other experimental animals. The conclusions were reached that tuberculosis is mutually transmissible between man and animals; that the bacilli may pass through the walls of the intestines without causing any lesions in the intestines; and that the virulence for cattle of the bacilli from some of the cases of infantile intestinal tuberculosis give strong evidence of the transmission of the disease from animals to man. The great variety of ways in which man may become infected makes it absolutely impossible to determine by clinical observation the source of infection in any case of human tuberculosis.

In the protracted discussion which followed the reading of these two papers, the consensus of opinion of the association appeared to be that a practical method for the control and eradication of tuberculosis has been found, and that the positive assertions of Koch as to the nonidentity of human and bovine tuberculosis has been definitely disproved. Attention was repeatedly called to the danger from a laxity of opinion with regard to the intertransmissibility of bovine and human tuberculosis.

J. J. Repp read a paper on a microscopic study of a case of tuberculosis in a cow, with reference to the distribution of bacilli, which was illustrated with lantern slides. The tissues examined included those of the heart, liver, intestine, lung, and mediastinal gland. Tubercle bacilli were very numerous in the ulcers in the intestinal mucosa. The villi and glands of Lieberkühn were entirely obliterated in the intestinal ulcers. It was suggested that large numbers of bacilli must have been constantly passed with the feces, and that these must have constituted a dangerous source of infection. The heart capillaries were much thickened, but no bacilli were found in the muscles of the heart or of the intestines. No giant cells were observed in the tuberculous lung tissue.

V. A. Moore, of New York, discussed Avian Tuberculosis, on the basis of investigations made in California, where the disease was found to be very prevalent, and gave brief notes on the literature of the subject from studies made in Oregon, Delaware, and Michigan. The disease was found to be gradually increasing in infected flocks. According to the author's investigations in California, from 5 to 20 per cent of the fowls die annually from tuberculosis. In one flock of 1,450, 300 died from this disease. The symptoms were not characteristic. Anemia and paleness of the visible mucous membranes were generally observed. The temperature varied from 102 to 107°. The blood was pale, showing 2,600,000 red corpuscles per cmm., with an increase of the leucocytes. The lesions were found most frequently in the liver, which was sprinkled with gray tubercles, thus giving the disease the common name of "spotted liver." Immense numbers of

bacilli occurred in the liver tissues. The lungs were affected in only one case. The tubercles in the liver were caseous, small, easily separable, and frequently occurred in two distinct crops. Tubercles were also observed in the walls of the intestines and on the mesenteries. In a second form of the disease a cellular infiltration was observed. The bones were affected in one case only. Among 17 cases carefully examined, the liver was affected in 13. The bacilli were exceedingly numerous in all lesions, and greatly resembled those of human and bovine origin. Considerable differences were observed in the growth and morphology of these organisms on different culture media. Difficulty was experienced in making cultures from infected tissues. Inoculation experiments with guinea pigs and fowls gave no positive results. The disease was easily mistaken from its symptoms for infestation with air-sac mites, and other troubles. The tuberculin test was applied but without very satisfactory results on account of the normal variation in the temperature of birds.

C. H. Higgins gave a brief report on anthrax and blackleg, including a historical account of both diseases, and mention of symptoms in detail. Attention was called to the differential diagnosis of these diseases. It was urged that in cases of anthrax an autopsy is dangerous and usually to be avoided. The carcass should usually be buried. Notes were given on serum therapy and biological laboratories for the manufacture of this product. A. S. Wheeler in the discussion of this paper stated that he had had no bad results in 1,000 cases of inoculation for anthrax in Louisiana. V. A. Moore referred to many difficulties which he had experienced in the microscopic diagnosis of anthrax.

J. G. Rutherford presented a report on the uses of mallein in dealing with glanders. Glanders was said to be quite prevalent in the Northwest Territories and Manitoba. Good results have been obtained, however, from the Government control of this disease. Fresh outbreaks naturally occur from time to time, due largely to importation from other Canadian provinces or from the United States. In some cases mallein appeared to exercise a curative effect. The usual method of procedure in the control of glanders in Canada is as follows: When the disease is reported clinical cases are destroyed without the mallein test, while the exposed horses are tested. Reactors without clinical symptoms are then isolated and such horses are branded with "E. R." on the hoof. These animals are retested at the end of 40 days, after which those which do not react are not so closely guarded. The third test is made after 60 days, at which time those that react are killed. No indemnity is paid for any glanderous animals. As a rule horses are not killed if improvement is noted during the period of quarantine. After 90 days, reactors are killed while nonreactors are considered comparatively safe. Lesions are always found in reacting horses,

while the glanders bacilli are never present in lesions in horses which have ceased to react. Few horses react more than three times. The speaker therefore believed that mallein may exercise a curative effect.

D. K. Smith briefly discussed malignant tumors, which he stated need further study. Their histological structure is well known but their etiology is quite doubtful. Mention was made of the various theories devised for explaining the cause of tumors, including the embryonic, inflammatory, and microbic theories. A call was made for a systematic study of these growths, and the hope was expressed that the cooperation of veterinarians along this line might lead to valuable discoveries.

A. S. Wheeler related some experiments with stomach worms in sheep. *Strongylus contortus* was reported as very prevalent in the flock of sheep at Biltmore, N. C., where 66 sheep died. The author suggested that possibly the eggs of this worm are taken into the stomach from the outside of the udder of the ewe. Sucking lambs raised on gravel and wood floors which had been thoroughly disinfected became badly infested with the stomach worm. Experiments were made in introducing male stomach worms directly into the fourth stomach, but this apparently was without results. Turpentine in 2 to 4 oz. doses was used without beneficial results. Many of the lambs died with the stomach full of worms. Fluid extract of spigelia and senna in 2 to 4 oz. doses had no therapeutic effect. Benzine in 4 oz. doses was equally ineffective, and many fatalities resulted from it. Chloro-naphtholeum in 6 oz. doses also proved ineffective. A number of experiments were tried in applying vermicides directly to the worms in glass vessels. These showed that a 5 per cent solution of chloro-naphtholeum would destroy the worms in a few minutes; turpentine and santonin had no effect; lysol proved quite efficient, and coal-tar products in general were most satisfactory remedies. Great difficulty was experienced in getting the remedies into the fourth stomach and in distending this organ. Some success was had in reaching the fourth stomach by means of a probang, and experiments were made in introducing the vermicide directly by means of a trochar and canula from the outside. In these experiments 50 per cent of success was had with chloro-naphtholeum. This method of introducing vermicides, however, is considered to be impracticable for the ordinary sheep raiser.

Dr. P. A. Fish presented a paper on The Effect of Certain Drugs upon Blood Pressure and Cardiac Inhibition. The usual apparatus for determining blood pressure was employed and the carotid artery was connected with the apparatus. Various drugs were injected intravenously. It was found that the vagus nerves of the two sides of the body vary greatly in the power of controlling the heart action. In dogs there was a decrease in cardiac action after stimulation of the vagus

nerve. The blood pressure was temporarily much reduced: respiration was at first inhibited, then increased in power and frequency. In the horse a strong stimulation of the vagus caused death. The pulse was rendered intermittent. Similar results were obtained in experiments with calves. The cow exhibited no inhibition of the heart action, but a great temporary increase. Eserin sulphate increased the force of the heart beat and slowed down its action. Nitroglycerin injected into the horse caused a fall of blood pressure, but increased the amplitude of the cardiac action. Barium chlorid, in doses of 12 grains, increased the force of blood pressure. Stimulation after the administration of this drug had an immediate inhibitive action. When the vagus was cut before being stimulated the action was similar. The dog exhibited an enormous increase in blood pressure and force of the heart action after treatment with barium chlorid. Atropin sulphate in doses of $\frac{1}{4}$ grain paralyzed the inhibitive action of the vagus in the dog. When the vagus was subsequently stimulated the blood pressure was increased. A cat treated with large doses of barium chlorid showed a great increase in blood pressure. The cardiac and diuretic effects of barium chlorid were similar to those of digitalis.

W. Dougherty presented a plan for the formation of a mutual benefit society of the veterinarians of the United States and Canada. After a thorough discussion of the matter a committee was appointed to investigate the desirability of forming such a society, and report at the next meeting.

The by-laws of the association were amended so as to make the time of meeting hereafter the third Tuesday in August in place of the first Tuesday in September. While the place for the next meeting was not definitely determined, the executive committee was requested to consider the proposition to meet at St. Louis.

During the various sessions of the meeting nearly 100 new names were added to the list of active members.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The standardization of analytical methods, H. D. Richmond (*Jour. Soc. Chem. Ind., 22 (1903), No. 11, pp. 676, 677*).—A general discussion recommending combined work and discussion as "the best method of finding out errors of and laws underlying a method."

The standardization of commercial methods of analysis, especially those applied to brewing materials, A. R. Ling (*Jour. Soc. Chem. Ind., 22 (1903), No. 11, pp. 677–684*).—The author maintains "the necessity of investigating certain empirical methods of analysis with a view of ascertaining what they actually measure when carried out under certain defined conditions. This constitutes the standardization of the method in question, and in my opinion ought be attempted only after the conjoint deliberations of those in the habit of carrying out the determinations and of applying the results. It is the first step toward the elaboration of standard methods. . . . It by no means follows that the ultimate result of such work will be to reduce all methods to one pattern."

On the unreliability of the citrate method for determining phosphoric acid in Thomas slag, N. von Lorenz (*Chem. Ztg., 27 (1903), No. 41, pp. 495, 496*).—Böttcher's later method, involving a preliminary test for silica (E. S. R., 14, p. 1042), is considered too complicated for practical use. Choice seems to lie between the methods of Woy (E. S. R., 14, p. 1042) and the author (E. S. R., 13, p. 14). The latter is considered more rapid.

Note on the citrate solution used in phosphoric acid determination, A. Verweij (*Ztschr. Analyt. Chem., 42 (1903), pp. 167, 168*).—Old citrate solution is stated to give too high results, due to silica dissolved from the glass vessels in which it is kept.

The determination of phosphoric acid in organic substances by Neumann's method, E. Poher (*Ann. Sci. Agron., 1902–3, I, No. 3, pp. 441–447*).—Neumann's later method of digestion in a mixture of sulphuric and nitric acids is preferred as more rapid and convenient than the older method using sulphuric acid and ammonium nitrate.

Nitrogen and its most important compounds, L. Spiegel (*Der Stickstoff und seine wichtigsten Verbindungen. Brunswick: Friedrich Vieweg & Son, 1903, pp. XII+912, figs. 6*).—A very full summary of information on this subject with numerous references to literature. Agricultural chemists will find the chapters on alkaloids, protein compounds, and analytical methods of special interest.

On the determination of nitric acid by the Ulsch method, F. Štolba (*Časopis pro Průmysl Chem., 13 (1903), p. 171; abs. in Chem. Ztg., 27 (1903), No. 53, Repert., p. 158*).—The author calls attention to the fact that the results by this method are sometimes too high on account of the presence of nitrites in the soda or potash solution used. He advises the testing of the alkali solution before use by distilling with aluminum.

The use of the Schloesing method for determining nitric nitrogen in presence of organic matter, P. LIECHTI and E. RITTER (*Ztschr. Analyt. Chem., 42 (1903), No. 4, pp. 205–232*).—The authors report tests which refute Pfeiffer and Thurmann's objections to this method and show its reliability. Certain modifications in detail are described.

Action of potassium permanganate on indigo, with reference to the determination of nitrates by the indigo-carmine method, W. R. LANG and W. M. WILKIE (*Jour. Soc. Chem. Ind., 22 (1903), No. 11, pp. 673, 674*).—The discordant results of a series of experiments with dilute potassium nitrate, sulphuric acid, and indigo titrated with tenth-normal potassium permanganate lead to the conclusion that "if this method of estimating nitrates is to be of any accuracy, an absolute similarity of conditions, both as regards time and temperature, must be observed."

Tintometric estimation of nitrites and nitrates in water, F. W. RICHARDSON and P. HOLLINGS (*Jour. Soc. Chem. Ind., 22 (1903), No. 10, pp. 616, 617*).—Sutton's phenol-disulphonic acid method using Lovibond's tintometer is recommended.

The preparation of ammonia-free water for water analysis, J. B. WEEMS, C. E. GRAY, and E. C. MYERS (*Contrib. Dept. Agr. Chem., Iowa State Col. Agr. and Mech. Arts, No. 5, pp. 112, 113*).—The use of sodium peroxid in preparing ammonia-free water is described.

A new method for the titration of free and combined sulphuric acid, W. MÜLLER (*Ber. Deut. Chem. Gesell., 35 (1902), No. 9, pp. 1587–1589; abs. in Bul. Soc. Chim. Paris, 3. ser., 30 (1903), No. 5, p. 478*).—The method proposed depends upon the fact that when a solution containing sulphuric acid is added to a hot solution of benzidine hydrochlorate sulphuric acid is precipitated and may be removed by filtration. The amount of sulphuric acid may be calculated by titration of a measured quantity of the benzidine reagent before and after precipitation by means of soda solution and phenolphthalein. The reaction which occurs is shown in the following equation: $R_2SO_4 + C_{12}H_8(NH_2)_2.2HCl = 2RCl + C_{12}H_8(NH_2)_2.H_2SO_4$.

A volumetric method of estimating free and combined sulphuric acid, G. FRERICHS (*Arch. Pharm., 241 (1903), No. 2, pp. 159, 160*).—The method, which is briefly described, depends upon the fact that free and combined sulphuric acid give a silver salt insoluble in alcohol.

Note on the determination of solids in the analysis of vinegars, W. FREAR and C. P. BEISTLE (*Pennsylvania Sta. Rpt. 1902, pp. 165–168*).—Comparative tests were made of drying to a constant weight in a water oven at about 100° C., and drying at ordinary room temperature over sulphuric acid. The solids determined by drying in the water oven averaged 1.39 per cent and by drying over sulphuric acid 2.03 per cent, making a difference by the 2 methods equivalent to 0.64 per cent of the entire vinegar. To determine the nature of this loss elementary analyses were made of the residues, which showed an average percentage of carbon calculated to the original weight of vinegar used of 0.48 by drying in the water oven and 0.72 by drying over sulphuric acid, making a difference of 0.24 per cent. The difference was greater than could be accounted for by the excess of the acetic acid in the residues obtained by drying over sulphuric acid. As the residue from the water oven was not acid the destruction of the fixed acids or their neutralization by bases set free from other combinations was indicated. "These results demonstrate beyond cavil the fact that the usual method of determining vinegar solids by evaporation at 100° C. is attended by the elimination, either by volatilization or decomposition, of constituents other than water, alcohol, and acetic acid, and that this loss of materials properly classed among the solids is entirely too great to be overlooked in any investigation requiring an absolute determination of the quantity of such materials. They further show that, while the ordinary method is still practicable where purely relative

results are sufficient, it is highly needful that the time of evaporation, surface exposure, and other details affecting the rate of evaporation be arbitrarily fixed and rigidly adhered to."

The methods of estimating mustard oil and the effect of the formation of mustard oil from Indian rape in the digestive tract of ruminants, O. HAGEMANN and W. HOLTSCHMIDT (*Fühling's Landw. Ztg., 51 (1902), Nos. 23, pp. 869–871; 24, pp. 895–901*).—The conditions of temperature, moisture, etc., under which mustard oil is formed were studied with especial reference to the conditions prevailing in the digestive tract of ruminants.

The choice of an antiseptic for preserving samples of milk for analysis, M. LINDET (*Rev. Gén. Lait, 2 (1903), No. 16, pp. 370–372*).—In this brief report, which is based upon numerous communications received from analysts in different countries, the author as referee recommends the use of potassium bichromate (0.5 gm. per liter) or formalin (60 drops per liter) for the preservation of samples of milk for analytical purposes.

Some unknown and some little known oils, J. J. A. WIJS (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 11, pp. 492–496*).—Chemical studies are reported of oil made from the seeds of *Echinops ritro*, *Perilla ocymoides*, watermelon, tea, garden cress, radish, and mustard.

A new mill for laboratories, T. KÖRNER (*Chem. Ztg., 27 (1903), No. 42, pp. 502, 503, fig. 1*).—The mill is constructed on the principle of beating rather than grinding. The material is kept thoroughly stirred by means of a current of air, the particles of the desired degree of fineness passing out through a sieve at the bottom of the mill. The interior of the mill is readily accessible and is easily cleaned.

International Congress of Applied Chemistry at Berlin, June 2–8, 1903—Agricultural chemistry (*Chem. Ztg., 27 (1903), No. 47, pp. 564, 565*).—A brief account is here given of discussions of the following subjects: Analysis of Nitrates, by H. Fresenius; The Determination of Potash by Means of Perchlorate, by Precht; The Direct Determination of Phosphoric Acid as Molybdic Anhydrid, by R. Woy; The Iodometric Determination of Phosphoric Acid, by Klason; The Report of the Committee on Analysis of Fertilizers and Feeding Stuffs, by von Grueber; The Construction of Balances for Analytical Work, by Felgenträger; A New Gravimetric and Volumetric Method of Determining Ammonia, by E. Riegler; and The Statement of the Results of Analysis, by W. Fresenius and Christomanos.

BOTANY.

A monograph of the genus Sorbus, T. HEDLUND (*K. Svenska Vetensk. Akad. Handl., 35 (1901), No. 1, pp. 1–147, figs. 37*).—In addition to a botanical study of the species of Sorbus, the author gives an account of their distribution, economic value, varieties, hybrids, and other modified forms. Fifty-five species are recognized and a number of forms and hybrids are considered distinctive enough to receive definite names.

A text-book of plant physiology, G. J. PEIRCE (*New York: Henry Holt & Co., 1903, pp. VI+291, figs. 23*).—This text-book is the outgrowth of the author's lectures at Leland Stanford University, and is designed as a treatise on plant physiology that shall cover the field less exhaustively than is done by Pfeffer and others, but more fully than in the so-called Bonn text-book. The author presents the main facts of plant physiology, adopting a conservative attitude regarding the various hypotheses of the phenomena of plant life and suggesting definite problems for further investigation. No attempt is made to give laboratory directions, as the book is strictly a text-book, which should be supplemented by laboratory work under the direction of the teacher. The subjects of respiration, nutrition, absorption, and movement of water; growth, irritability, and reproduction are treated in detail, and the copious

references to literature given in footnotes serve as a considerable bibliography to the subjects treated. This new plant physiology will be found an important addition to the rapidly increasing American literature of botany.

On the physiology of the anaerobic growth of the higher plants, A. Nabokikh (*Selsk. Khoz. i Lyesov., 208 (1903), Feb., pp. 350–388; Mar., pp. 568–602*).

The cohesion theory of the ascent of sap, H. H. Dixon (*Sci. Proc. Roy. Dublin Soc., 10 (1903), No. 4, pp. 48–61*).—This paper is a defense of the author's theory regarding the ascent of sap and a criticism of the conclusions of others relating to that theory.

Formation of the spores in the sporangia of Rhizopus nigricans and of Phycomyces nitens, D. B. Swingle (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 37, pp. 40, pls. 6*).—A technical paper giving the results of studies of the formation of the spores of *Rhizopus nigricans* and of *Phycomyces nitens*.

Bacteria in modern economic agriculture, A. Schneider (*Pop. Sci. Mo., 63 (1903), No. 4, pp. 333–343*).—A popular account is given of nitrogen assimilation by leguminous plants through the bacteria occurring in the tubercles upon their roots.

Outline of the history of leguminous root nodules and rhizobia, with titles of literature concerning the fixation of free nitrogen by plants, A. Schneider (*Minnesota Bot. Studies, 3. ser., 1903, pt. 2, pp. 133–139*).—A brief historical résumé is given of investigations regarding the assimilation of nitrogen through the root tubercles of leguminous plants, and a list of titles of recent publications bearing upon this subject is appended.

The inoculation of leguminous plants and its practical importance, Hiltner (*Chem. Ztg., 27 (1903), No. 49, p. 611*).—A brief general discussion before the section of agricultural chemistry of the recent International Congress of Applied Chemistry.

Alinit, its bacterial composition and physiological rôle in the soil, Severin (*Vyestnik Imp. Russ. Obsh. Akklimat. Zhiv. i Rast. Bakt. Agron. Stantz., No. 9, pp. 36–57; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 1, pp. 116, 117*).—The author investigated a preparation of Alinit obtained from Bayer's factory and found that it consisted of 2 micro-organisms: (1) *Bacillus ellenbachensis*, which is described by all investigators, and another—its race variant—differing from the former mainly by its inability to reduce nitrates. The author proposes to name it *B. ellenbachensis β*. When growing in horse manure both races appear to show little activity in destroying organic matter; neither induces ammoniacal fermentation in urine. The author, on the basis of his experiments, concurs with the conclusion of the majority of investigators that Alinit is of no value for agricultural practice.—P. FIREMAN.

Michigan mushrooms, B. O. Longyear (*Michigan Sta. Bul. 208, pp. 79–100, figs. 21*).—Descriptions are given of a few of the more common edible fungi known to occur within the State. Various species of Morchella and some of the puffballs are described.

METEOROLOGY—CLIMATOLOGY.

Climatic conditions at California substations, C. H. Shinn (*California Sta. Bul. 147, pp. 8, 30, 45, 63, 90, 102*).—Observations on temperature, rainfall, frosts, etc., during several years are recorded for the Foothills Substation near Jackson, the Southern Coast Range Substation at Paso Robles, the San Joaquin Valley Substation at Tulare, the Southern California Substation near Pomona, and the Forestry substations near Santa Monica and Chico.

Meteorological observations, W. T. Ellis, R. Robertson, W. S. Blair, S. A. Bedford, A. Mackay, and T. A. Sharpe (*Canada Expt. Farms Rpts. 1902, pp. 47, 231, 263, 318, 356, 389*).—Observations of the same character as those of previous years are recorded.

Meteorological observations, Moscow, Idaho, 1901, J. E. Bonebright (*Idaho Sta. Rpt. 1902, p. 23*).—A tabular summary of observations on temperature, pressure, precipitation, cloudiness, and late and early frosts. The mean temperature for the year was 47.46°, the precipitation 22.56 in., the barometric pressure 27.25 in., number of cloudy days 121. The last killing frost in the spring occurred May 19, the first in the fall September 16.

Meteorological observations, J. E. Ostrander, S. C. Bacon, and F. F. Henshaw (*Massachusetts Sta. Met. Buls. 172, 173, 174, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during April, May, and June, 1903. The data are briefly discussed in general notes on the weather of each month.

Summaries of temperature, rainfall, and sunshine, E. F. Ladd (*North Dakota Sta. Rpt. 1902, pp. 13–19*).—Observations at Fargo and at several other places in North Dakota during 1902 and previous years are summarized. The mean temperature at Fargo during 1902 was 39.4° F., the rainfall 23.16 in. The average rainfall at Fargo for 11 years ending with 1902 was 20.62 in., for the State (17 places) during 10 years 18.5 in. The hours of recorded sunshine at Fargo during 1902 were 2,034.8 or 45.2 per cent of the possible.

Meteorology, C. W. Norris (*Pennsylvania Sta. Rpt. 1902, pp. 172–186, 451–479*).—The observations here recorded are of the same character as those reported in previous years (E. S. R., 14, p. 638). Monthly summaries of observations are given in the body of the report and the detailed record in an appendix. The summary for 1901 is as follows:

Summary of meteorological observations, 1901.

	1901.	Growing season (Apr.-Sept.).
Barometer (inches):		
Mean	29.993	
Highest	30.709 (Jan. 3)	
Lowest	29.280 (Jan. 27)	
Temperature (° F.):		
Mean	48.1	63.6.
Highest	94 (July 1)	94 (July 1).
Lowest	—2 (Dec. 22)	25 (Apr. 1).
Mean daily range	17.1	18.8.
Greatest daily range	37 (Mar. 18–Dec. 15)	35 (Apr. 28–29).
Least daily range	3 (Jan. 10-11)	
Mean daily relative humidity (per cent)	81.7	78.8.
Rainfall (inches):		
Total	43.45	28.11.
Greatest monthly	8.97 (Aug.)	
Greatest daily	3.19 (Aug. 18)	3.19 (Aug. 18).
Number of days on which 0.01 in. or more of rain fell	141	72.
Mean percentage of cloudiness	48.9	48.1.
Number of days on which cloudiness averaged 80 per cent or more.	109	55.
Average hours of sunshine per day		7 h. 39 m.
Maximum velocity of wind per hour (miles)	30 (Dec. 14)	
Last frost in spring		June 9.
First frost in fall		Sept. 30.

Report of the meteorologist, N. Helme (*Rhode Island Sta. Rpt. 1902, pp. 379–395*).—This includes general notes on the weather during the year ended June 30, 1902, and a tabulated record of observations at Kingston on temperature, precipitation, cloudiness, and prevailing winds during each month from July, 1901, to June, 1902, inclusive, with a summary for the year ended June 30, 1902. The latter summary is as follows:

Temperature (degrees F.).—Maximum, 93, July 1, 1901; minimum, 1, January 4, 1902; mean, 48; highest monthly mean, 72, July, 1901; lowest monthly mean, 24.8, January, 1902; highest daily mean, 80, July 1, 1901; lowest daily mean, 8, January 4, 1902. *Precipitation* (inches).—Total (rain and melted snow), 53.14; greatest

monthly, 10.3, December, 1901; least monthly, 1.34, May, 1902; greatest in 24 consecutive hours, 2.42, December 29, 1901; snowfall—total, 53.5; greatest monthly, 31.5, February, 1902; least monthly, 2.5, November, 1901. *Weather.*—Number of clear days, 138; number of fair days, 116; number of cloudy days, 111; number of days on which there was precipitation of 0.01 in. or more, 109. *Prevailing wind*, west and southwest.

Meteorological chart of the Great Lakes, A. J. Henry and N. B. Conger (*U. S. Dept. Agr., Weather Bureau, Meteorological Chart of the Great Lakes, 1903, No. 1, pp. 23, pl. 1*).—This is the usual summary of observations on the weather for the season of navigation; precipitation and ice during the winter of 1902–3; opening of navigation for the season of 1903; and maximum wind velocities, April to December.

Meteorological observations on Ben Nevis, A. Buchan et al. (*Rpt. British Assoc. Adv. Sci., 1902, pp. 93–97*).—Observations on temperature, pressure, rainfall, humidity, velocity of wind, sunshine, cloudiness, and casual phenomena are summarized for each month of 1901.

The meteorological year, 1902 (*Bul. Sta. Agron.* [*Laon*], *2. ser., 13* (*1902*), *pp. 7–16*).—Observations at Laon on atmospheric pressure, temperature, rainfall, cloudiness, condition of crops, etc., are recorded for each month of the year.

The geographic determinants of climate, L. Dumas (*L'Ing. Agr. Gembloux, 13* (*1903*), *No. 8, pp. 329–336, figs. 2*).—The influence of the movements of the sun on climate is discussed and shown graphically. It is claimed that weather conditions are most unsettled during the passage of the sun from the southern to the northern hemisphere, less so during the return in the opposite direction. The principal centers of disturbance as regards Europe seems to be the Venezuelan llanos and the South Saharan desert. They cause a predominance of a marine climate over a continental climate in western Europe. The influence of the moon in dissipating aqueous vapor and on rainfall and the formation of lunar halos and coronas are also briefly discussed.

Investigation of the upper atmosphere by means of kites in cooperation with a committee of the Royal Meteorological Society, W. M. Shaw et al. (*Rpt. British Assoc. Adv. Sci., 1902, pp. 77–80*).—Apparatus installed on the island of Crinan, west coast of Scotland, is described, and data for 68 flights are reported. The results indicate "that the apparatus and methods are effective for securing valuable information as to the upper air in various conditions of weather."

WATER—SOILS.

Evaporation from a water surface, E. F. Ladd (*North Dakota Sta. Rpt. 1902, pp. 20, 21*).—Observations were made as follows: "A galvanized iron tank 3 ft. square by 14 in. in depth painted black contained a second smaller tank 12 by 12 by 12 in. in dimensions, likewise blackened. These were sunk in a grass plat level with the surface of the ground. The small tank contained distilled water and this tank within the larger was surrounded with water. Daily measurements were made of the amount of evaporation, and the results by months are given. . . . The total amount of water evaporated from a water surface for the 5 months, May to September, inclusive, was 28.12 in., or an average of 5.624 in. per month, or a daily average of 0.183 in. The total rainfall for the same period of time was . . . but little more than one-half as much as the water evaporation for the same period, or an average of 2.864 in. per month, or an average daily rainfall of 0.0936 in., as compared with an evaporation of 0.183 in. per day."

Forests and underground water, A. Tolsky and E. Henry (*Ann. Sci. Agron., 1902–3, I, No. 3, pp. 396–422*).—Observations made in Russia and France are reported to show that the level of the ground water is decidedly lower under forests than under cleared land.

The movements of underground waters of Northwest Yorkshire, W. W. WATTS ET AL. (*Rpt. British Assoc. Adv. Sci., 1902, pp. 224–229, pl. 1*).—An account is given of observations by means of fluorescin. (See also E. S. R., 14, p. 847.)

Stock waters, F. W. TRAPHAGEN (*Montana Sta. Rpt. 1902, p. 64*).—The amounts of chlorin, sodium chlorid, sulphuric acid, and Glauber's salt in 3 samples of alkali waters are reported.

Water investigations, M. MONHAUPT (*Chem. Ztg., 27 (1903), No. 42, pp. 501, 502*).—Tests are reported which indicate that methyl orange is preferable to alizarin as an indicator in Pfeiffer's modification of Wartha's method for determining temporary and permanent hardness.

Soil moisture in relation to crop yield, S. FORTIER (*Montana Sta. Rpt. 1902, pp. 101–112, pls. 2, figs. 3*).—The apparatus used and methods followed in experiments with oats grown in metal tanks sunk in the earth are described. In order to keep the temperature of the soil surrounding the tanks uniform "oak barrels were cut in half and placed with their top edge about 14 in. below the surface of the ground. Gravel to the depth of a few inches was placed in the bottom and ordinary soil on top. Water was conveyed to the gravel through a $\frac{3}{4}$-in. iron pipe. It was hoped that this device would not only lessen the temperature in the lower portion of the tank, but that the water placed in the half barrel would be drawn up by capillarity and evaporated at the surface, thus tending to cool the upper portion. . . . To afford a convenient method of hoisting and weighing the tanks, a $\frac{1}{2}$-in. steel cable was stretched over supports 93.2 ft. apart and 14 ft. high. Differential pulley blocks were then suspended from a pulley on the cable and a strong bale and beam scale were attached to the blocks. . . . In applying irrigation water to the tanks, about two-thirds of the amount was spread over the surface, the balance was run through the hose pipe to the bottom of the vessel. . . . The evaporation and transpiration from the grain was about 16 per cent greater than the evaporation from the bare soil. For the period named, the former averages $1\frac{1}{7}$ in. and the latter $\frac{9}{10}$ in. per week over the surface. For the same period the evaporation from a water surface was 13 to 16 in. per week. . . . The crop in every case not only evaporated all of the irrigation water, but robbed the soil of part of the moisture which it contained at seed time." Observations on evaporation from stubble fields and from a water surface are also recorded.

The conservation of soil moisture in orchards, F. T. SHUTT (*Canada Expt. Farms Rpts. 1902, pp. 137–139*).—Studies in continuation of those of the previous year (E. S. R., 14, p. 127) on the variation in moisture content of orchard soils (1) cultivated throughout the season, (2) cropped part of the season with clover which was turned under as a green manure, and (3) cropped in clover or in sod throughout the season are reported. The author concludes that moisture is most effectively conserved in cultivated soil, but that sod exhausts the water supply more than cover crops.

Summer fallows, A. MACKAY (*Canada Expt. Farms Rpts. 1902, pp. 349–351*).—A brief discussion of observations and experience tending to show the advantages of summer fallowing. Different methods are described, but deep plowing, 7 to 8 in., before the last of June has given the best results in the author's experiments.

Conservation of soil fertility, F. W. TRAPHAGEN (*Montana Sta. Rpt. 1902, pp. 61–63*).—This is a comparison of the amount of fertilizing constituents removed from the soil by wheat, with the amount returned in irrigation water from 5 streams in Montana. The latter is shown to be much smaller than the former.

Note on the composition of the adobe soil of a hilltop, E. W. HILGARD (*California Sta. Bul. 147, pp. 119, 120*).—Mechanical and chemical analyses of a hard, black adobe clay used for an orange grove are reported. The soil contained over 80 per cent of very fine particles. Chemical analysis showed it to be of about the average composition for soils of this class and region except as regards potash which was low.

0.33 per cent. For so heavy a soil the amount of lime is considered somewhat low, 0.76 per cent. The soil contained 0.07 per cent of phosphoric acid and 0.16 per cent of nitrogen. The humus content was 1.85 per cent.

Soil investigations, F. T. SHUTT (*Canada Expt. Farms Rpts. 1902, pp. 132–136*).—Chemical analyses of soils from different parts of Canada are reported and briefly discussed.

A study of the arable soils of the Department of Aisne (*Bul. Sta. Agron. [Laon], 2. ser., 13 (1902), pp. 35–74*).—Partial chemical analyses of soils and subsoils from 27 cantons of the Department of Aisne, France, which were made for the purpose of preparing agricultural soil maps, are reported.

The amounts of nitrogen and organic carbon in some clays and marls, N. H. J. MILLER (*Quart. Jour. Geol. Soc., 59 (1903), pp. 133–140*).—This article discusses changes which organic matter undergoes in the soil, as shown by studies of Rothamsted, California, and other soils, and reports determinations of carbon and nitrogen in several samples of clays and marls. The amounts of these are shown to be considerable. "It seems very desirable that the organic matter present in the deposits which form the basis of many soils should receive far more attention than has hitherto been given to them."

The practical use of soil analysis: An analytical study of an Espinouse schist, H. LAGATU and L. SICARD (*Ann. École Nat. Agr. Montpellier, n. ser., 2 (1903), No. 4, pp. 267–290*).—Physical and chemical analyses of several samples of soil from an estate in the commune of Labastide, arrondissement of Castres, are reported with some discussion of the practical value of the analytical results.

Remarks on Loew's hypothesis concerning the rôle of lime in soils, A. DOJARENKO (*Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 2, pp. 183–187*).—Experimental data are reported to show that the beneficial action of lime is not entirely due to the neutralizing of the injurious effects of an excess of magnesia. Marked benefit was obtained in pot experiments with oats from applications of lime on soils which already contained more than enough of the substance to neutralize the action of the magnesia present according to the Loew hypothesis.

Bacteria of the soil, N. S. MAYO and A. T. KINSLEY (*Kansas Sta. Bul. 117, pp. 167–184*).—The bulletin includes a discussion of the general characteristics and functions of bacteria and of the conditions necessary to their growth, and reports the results of counts of bacteria in different kinds of soils, tabulated with reference to kind of soil, crop grown, depth, time of year, and locality. Sixteen species were isolated and are described.

Contributions to the morphology and the physiology of denitrification, J. G. LIPMAN (*New Jersey Stas. Rpt. 1902, pp. 183–241, pl. 1*).—The literature of this subject is reviewed and experiments with pure cultures of various denitrifying organisms are reported. The results of comparative tests of 8 pure cultures of soil organisms and one mixture show a wide variation in the capacity of these organisms for rendering the nitrogen of nutrient bouillon soluble, the mixture being more effective in this respect than the pure cultures (from 1.3 per cent with *Bacillus New Jersey* to 35.2 per cent with the mixtures in 15 days). Two new organisms, *B. New Jersey* and *B. New Jersey* var., were isolated from horse manure, and two, *B. 20* and *B. 21*, from cow manure. These were studied in different media, and their characteristics are described in detail. *B. 20* is stated to be similar to the *B. nitrificans* of Burri and Stutzer. The others are believed to be entirely distinct from any previously described organisms. A special study was made of the behavior of these organisms and *B. pyocyaneus* toward organic acids and salts, as well as various other sources of carbonaceous nutrients (carbohydrates). The results show a wide variation in the nutrient value of the organic substances tested, and also "prove that the development of the denitrifying bacteria is not necessarily proportionate to their denitrifying power. On the one hand, there may be considerable growth and

development with scarcely any reduction of the nitrate present in the solution; on the other hand, there may be a comparatively limited growth, accompanied by the complete reduction of the nitrate."

Data showing the variations in the capacity of the different organisms to transform nitrogen in nitrate bouillon are also reported.

The results of a study of the question of fixation of nitrogen by denitrifying bacteria indicate "that *B. pyocyaneus* has the power of fixing small quantities of atmospheric nitrogen; that this fixation is largely influenced by the organic compound used as the source of carbon and of energy. Lactic acid is decidedly superior to citric acid, but with thorough aeration, also, the latter can be used for the purpose. Furthermore, the amount of nitrogen fixed is influenced by the depth of the liquid layer, and other things being equal the greater the surface exposed the greater the amount of nitrogen fixed."

Studies of the nitrogen content of 15 soils (with subsoils) from different parts of New Jersey are reported.

FERTILIZERS.

Methods of steer feeding: Manurial results; Losses in manure, W. FREAR (*Pennsylvania Sta. Rpt. 1902, pp. 88–107; Bul. 63, pp. 6*).—In connection with a series of feeding experiments with steers (E. S. R., 13, p. 880) a study was made of the relative economy of (1) allowing the manure to accumulate during about 2 months (April and May, 1901) under the animals in cement-lined stalls, and (2) removing it daily and storing in heaps under a covered shed. The details of this study as here reported show that: "(1) The trampled manure suffered little loss of fertilizing constituents, though less than two-fifths of the dry matter of food and litter was recovered in the manure; (2) The covered-shed manure lost one-third of its nitrogen, one-fifth of its potash, and one-seventh of its phosphoric acid. Only one-third of the dry matter of food and litter was recovered in the manure. The potash and phosphoric acid losses must be explained by seepage of liquid manure into the clay floor. The loss of nitrogen is, however, chiefly due to volatilization of carbonate of ammonia; (3) The money value of the fertilizer constituents lost by the second as compared with the first method is equivalent to $2.50 for each steer stabled for six months; (4) Therefore, manure, if prepared upon a tight floor and with such proportion of litter that it can be trampled into a compact mass, loses very little, if any, of its fertilizer constituents so long as the animals remain upon it. This method of preserving steer manure is therefore distinctly superior to that of the covered shed, though the latter method may not always exhibit as great loss as that observed in this experiment."

On the preservation of barnyard manure by chemical means, H. IMMENDORF (*Mitt. Deut. Landw. Gesell., 18 (1903), No. 21, pp. 99–101*).—As a result of the experiments here reported the author concludes that sulphuric acid is unsatisfactory as a preservative because it is not easily obtained, is dangerous to handle, and imparts an acid reaction to the manure; superphosphate-gypsum in amounts ordinarily employed is very unreliable in its action, and kainit and gypsum are of no value. "Utilit," like sulphuric acid, is an effective preservative, but is expensive and is subject to much the same objections as apply to sulphuric acid.

Investigations relative to the use of nitrogenous materials, E. B. VOORHEES (*New Jersey Stas. Rpt. 1902, pp. 133–180*).—This is a report of a continuation of experiments of previous years (E. S. R., 14, p. 557), which "were undertaken mainly to determine the relative availability and value of nitrogen in farm manure and in the nitrogen salts and high-grade organic nitrogenous materials found in the market. In the study of these substances, there was also included the study of the changes which take place when farmyard manures are exposed to the leaching action of rain. The changes in the manures thus exposed involve not only a loss of a portion of the fertilizing material originally contained in the manure, but they also cause a

relative decrease in the availability of the portion still remaining. The soluble nitrogen, potash, and phosphoric acid are very readily washed out from the unprotected manure, and the resources of the farmer for replacing the plant-food taken out of his soil by the crops are thus very materially diminished."

Data for the composition of leached and unleached manure of various kinds and for comparative tests of the manure and other nitrogenous materials are reported as for previous experiments. The results show that the temperature and character of the season, as well as the length of exposure, are important factors in determining the loss from leaching of manure, the losses being greatest during periods of high temperature and abundant rainfall

"In all cases but one, the loss, both relative and absolute, was greater from the solid and liquid manure when taken together than it was from the solid manure alone. The absolute loss of phosphoric acid was about the same, although there was a relatively greater loss from the solid and liquid manure when taken together. The loss of nitrogen varied from 25 per cent to 46 per cent in the solid manure and from 39 to 69 per cent in the solid and liquid manure. The loss of potash varied from 10 per cent to 80 per cent in the solid manure and from 28 to 72 per cent in the solid and liquid manure."

Experiments were conducted on heavy loam soils with wheat followed by timothy and on light sandy loam with cabbage. The results with the wheat show that—

"On the whole, the fresh manures have returned greater amounts of nitrogen in the crop than was returned by the leached manures. This is in accord with previous experience, and shows the greater availability of the fresh manures. The nitrogen in ammonium sulphate made greater returns in the crop, when used either alone or together with solid leached, than was returned by the corresponding series where dried blood was used. The proportion of the nitrogen in the grain to that in the straw is, on the whole, rather constant. The fresh manures, where used alone, caused a more rank growth, and as a result there was more straw and more nitrogen in the straw in proportion to the grain on those series. . . . Through the long season the solid manure fresh was fully as efficacious as the solid and liquid fresh. . . . The solid fresh proved superior to the solid leached, and the solid and liquid fresh superior to the solid and liquid leached." Nitrogen in the form of nitrate gave a greater return than ammonium sulphate or dried blood. The results of the experiments with cabbage on the lighter soil in the main confirm those obtained with wheat.

The relative availability of the nitrogen in the various nitrogenous materials experimented with is summarized as follows:

Relative availability of nitrogen in different nitrogenous fertilizers.

Nitrate of soda	100
Sulphate of ammonia	94.8
Dried blood	94.7
Solid manure, fresh	36.3
Solid manure, leached	36.6
Solid and liquid, fresh	70.5
Solid and liquid, leached	48.1

"These figures show that the availability of the nitrate nitrogen is greater than that of the ammonia and of the organic nitrogen in dried blood. They show that the availability of the nitrogen in the solid and liquid fresh is greater than that in the other forms of manure. They show that the availability of the nitrogen in the solid and liquid manure leached is greater than that in either the solid fresh or the solid leached. They show that the avilability of the nitrogen in the ammonia or dried blood is greater than that of the nitrogen in any of the manures. These facts have been found to be so, with but few exceptions, in the other experiments."

Data relating to changes in the nitrogen content of sandy soils are reported and discussed in detail.

The duration of the effect of green manures, A. Petermann (*Bul. Inst. Chim. et Bact. Gembloux, 1903, No. 73, pp. 11–21; Bul. Agr.* [*Brussels*], *19* (*1903*), *No. 4, pp. 504–514*).—Experiments with a number of crops grown on soil which had been in grass, the sod being turned under, and on soi which had been under clean culture, indicated that the effect of such green manuring is quite noticeable on early potatoes, less marked on late potatoes, still less marked the second year, and disappears the third. The use of lime to accelerate the action of green manures is suggested.

Fertilizer experiments on the sewage-irrigation fields of the town of Dortmund, Heppe and Gnirss (*Deut. Landw. Presse, 30* (*1903*), *No. 55, pp. 490, 491, fig. 1*).—Experiments are reported which show the importance of using potash and phosphoric acid in connection with sewage irrigation.

Some remarks on the object and method of conducting field experiments with fertilizers, F. W. Dafert (*Landw. Jahrb., 32* (*1903*), *No. 1, pp. 149–159*).—A reply to a criticism by T. Pfeiffer of the failure to include check plats in the plan of experiments carried out by the author, E. Meissl, and O. Reitmair (E. S. R., 12, p. 839). The general questions of the purpose, plan, and method of conducting field experiments are discussed.

The action of commercial fertilizers on sandy soils of different degrees of fertility, Bachmann (*Fühling's Landw. Ztg., 52* (*1903*), *No. 11, pp. 373–378*).—The results of 14 experiments with rye on sandy soils of different degrees of fertility show that on the average the yield of grain was doubled by the use of mixtures of Thomas slag, kainit, or 40 per cent potash salt, and nitrate of soda or sulphate of ammonia. The use of fertilizers was profitable in all cases.

Investigations on the value of the new 40 per cent potash fertilizer as compared with kainit, W. Schneidewind et al. (*Arb. Deut. Landw. Gesell., 1903, No. 81, pp. 168*).—The results of 3 years' comparative tests on a variety of crops are discussed in detail. Previous experiments have been referred to (E. S. R., 14, p. 852).

Conditions determining the poisonous action of chlorids, H. J. Wheeler and B. L. Hartwell (*Rhode Island Sta. Rpt. 1902, pp. 287–304, figs. 6*).—This question has been studied in a series of pot experiments begun in 1894. The experiments included tests of the effect of calcium chlorid on potatoes, and magnesium and ammonium chlorids on barley, rye, and oats.

"Calcium chlorid and ammonium chlorid were found to exert a marked poisonous action upon certain plants, when applied to a soil which was already somewhat acid. Magnesium chlorid was not found to be poisonous under conditions where great injury from calcium chlorid and ammonium chlorid resulted.

"Calcium carbonate and caustic magnesia used singly, also a mixture of basic slag meal with the carbonates of potash and magnesia, were found to prevent or overcome the ill effect produced by applications of either calcium chlorid or ammonium chlorid.

"There seems to be no good foundation for the caution about using sulphate of ammonia and muriate of potash or kainit in the same mixture on account of the formation of ammonium chlorid, provided the soil is duly tested with blue litmus paper, and lime, wood ashes, or other suitable substances are applied to correct or partially overcome the existing acidity.

"It is probable that all of the apparently conflicting evidence regarding the poisonous and nonpoisonous action of chlorids upon plants, when they are applied in reasonable quantities, could be explained without difficulty, had due attention been paid in all cases to the chemical reaction of the soil."

Field experiments with ammonium sulphate and sodium nitrate, Kloepfer (*Fühling's Landw. Ztg., 52* (*1903*), *Nos. 10, pp. 341–345; 11, pp. 388–393*).—The results obtained in field experiments were variable, depending apparently largely

upon conditions of soil, season, etc. The sulphate was slower in action than the nitrate, and for this reason it is recommended that it be applied earlier than nitrate.

Production, exportation, and consumption of nitrate of soda in 1902 (*Assoc. Sal. Propaganda Circ. Trimestral No. 30, 1903, pp. II, X–XXIV*).—The production is stated to have been 1,387,426.9 long tons, the exportation 1,399,508.8, the consumption 1,320,969.3. The nitrate was distributed as follows: Germany 490,210.2, United States 212,714.5, France 205,309.8, Belgium 144,831.2, Great Britain 109,790.2, Holland 96,225.6, Italy 30,381.4, Austria 8,012.5, Hawaii 5,964.3, other countries 17,777.8 long tons.

The utilization of the free nitrogen of the air in agriculture and industry, A. Frank (*Chem. Ztg., 27 (1903), No. 46, p. 543*).—Brief notes on the preparation and on tests of the fertilizing value of the so-called "lime nitrogen" (calcium cyanamid), a by-product of the manufacture of acetylene gas.

The new fertilizer law (*California Sta. Circ. [1903], pp. 6*).—This law, which went into effect July 1, 1903, requires the registration (with director of the State experiment station) and labeling of all fertilizing materials selling for $8 or more per ton. The labels must not only state the percentages but the sources of nitrogen, phosphoric acid (total and available), and potash. A registry fee of $50 and a tonnage tax of 25 cts. are required. The penalty for violation of the law is a fine of $50 and costs for the first offense and $100 and costs for each subsequent offense. The act also provides a sum of $1,800 for the equipment of a laboratory for the inspection work.

Fertilizers, F. T. Shutt (*Canada Expt. Farms Rpts. 1902, pp. 154–156*).—Analyses of 1 sample of squid, 1 of caplin, 3 of peat, and 5 of limestones are reported.

Report on official inspection of commercial fertilizers and agricultural chemicals during the season of 1902, C. A. Goessmann (*Massachusetts Sta. Rpt. 1902, pp. 9–21*).—The results of examinations of 451 samples representing 273 brands are summarized. Tables show the average composition of the different classes of all fertilizers analyzed, and the maximum, minimum, and average composition of special crop fertilizers. There was found to be wide variations in the composition of different brands of fertilizers recommended for the same crop. Thus in the tobacco fertilizers examined the nitrogen varied from 1.76 to 6.68 per cent, the total phosphoric acid from 3.38 to 13.71 per cent, the available phosphoric acid from 2.84 to 11.59 per cent, the potash from 1.54 to 14.15 per cent A schedule of trade values of fertilizing constituents and a list of licensed manufacturers and dealers are given.

Report on general work in the chemical laboratory, C. A. Goessmann (*Massachusetts Sta. Rpt. 1902, pp. 22–25*).—A brief note on the examination of wood ashes and miscellaneous material, including references to work on methods of soil and plant analysis.

Analyses and valuations of fertilizers, L. A. Voorhees et al. (*New Jersey Stas. Rpt. 1902, pp. 17–81*).—This is a reprint of Bulletin 163 of the station (E. S. R., 14, p. 749) with the addition of a list of manufacturers doing business in the State and data regarding market prices of fertilizers in New York during 3 years, 1899–1901, and a compilation showing the average composition of fertilizing materials examined by the station since its organization.

Fertilizers, C. V. Garola (*Engrais. Paris: J. B. Baillière & Son, 1903, pp. XI+502, figs. 33*).—This volume forms a part of the *Encyclopédie agricole* issued under the direction of G. Wery. It treats in simple manner of general principles of plant nutrition; calcareous amendments; farm manures and miscellaneous organic fertilizers; commercial sources of nitrogen, phosphoric acid, and potash; fertilizer laws, companies, and valuation; and practical methods of fertilizing cereals, hoed crops, leguminous plants, grass lands, oil-producing plants, gardens, and ornamental plants.

Recent progress in the fertilizer industry, R. von Grueber (*Chem. Ztg., 27 (1903), No 40, pp. 479–481*).—Reviews briefly general business progress and discusses raw products, methods of preparation, technical and scientific phases.

FIELD CROPS.

Annual Report of the Alaska Agricultural Experiment Stations for 1902. C. C. GEORGESON (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 233–307, pls. 11*).—The agricultural work of the stations for the year is summarized and discussed. Excessive rains very much interfered with the work.

Work at Sitka Station.—Excelsior winter rye seeded September 7 made a growth of $6\frac{1}{2}$ ft., and was sufficiently mature for harvesting by August 15. Its strong elastic straw enabled it to withstand storms and unfavorable weather for some time after complete maturity. While not as good as the Swedish winter rye, it is regarded as one of the varieties of value for Alaska. Carman wheat-rye, considered a hybrid between wheat and rye, largely winterkilled. The straw is strong and stands up well, and this character is the only one which might suggest that rye is one of the parent plants. Romanow spring wheat was grown on old and new ground. The crop lodged on the old ground, but was ripe enough to harvest by September 15, while on the new land it did not lodge badly, but did not begin to ripen until October 1.

The varieties of oats under test were Sixty-day, North Finnish Black, Burt Extra Early, Swedish Select, White Russian, and Improved Ligowa. Detailed notes on the behavior of each variety are given. All except Sixty-day were grown on new ground. Swedish Select suffered least from the unfavorable weather conditions. Sixty-day was sown May 8 and was ripe September 1. The earliness of this variety is considered its chief recommendation. Four varieties of barley were sown May 12 and 15. Manshury and Sisolsk were ripe September 15, and Black Hulless September 1. No difference was noticed in Lapland barley grown from imported and Sitka-grown seed. Riga flax was sown for fiber May 23. About three-fourths of the crop lodged, but the portion which stood up was of fine quality. About 5 per cent of the seed was ripe September 15. Common hemp sown May 23, on very poor soil, grew 5 ft. high and produced a fairly tough fiber.

The growth of furze and buckwheat and a number of grasses at the station is also noted. The grasses were sown May 14, and nearly all showed a good stand. The best growth was made by tall meadow oat grass, being about 2 ft. tall on August 1. Brief notes are also given on the growth of vegetables, nursery stock, and flowers. A concise report is presented on the construction of station buildings and the clearing and draining of station land.

Work at Kenai Station.—The progress of work at this station is reviewed and culture tests with vegetables and field crops are noted. The weather conditions were unfavorable. Nearly all the grasses grown made good stands, but produced only a light growth. Timothy and tall meadow oat grass reached a height of 27 and 30 in., respectively. Spring wheat did not ripen, and rye and winter wheat were winterkilled. Early Jersey Wakefield cabbage, Large Boston Market and Early Curled Simpson lettuce, and Extra Curled parsley, started in cold frames and transplanted, made a very satisfactory growth. Peas, beets, carrots, and parsnips were planted in the open ground May 13. Alaska and American Wonder peas gave good results, and Half-long Chantenay carrots and Hollow Crown parsnips did quite well, while Egyptian beets made but little growth. Rhubarb survived the winter and yielded abundantly this season. Specimens of White Dutch turnips weighing 8 lbs. and of Early Rose potatoes weighing 1 lb. were obtained.

Work at Rampart Station.—Romanow spring wheat, winter rye, Manshury barley and Black Finnish, Burt Extra Early, Flying Scotchman, and common oats grew to maturity.

In addition to the above reports the growth of different field, forage, and garden crops at Kadiak is briefly reviewed, and the opening of an experiment station in the Copper River Valley is described. The description of this station includes notes on its location and area, the topography of the region, the altitude, soil, and vegetation.

The results obtained with grasses and grains at the station and by parties living in that section are briefly given.

Seeds of field and garden crops were distributed in all parts of the territory, and the reports on this work are submitted. Tables are given showing the soil temperatures at the different stations for each day from May 1 to September, inclusive, and the meteorological observations made at the different points throughout the territory.

Annual Report of the Hawaii Agricultural Experiment Station for 1902, J. G. Smith (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 309–330, pls. 8*).—The improvements made at the station during the year are briefly mentioned. Experiments with taro indicate that the root rot of the crop may be prevented by proper liming and fertilizing of the soil and by planting slips which are free from the disease. A test was made of 45 varieties of potatoes to find a variety resistant to the black wilt disease. The seed potatoes were obtained from Maine. Only one variety, the June, was entirely resistant to the disease. Two varieties were partially resistant, while the rest were completely destroyed. The coffee industry is reviewed and the culture of different fiber plants, including sisal, malina (*Furcræa gigantea*) and olona (*Touchardia latifolia*) is described. An account of the occurrence and preparation of olona fiber is given.

Notes on the culture and growth of pineapples, figs, papayas, guavas, mangoes, alligator pears, grapes, limes, and peanuts are presented. The principal insect enemies of Hawaiian agriculture are enumerated, and the work of the station in dealing with this problem is outlined. Farmers' institute work in Hawaii is described and climatic conditions of the islands are noted.

Annual Report of the Porto Rico Agricultural Experiment Station for 1902, F. D. Gardner (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 331–357, pls. 8, fig. 1*).—This report contains an account of the present status of the station and a general review of the principal work for the year. The station farm, together with its equipment, is described. The propagation of coffee plants from seed was accomplished in seed beds protected by straw-covered sheds, and the young plants were transplanted to continue their growth in nursery beds. An experiment in improving old coffee groves has been begun and arrangements are being made to test different varieties on a 25-acre tract of new forest land.

Temporary field experiments were conducted at Rio Piedras with field, garden, and forage crops, and with flowering bulbs. The results are summarized in a table, and the growth of the most important crops is briefly noted. Insect and plant diseases attacked the garden crops, in some instances causing total destruction. A good stand of blue grass was obtained, but so far nothing further as to its value under Porto Rico conditions has been learned. Alfalfa gave some promise of success, and cotton produced abundantly, although the plants were small. Kafir corn and teosinte succeeded well. The problem of combating insect enemies is discussed. Special attention is given to the changa, or mole cricket, and statements regarding its classification and distribution are presented.

Attention is called to the soil conditions existing in the island, and the influence of fertilizers is shown by the results of an experiment with sweet potatoes. The average yield per acre from fertilized plats was at the rate of 14,478 lbs., or an increase of 8,758 lbs. over unfertilized plats. The largest yield was obtained where 188 lbs. each of acid phosphate and muriate of potash and no nitrogen had been applied. The soil upon which the experiments were made was found to be acid, and an application of 1,000 lbs. of lime per acre caused a noticeable improvement in the crop.

Notes on the growth and culture of tropical fruits, and the value of forest reservations on the island are given, and meteorological records for 1899 to 1902, inclusive, are shown in tables.

Culture work at the substations, 1899-1901, C. H. SHINN (*California Sta. Bul. 147, pp. 20–27, 36–41, 55–61, 83–88, figs. 5*).—This is a general summary of the field work of the California substations from 1899 to 1901, inclusive. (For the work in horticulture see p. 148.) The experiments with field crops consisted mainly of culture tests of a large number of different plants, including plants and seeds sent out by this Department for trial.

The Foothill Substation (at Jackson) (pp. 20–27).—A large range of cultures has been under test since 1899 and the more striking results are here noted. Australian saltbush did not show any decided advantage over other forage crops, but is considered worth growing on a small scale. Hairy vetch seemed better adapted to the region than the saltbush. *Atriplex leptocarpa* did not naturalize at all, while *Rhagodia spinescens inermis* furnished much fodder, but its adaptability has not yet been determined.

Bromus inermis has been thoroughly tested and is recommended for extensive culture. The grass was improved and its season lengthened by light irrigation. Evergreen and perennial rye grasses from England proved of great value when irrigated. Selected Perennial is regarded as one of the best. Sutton perennial red clover made a growth of 14 in. from March 1 to June 1, 1900. Common white clover, alsike clover, Egyptian clover (*Trifolium alexandrinum*), and snail clover (*T. turbinatum*) gave good results when irrigated.

Tests with root crops were carried on with and without irrigation on granite and slate soils. With irrigation beets, mangels, parsnips, and carrots gave large yields. Champion Yellow Globe mangel yielded 72.5 tons per acre, and of the 20 varieties grown none yielded less than 30 tons.

Notes on the growth at the station of Jersey kale, tagasaste, New Siberian golden millet, buckwheats, flax, and lupines are given. California, Royal, White Flowering, Belgian Improved, Russian Pskoff, Pure Riga, White Dutch, and Yellow Seeded flax produced excellent fiber and plump, bright seeds. The flax plants ranged in height from about 25 to 42 in. Among the varieties of lupines the Large European White proved most satisfactory. *Lupinus tricolor* and *L. angustifolius* were failures. The yields of the best vetches sent out by this Department are given in the following table:

Yields of vetches in 1900.

Name.	In full bloom.	Yield of green fodder per acre.
		Pounds.
Vicia peregrina	June 4	14,620
Vicia atropurpurea	...do....	17,240
Vicia fulgens	...do....	18,150
Vicia bythinica	June 5	19,057
Vicia narbonensis	May 25	25,400
Vicia sativa	June 4	25,410
Vicia sativa cordata	...do....	30,885
Vicia villosa	...do....	32,670

Lentils when early sown are considered well adapted to the red soils of the region. Turkestan alfalfa seemed hardier and more drought resistant, but did not yield better than the common varieties. Cuzco maize from Brazil and velvet beans did not succeed. Peruvian cotton did not mature, while Georgia upland varieties matured well and made a medium growth without irrigation on the red soils. The safflower (*Carthamus tinctorius*) was not equal to Russian sunflowers in the yield of seed for oil or chicken feed. March rape proved better than Essex, and sown on slate soil yielded 47 tons of green forage per acre. Rape had no value for summer pasture in that locality. Notes are also given on tests of horse beans, field peas, and artichokes. The hard wheats grown at this substation showed a tendency to increase their starch content.

Southern Coast Range Substation (*at Paso Robles*) (pp. 36–41).—Seventy-two perennial grasses were tested for their drought resistance, and the growth of the most promising species is briefly described. In 1899, 50 varieties of wheat, including 13 Algerian varieties and a number of cross-bred sorts, were under trial. All the Algerian wheats yielded above the average and ripened among the earliest. Some of the cross-bred sorts proved valuable. In a test of varieties of wheat for hay a cross between Frame New and Australian gave the heaviest yield and the best quality of hay. Notes are also given on the several varieties of wheat obtained from this Department. Cañaigre, Dwarf Essex, and March rape, *Bromus inermis*, safflower, foxtail furze, and Jersey kale made good growths at this substation; but Egyptian clover, vetches, Turkestan alfalfa, Russian millet, horse beans, lentils, goat rue, *Iris pabularia*, and *Lathyrus sylvestris* were not so generally promising. The rye grasses and clovers on trial were nearly all in need of irrigation. Giant rye grass (*Elymus condensatus*), in 1899, remained green without irrigation until autumn. The results with saltbushes at the substation have been previously noted (E. S. R., 14, p. 653).

San Joaquin Valley Substation (at Tulare) (pp. 55–61).—A large number of saltbushes have been under test at this substation and all withstood much drought and alkali. Those giving the best results, named in the order of their value, were *Atriplex semibaccata*, *A. pamparum*, and *Rhagodia spinescens inermis*. All varieties of alfalfa gave the best results with irrigation and withstood considerable alkali. Turkestan alfalfa grew more compact and produced more foliage than the common form. Species of *Lathyrus*, goat rue (*Galega officinalis*), horse beans, lentils, chick peas, and lupines have not generally given good results. Perennial rye grass, brome grass, Italian rye grass, and Texas blue grass (*Poa arachnifera*) were the best grasses under test. Most grasses and clovers needed some irrigation. The artichoke (*Cynara scolymus*) grew as well in strong alkali as the Australian saltbush. The growth of Tsama or Khama stock melon was much better than that of any other cucurbit, but the alkali in the soil reduced its yield.

Southern California Substation (*at Pomona*) (pp. 83–88).—Notes are given on the growth and value of a large number of field and garden crops. Turkestan alfalfa gave somewhat better results than the common varieties. The yields of carrots were very low, which result is attributed to the effect of alkali. Egyptian varieties of cotton rooted much deeper and outgrew the American varieties with which they were compared. No definite conclusion as to the value of Egyptian cotton culture in that region has been reached. *Bromus unioloides* made a much better growth than *B. inermis*. Soy beans were grown, and early and medium early varieties are recommended. The vetches tried were not a success. The Tsama or Khama stock melon yielded much better than the Kansas stock melon and showed its superiority in drought resistance.

Field experiments with farm crops, W. Saunders, J. H. Grisdale, W. T. Macoun, F. T. Shutt, J. Fletcher, R. Robertson, S. A. Bedford, A. Mackay, and T. A. Sharpe (*Canada Expt. Farms Rpts. 1902, pp. 7–45, 81–89, 112–120, 156–160, 196–201, 232–249, 279–298, 319–339, 357–373*).—The results of the work with field crops at the Canada Experimental Farms in 1902 are reported and discussed. The average results of variety tests carried on in this connection at the different farms with most of the crops here mentioned have been noted from a previous bulletin (E. S. R., 14, p. 751). The data obtained in the variety tests at each of the farms are tabulated in detail, and include a larger number of varieties of the different crops than is given in the bulletin above mentioned. The report for 1901 is noted in E. S. R., 14, p. 130.

Wheat.—At the Central Experiment Farm at Ottawa 20 varieties of winter wheat were tested. The leading varieties were Dawson Golden Chaff, Imperial Amber, and Egyptian Amber, yielding 53¼, 46, and 45⅓ bu. per acre, respectively. American Bronze, the least productive variety, yielded 28⅔ bu. Spring wheat at Ottawa yielded best when sown at the rate of 1 bu. per acre on sandy loam and 2½ bu. per

acre on clay loam soil. Varieties of spring wheat grown from selected and unselected heads at the Manitoba farm gave practically the same average yields. At this same farm summer fallowing showed a great advantage over spring plowing for wheat. The yields from selected, well cleaned, and small seed at the farm for the Northwest Territories were $37\frac{1}{3}$, $32\frac{1}{3}$, and $29\frac{1}{3}$ bu. per acre, respectively. On fallow and new ground at this station fair yields were obtained, but on land which had produced root crops the year before the growth of straw was abnormal, and an attack of rust largely reduced the yield and quality. A culture test of winter wheat at this farm was a complete failure.

Oats.—At Ottawa the best yield on sandy loam was obtained by sowing $1\frac{1}{2}$ bu. of seed per acre and on clay loam by sowing $2\frac{1}{2}$ bu. At the experiment farm for the Northwest Territories, selected, well cleaned, and small oats for seed yielded $86\frac{7}{17}$, $80\frac{10}{17}$, and $72\frac{1}{17}$ bu. per acre, respectively.

Barley.—Different quantities of seed ranging from $1\frac{1}{2}$ to 4 bu. per acre were sown on sandy loam and clay loam soil at Ottawa. On the sandy loam the best yield was 45 bu. per acre, obtained from 4 bu. of seed, and the next best from the use of only $1\frac{1}{2}$ bu. On the clay loam soil 2 bu. of seed per acre gave the highest yield.

Spelt.—The yields of spelt sown on May 6, 13, 20, and 27 at the Manitoba farm were 59, 52, 56, and 61 bu. per acre, respectively. Sowing at the rate of $87\frac{1}{2}$ lbs. of seed per acre proved most profitable, the yield per acre being 54 bu. 40 lbs. At the station for the Northwest Territories a yield of 36 bu. 20 lbs. per acre was obtained and the crop required 108 days to mature.

Corn.—At Ottawa, Champion White Pearl, Selected Leaming, and Longfellow were sown in rows 21, 28, 35, and 42 in. apart. Champion White Pearl yielded best in rows 35 in. apart, and Selected Leaming and Longfellow in rows 28 in. apart. At the farm in the Maritime Provinces the yields of these same varieties were all in favor of 28 in. between rows. At the Manitoba farm where these varieties were grown in rows 24, 30, 36, and 42 in. apart the average yield of green corn per acre amounted to 15 tons and 1,328 lbs., and was in favor of the greatest distance. The yield at the farm for the Northwest Territories was in favor of 35 in. with Selected Leaming and Longfellow, and 42 in. with Champion White Pearl. At the British Columbia farm this same experiment was made but with the addition of plats planted in hills. The corn planted 6 in. apart in 21-in. rows gave the best yields in all cases, while the hill-planted crop of Champion White Pearl was in favor of 21 in., and that of the other 2 varieties in favor of 28 in. The highest average yield of green crop was obtained in drills.

Potatoes.—Experiments in planting at different dates have been conducted at Ottawa for several years. Plantings of an early and late variety were made at intervals of 2 weeks until late in the season. In 1902 the planting made May 15 gave the best results. The experiments, in general, have shown that a good crop of marketable potatoes can be obtained at Ottawa by planting as late as July 10. The best total average yield with the early as well as the late variety was obtained by planting during the last week of May. The average results of a 7-years' test of planting at different distances show that planting in rows $2\frac{1}{2}$ ft. apart, with the sets 14 in. apart in the row gave the best yields. For 6 consecutive years the largest yields were obtained in sandy loam soil from planting the sets 1 in. deep. For field culture the author recommends planting from 4 to 5 in. deep. While the largest yields have been obtained by planting large whole potatoes it is believed most economical to use medium to large tubers cut into sets having at least 3 eyes with a good amount of flesh. In a fertilizer test with superphosphate of lime at the British Columbia farm the yield per acre on the check plats was 355 bu. 18 lbs., while on the plats receiving 100, 150, and 200 lbs. of superphosphate of lime per acre the yields were 371 bu. 48 lbs., 391 bu. 36 lbs., and 409 bu. 12 lbs., respectively.

Soy beans and horse beans.—Soy beans were grown in rows 21, 28, and 35 in. apart. At Ottawa the plat with the rows 28 in. apart gave the highest yields of total green crop and of beans per acre, while at the farms in the Maritime Provinces and the Northwest Territories the yields of green crop were in favor of the 21 and 35 in. rows, respectively. Drills 28 in. apart gave the best results at the British Columbia farm but the yields for the other distances were nearly as great.

The same experiments were made on these farms with horse beans. At Ottawa the best total yield, 8 tons 160 lbs. per acre, was obtained from the rows 28 in. apart, while the 21-in. rows gave the best yield of beans, 37 bu. 20 lbs. per acre. At the farm in the Maritime Provinces the best yield was in favor of the 28 in. rows, while at the farm for the Northwest Territories the best yield was produced by the 28 and 35 in. rows, the yield being the same for both distances. A culture test at the Manitoba farm showed a growth of 36 in. in height and a yield of $10\frac{6}{10}$ tons per acre of green crop. Drills 28 in. apart gave the best yield at the British Columbia farm.

Flax.—Experiments at Ottawa to determine the best time for sowing and the quantity of seed required resulted in the best yield of straw, 6,440 lbs. per acre, from 80 lbs. of seed per acre sown May 21, and the heaviest yield of seed, 9 bu. 20 lbs. per acre, from the same quantity of seed sown April 30. Five different quantities of seed varying from 15 to 50 lbs. per acre were sown at the Manitoba farm, and the results showed that the yield of seed increased with the quantity of seed sown. Results on newly broken land were also in favor of the larger quantity of seed. In a test of several varieties made at this farm during the year, Novarossick yielded 22 bu. 28 lbs. of seed per acre, being nearly double the quantity yielded by any other variety. In the Northwest Territories sowing on May 17 gave better average results than sowing on May 26. Sixty lbs. of seed per acre yielded 16 bu. 16 lbs., as compared with 15 bu. for 80 lbs. of seed. Where 25 and 40 lbs. of seed had been used the yields were smaller.

Millets.—Among 9 varieties of millet tested at Ottawa, Algerian and Japanese led in productiveness, both varieties yielding over 17 tons of green crop per acre. The yields of hay per acre were 8 tons 800 lbs., and 8 tons 1,920 lbs., respectively. Italian or Indian millet at the farm for the Maritime Provinces gave a yield per acre of 13 tons of green substance, which was over 4 tons more than was obtained from any of the 4 other varieties grown. At the Manitoba farm 6 varieties were sown June 6 and cut September 4. The best yields were obtained from Algerian or Early Pearl and Italian or Indian. Algerian produced the largest stems and Italian the longest heads. Italian millet also produced the highest yield at the farm for the Northwest Territories. At the British Columbia farm Round White Extra French led in productiveness, followed by Algerian. The yields of all varieties at this station were small.

Buckwheat.—Of 5 varieties grown at the farm for the Maritime Provinces, Silver Hull, Rye, and Tartarian or Siberian were the most productive, the yields being 46 bu. 32 lbs., 45 bu. 40 lbs., and 41 bu. 32 lbs. per acre, respectively. In a field test 5 acres previously in buckwheat and fertilized, yielded 31 bu. 14 lbs. per acre, and 4½ acres of new land unfertilized produced 14 bu. 16 lbs. per acre.

Miscellaneous.—The conclusions drawn from fertilizer experiments in progress at Ottawa since 1888 are the same as previously noted (E. S. R., 14, p. 130). The effects of clover as a green manure for oats, corn, and potatoes for 1 and 2 years after the crop was plowed under are noted. In every instance during the 2 years the yields were markedly in favor of the green-manured plats. Experiments to determine the effect of superphosphate of lime and Thomas slag, used singly and in combination with kainit and nitrate of soda, on the yields of spring wheat, oats, and brome grass have been in progress since 1900 and are to be continued for a series of years. This year the best yield of spring wheat (both grain and straw) was with a mixture of 400 lbs. Thomas slag, 200 lbs. kainit, and 100 lbs. nitrate of soda per acre. In the

experiments with oats the check plats gave yields equal to those of the fertilized plats. The complete fertilizer application, containing superphosphate of lime, yielded the largest quantity of green crop of brome grass, but the check plat, producing over 1 ton of green crop less per acre, gave the highest yield of hay. In a test at the farm for the Maritime Provinces an application of muriate of potash gave better results than nitrate of soda and superphosphate, applied singly or in combination with the muriate. The results of special fertilizer experiments at this farm with barnyard manure and complete commercial fertilizers on different crops and crop mixtures are tabulated without comment. At the Manitoba farm, in a test with spring wheat, a mixture of 200 lbs. superphosphate, 100 lbs. nitrate of soda, and 100 lbs. muriate of potash per acre, one-half applied before sowing and the rest when the grain was 2 or 3 in. high, gave the highest yield of straw and grain—3,840 lbs. and 38 bu. per acre, respectively. In a test in the Northwest Territories the yield of wheat, and at the British Columbia farm the yield of oats, was also in favor of this combination and method of application.

The yields of different root crops and vegetables grown in various combinations at Ottawa are given in a table. Shallow cultivation and management of soils is discussed by the agriculturist of the Ottawa farm, and a series of crop rotations are recommended. The itemized cost of growing oats, mixed crops, hay, corn, mangels, turnips, sugar beets, and pumpkins is reported. The yields of hay obtained from different mixtures of grasses and clovers are shown and a number of important species of grasses are described. The best yield of hay this year was obtained from a mixture of meadow fescue 6 lbs., orchard grass 2 lbs., Kentucky blue grass 1 lb., common red clover 4 lbs., alfalfa 3 lbs., and white Dutch clover 1 lb. The first cutting, July 10, yielded 2.6 tons of hay, and the second cutting, August 30, 3.16 tons. Austrian brome grass compared with timothy and a mixture of alfalfa and brome grass at the Manitoba farm led in the yield of hay. The results for 3 years of a plan of crop rotation followed at the farm for the Northwest Territories are summarized. Brief notes are given on the growth of various forage crops at the different farms.

Cooperative experiments in agriculture, C. A. Zavitz (*Ontario Agr. and Expt. Union Rpt. 1902, pp. 10–24*).—The average results of cooperative variety tests carried on by the Ontario Agricultural and Experimental Union in 1902 with oats, barley, wheat, buckwheat, peas, soy beans, corn, mangels, sugar beets, swedes, kohl-rabi, turnips, parsnips, carrots, millet, sorghum, vetch, rape, kale, clover, grasses, and other forage crops are reported in tables and briefly discussed.

The leading varieties were Oderbrucker oats, Oderbrucker Six-rowed barley, Black Hulless barley, Japanese buckwheat, Early Britain pea, Medium Green soy bean, Compton Early corn, Dawson Golden Chaff winter wheat, Evans Improved mangel, New Danish Improved sugar beet, Sutton Magnum Bonum swede, Greystone and Early White Vienna kohl-rabi, Bruce Mammoth Intermediate carrot, Improved Half Long parsnip, Wisconsin Earliest White Dent fodder corn, Japanese millet, Early Amber sorghum, hairy vetch, Dwarf Essex rape, Thousand Headed kale, Mammoth red clover, and tall oat grass. Alfalfa gave a larger crop than sainfoin and burnet.

In a cooperative test fertilizers were applied singly and in combination. Nitrate of soda and muriate of potash were each used at the rate of 160 lbs. per acre, and superphosphate at the rate of 320 lbs. The mixed fertilizer consisting of one part of nitrate of soda, one part of muriate of potash, and two parts of superphosphate was applied at the rate of 213.3 lbs. per acre. The average results for the number of years the work has been in progress show that the greatest yields were produced by the mixed fertilizer with oats, turnips, and corn for grain; by nitrate of soda with mangels, and by muriate of potash with corn for fodder. The fertilizer apparently exerted a greater influence on mangels and swedes than on either corn or oats.

Among 7 early varieties of potatoes, Rose of the North, as shown by the average results of 135 tests, led in productiveness, with a yield of 197.5 bu. per acre, followed by Early Dominion, Burpee Extra Early, and Stray Beauty. The average results in the yields of these 4 varieties did not vary 10 bu. per acre. In 1901 level culture produced 8.5 bu. and in 1902 4.8 bu. more per acre than hill culture. Potato sets sprinkled with land plaster gave an increase of 16.4 bu. per acre in 1900, 14.4 bu. in 1901, and of $\frac{1}{3}$ of a bu. in 1902 as compared with untreated sets.

Report of the agriculturists, W. P. Brooks and H. M. Thomson (*Massachusetts Sta. Rpt. 1902, pp. 102–153*).—The work here reported followed the general lines of the preceding years (E. S. R., 14, p. 133).

In the comparison of dried blood, sulphate of ammonia, barnyard manure, and nitrate of soda as sources of nitrogen for potatoes in 1902, the yields obtained ranked the different fertilizers in the order mentioned. The average results since 1890 with different crops place them as follows: Nitrate of soda, barnyard manure, sulphate of ammonia, and dried blood. Potatoes this year followed soy beans and the plats receiving no nitrogen produced a yield almost as large as the plats to which nitrogen had been applied yearly.

Sulphate of potash was superior to muriate of potash as a fertilizer for cabbage, mixed timothy and clover, and potatoes. A summary of the results for the series of years shows that the best yields of potatoes, clover, cabbage, and soy beans have been obtained with the sulphate, while the yields of corn, grasses, oats, barley, vetch, and sugar beets were about equal for the 2 salts. The sulphate produced potatoes and sugar beets distinctly better in quality than the muriate.

Nitrate of soda, dried blood, and sulphate of ammonia, used in connection with manure, ranked in the order mentioned as sources of nitrogen for garden crops. A comparison of sulphate and muriate of potash for this class of crops indicated that the sulphate was better for onions, tomatoes, and celery, while the muriate gave slightly better results with strawberries and squashes.

Among different potash salts used as fertilizers for clover, silicate, high-grade sulphate and nitrate of potash were most effective. The salts containing chlorin, especially kainit, proved injurious to the young clover.

The results with phosphates in quantities furnishing equal amounts of phosphoric acid as fertilizer for onions were in favor of dissolved bone meal, fine ground raw bone, phosphatic slag, and steamed bone meal, in the order given. Tennessee phosphate and Florida soft phosphate gave results very much inferior to all others.

Soil tests were continued this year with corn and potatoes. The results indicate that potash was the most prominent plant-food element controlling the yield of corn. The plat which had received 160 lbs. of muriate of potash per acre annually for 14 years yielded 47.7 bu. of shelled corn per acre, and the plat receiving 320 lbs. of dissolved boneblack per acre in addition to the muriate gave a crop of 55.9 bu. In the entire series of tests the plat receiving annually 5 cords of manure produced the highest yield of corn and stover. Four plats which had not been fertilized for 14 years showed a high degree of exhaustion. The crop of potatoes on lime soil was increased more by muriate of potash than by fertilizers furnishing either of the other plant-food elements. Nitrogen and phosphoric acid were more effective in increasing the yield of potatoes than the yield of corn.

Manure alone gave a larger yield of mixed grass and clover than manure applied with potash, but the increase was not sufficient to make it profitable. The preceding year corn was grown on these same plats with like results. A mixture of grass and clover was also grown with a special corn fertilizer as compared with an application richer in potash. The fertilizer mixture containing the greater quantity of potash produced 1,520 lbs. of hay more per acre than the special corn fertilizer which cost about $4 per acre more. The larger quantity of potash gave a greater relative abundance of clover.

As in the previous year, the results of fertilizing grass lands in rotation with wood ashes, nitrate of soda, ground bone, muriate of potash, and barnyard manure proved decidedly profitable.

The results in the experiment on the methods of applying barnyard manure were in favor of the spring application as compared with the fall application, but the difference in yield was not sufficient to pay for the extra handling.

The use of 150 to 250 lbs. per acre of nitrate of soda on timothy sod gave a profitable increase in the yield of rowen in every instance.

In a variety test of potatoes, Beauty of Hebron (first and second generations from Maine seed), IXL, Steuben, Early Nancy, Million Dollar, Ensign Bagley, Early Rose, Gem of Aroostook, and Daughter of Early Rose, in the order of productiveness, produced over 250 bu. of merchantable tubers per acre.

Report of the agriculturists, R. S. Shaw and F. B. Linfield (*Montana Sta. Rpt. 1902, pp. 21–56*).—Earlier results of the work described have been previously noted (E. S. R., 14, p. 26), and the data here reported include the average results for 1899, 1900, 1901, and the yields obtained in 1902.

The results of tests with 42 varieties of wheat are given in a table. The data include the yields of grain and straw, the weight per bushel, and the time required to mature. Onyx, Opal, Chili, and Russian 2955 led in productiveness and yielded 65.7, 65.2, 63.5, and 60.7 bu. per acre, respectively. The smallest yield obtained in the test was 36.6 bu. The macaroni wheats, Kubanka and Wild Goose, were grown under irrigation without any apparent softening of the kernel. Russian 2955 was obtained through this Department and has proved a most promising milling wheat.

Of 19 varieties of oats under test Swedish Select 2788, White Swedish, White Danish, American Banner, and American White yielded 100.3, 98.1, 91.8, 91.3, and 90.7 bu. per acre, respectively. The smallest yield in the test was 73.3 bu. Among 6 varieties introduced in 1901, Salzer Big Four led with a yield of 129 bu. per acre, followed by Irish Victor and Alaska with 126.3 and 104.6 bu., respectively. Swedish Select 2788 and Nameless Beauty were selected by the station for distribution throughout the State.

Seventeen varieties of barley under test for the same period have given average yields ranging from 43.2 to 71.4 bu. per acre. The leading varieties were: Goldenthorpe, New Zealand, Mandscheuri, and Highland Scotch, yielding 71.4, 69.9, 67.6, and 60.6 bu. per acre, respectively. Eight varieties of hulless barleys yielded from 33.8 to 56.8 bu. per acre. The Black Hulless, New White Hulless, Guy Male, and Delnoote yielded over 54 bu. per acre. The straw in the New White and Smooth Hulless barleys is considered superior to that of the Black Hulless for feeding purposes. A number of varieties of barley obtained from this Department and grown under extremely favorable conditions proved very promising. The yield of one of these varieties, Number 5473, was at the rate of 101.9 bu. per acre. Of the brewing barleys Chevalier, Goldenthorpe, New Zealand, and Mandscheuri have given the most satifactory results in field culture.

Of 43 varieties of potatoes grown in the 3 years, 23 gave average yields of over 400 bu. per acre. The leading varieties, Montana Beauty, White Elephant, Charles Downing, and Rural New Yorker No. 2, yielded 478.9, 475.8, and 470.8 bu. per acre, respectively. The statement is made that early varieties may be grown at an altitude of 6,500 feet, but that medium sorts are not a success when grown above 4,750 ft.

In 1902 the yields of wheat ranged from 29 to 77 bu. per acre, but there was only one yield below 50 bu. In oats the yields ranged from 90 to 174 bu., and with barley from 29 to 96.8 bu. per acre. The Pringle Champion wheat, Early Everett oats, and Guy Male barley were the leading varieties.

The cooperative work of the station with the farmers of the State is described, and the results of the same reported. In 1902, 86 farmers including 53 cooperators grew grain from station seed. The yields of cereals, hay, and root crops grown under irrigation are reported.

The results of a 6-year rotation experiment completed this season are given for the entire period. The rotation consisted of wheat, clover, barley, root crops, oats, and peas. No fertilizer was applied to any of the crops. The general conclusion was that the fertility of the land had been maintained. The rotation is, however, not considered practical and the work is to be continued in another form.

Report on field crops, J. H. SHEPPERD and A. M. TEN EYCK (*North Dakota Sta. Rpt. 1902, pp. 66–122*).—A general description is given of the work of the agricultural department for 1902, and the results obtained in the different experiments are presented in tables and discussed.

A review of the plant breeding work of the station shows that the nursery during the season contained the following number of individual plants: Wheat 10,800, oats 3,600, barley 3,200, buckwheat 1,525, flax 4,300, millet 2,300, and grass and alfalfa 2,002. During the season seed of improved grains and potatoes was sent to 119 farmers.

Notes are given on the growth at the station of red clover from various States and countries and of common Turkestan and Grimm alfalfa.

Forty-eight varieties of macaroni, fife and blue stem wheats were tested. In yielding capacity the macaroni varieties stood first. The average yields of the 3 best producing varieties of each class were 32.6, 26.8 and 23 bu. per acre for the macaroni, fife and blue stem varieties, respectively. The results for 9 years show that the blue stem varieties gave an average yield of 24.7 bu. and the fife varieties of 24.3 bu. per acre. In 1901 and 1902 the average yields per acre for the leading variety in each class was as follows: Yellow Gharnovka macaroni wheat 31.9 bu.; Selected Minnesota No. 285 fife 27.6 bu., and Haynes Pedigree blue stem 26.1 bu. Sowing on April 30 gave better results than sowing on later dates, but there was only a slight difference in the yields for April 30 and May 9 and 15.

Forty varieties of oats were tested, and the best yields were obtained from the earliest and the latest sorts. Sixty Day stood at the head of the list with a yield of 72.2 bu. per acre, followed by Selected Tartarian with 63.9 bu. This same variety also gave the largest average yield for the last 2 years. The data for all varieties is given in tables.

The results with barley for 9 years indicate Manshury six-rowed to be one of the best varieties. This season 19 varieties were grown, Houston Golden Queen leading in productiveness with a yield of 59.4 bu. per acre. For the past 2 seasons Mandscheuri, Manshury, Minnesota No. 87, Barnard, Minnesota No. 32, and Silver King, in the order given, have produced the best average yields. McEwan hulless has been the best producer in its class.

North Dakota emmer, a variety grown in the State for a number of years, has given better results than imported varieties.

In the experiments with flax selected Russian led with a yield of 25.9 bu. per acre, the heaviest yield on record at the station. Selected Riga produced long straw with few branches and little seed and an extra quality of fiber. The results of seeding experiments seemed to favor seeding less than 3 pecks per acre. The largest yield was obtained this season from the earliest sowing, which was made May 24, but nearly as large yields were obtained from sowings made June 17 and 23. The results of growing flax and wheat as a mixture showed an average yield of 14.3 bu. for wheat alone and 14.5 bu. of wheat and 3.9 bu. of flax for the mixture. The results of all trials apparently favor sowing at the rate of 3 to 4 pecks of wheat with 1.5 to 2 pecks of flax per acre.

The test with millet comprised 21 varieties, including Russian broom-corn millets and varieties under selection by the station. The object of the selection is the production of good crops of forage, and North Dakota No. 2 is proving excellent in that direction. In addition to the work with millets this season a trial of corn, millet, peas, oats, barley, and emmer, sown alone and in combination, was made to determine the comparative value for fodder.

Of 27 varieties of potatoes under test Rural New Yorker No. 1, Banner, Hammond Wonderful, Maule Commercial, May Netted Gem, and Tayler Best showed little or no scab, and Early Ohio, All the Year Around, Earliest Six Weeks, Quick Crop, and Early Minnesota ripened earliest. Early Harvest, Quick Crop, May Netted Gem, and Carman No. 1, mentioned in the order of their production, gave the greatest yields in 1902.

The yields for 1901 and 1902 of different root crops, including carrots, ruta-bagas, mangels, and sugar beets are shown in tables. Owing to its texture the station soil does not produce very large roots.

Eight varieties of beans were grown. White Wonderfield gave the largest total yield, Brown or Swedish the largest yield of marketable beans, and Dewey Navy was the earliest.

The growth of 44 varieties of corn during the season is shown in a table. The earliest varieties were French Squaw No. 32, Yellow and White Fodder No. 122, Gehu No. 123, Northwestern Dent No. 124, North Dakota No. 148, and Early Ripe Fodder No. 152. All of these varieties usually mature fully at the station. Mercer, Triumph, Longfellow, and King Philip, which ordinarily mature sufficiently to produce good corn, did not produce seed this season. The yield of corn planted on different dates in drills 6 and 42 in. apart was, for each date of planting, in favor of the 6-in. drills. The time of planting ranged from May 30 to June 23. The largest yield of fodder was produced by the earliest planting. In another experiment 12-in. drills gave the best yield of fodder, followed by planting in hills in rows 22 in. apart. Former results with planting in drills have indicated that for the production of ears the drills should be 36 or 42 in. distant. Experiments on the thickness of planting in drill rows with 1 kernel every 6 in. in the drill has given the best yield of fodder in 1902 and also the largest average yield for 3 seasons. Five stalks in a hill gave the largest yield of fodder for this season and 6 stalks in a hill the largest average yield for 3 trials. Cultivating corn deep and early, and shallow the last time proved best in 1902. Shallow cultivation throughout the season gave the second largest yield, and this method has also given the best average results for 3 years.

A soil moisture study was conducted during the winter and variations in the percentage of soil moisture during the season are given. During the 3 winter months fall plowed wheat stubble gained 2.68 in. of water in the first 3 ft. of soil, but lost 1.6 in. in the second 3 ft. Fall plowed wheat stubble harrowed immediately after plowing lost water in every foot of soil, but contained considerable more water than the soil in the preceding test at the beginning of the observations. Wheat stubble not plowed gained water in every foot, the total gain in 6 ft. amounting to 6.12 in., and brome grass sod lost water except in the first foot, the total loss amounting to 1.53 in. from the 6 ft. of soil.

The work with field and forage crops at the Edgeley Substation during the year is reported in brief notes. Brome grass made a very good growth and gave a yield of 400 lbs. of seed per acre.

Report of the work at the McNeill Branch Station for 1902, E. B. Ferris (*Mississippi Sta. Bul. 79, pp. 35, figs. 13*).—This bulletin contains a description of the station buildings and grounds, gives an account of how the land was cleared and improved, and reports the results of various fertilizer and culture experiments carried on during the year.

Wardwell Kidney Wax and Improved Valentine beans were grown on new soil which received a complete fertilizer application. The general financial results were in favor of an application of 27 lbs. cotton-seed meal, 13.05 lbs. dried blood, 60 lbs. acid phosphate, and 25 lbs. kainit per acre. The Improved Valentine variety yielded an average of 20 bu. more per acre than the Wardwell Kidney Wax bean, but was about a week later in ripening.

After the beans were removed the plats were planted with sweet potatoes about the middle of July. The yields on the different plats ranged from 140 to 164 bu. per acre.

The use of cotton-seed meal and acid phosphate for sugar cane gave yields varying from 22,140 lbs. to 24,711 lbs. of cane per acre, as compared with yields of 7,205 lbs. and 9,324 lbs. with no fertilizer.

Drought seriously interfered with corn experiments, but the results of a variety test show that under the conditions Mosby Prolific and Tatum Choice yielded the most grain. Mosby Prolific also headed the list in the production of stalks.

Fertilizer tests with cotton included 30 plats. The largest yield of seed cotton, 1,360 lbs. per acre, was obtained from an application of 300 lbs. per acre of each cotton-seed meal and acid phosphate. Among 14 varieties King Improved gave the highest yield, 1,159 lbs. of seed cotton per acre. This variety was followed by Peterkin with 950 lbs.

Culture tests with chufas, sweet potatoes, Spanish peanuts, sorghum, cowpeas, fall potatoes, and several orchard and garden crops are briefly noted.

General fertilizer experiments, G. C. WATSON (*Pennsylvania Sta. Rpt. 1902, pp. 191–267, pls. 7, dgm. 1*).—The results obtained from experiments with commercial fertilizers and barnyard manure, extending through a period of 20 years, are reported at some length. The experiments were designed to test the comparative effects of single fertilizer elements, complete and incomplete applications, and different forms and different quantities of nitrogen; to compare commercial fertilizers with barnyard manure, and lime and plaster with commercial fertilizers and barnyard manure; and to note the influence of lime, ground limestone, and plaster. The commercial fertilizers supplying the essential elements of plant food were dried blood, nitrate of soda, sulphate of ammonia, dissolved boneblack, and muriate of potash. The quantity of phosphoric acid and potash applied per acre every 2 years was in general 48 and 100 lbs., respectively, while the nitrogen was given in most instances in quantities of 24, 48, and 72 lbs. Barnyard manure was applied at the rate of 12,000, 16,000, and 20,000 lbs. per acre. Corn, oats, wheat, and clover and timothy were grown in rotation, and the fertilizers, save lime, which was applied to corn only, were applied to corn and wheat.

Corn.—In the test with the plant food elements used singly, phosphoric acid, potash, and nitrogen ranked in the order mentioned in the production of grain, while in the yield of stover potash stood first and phosphoric acid second. Where the 3 essential elements were given in combinations of 2, they ranked as follows: Potash and phosphoric acid, phosphoric acid and nitrogen, and potash and nitrogen, in the production of grain; and potash and phosphoric acid, potash and nitrogen, and phosphoric acid and nitrogen in the production of stover. Different amounts of dried blood in the complete application increased the yield of grain as the quantity of nitrogen increased, while rations of nitrate of soda under the same conditions had the opposite effect. The intermediate quantity of nitrogen (48 lbs.) in the form of sulphate of ammonia in the complete application gave the best results. The largest yields of grain were obtained when the quantity of nitrogen in the complete fertilizer varied inversely as its availability. The use of 12,000 lbs. of barnyard manure per acre gave better yields of grain than the use of a larger application, while a better yield of stover was secured from 20,000 lbs. than from a smaller quantity. The total yields were greater with barnyard manure alone than when the same was applied with lime. Ground limestone was more effective in increasing the yield of grain than the same quantity of lime, and land plaster was more effective in this respect than either lime or ground limestone. The application of 4,000 lbs. of lime per acre reduced the total yield as compared with the use of no fertilizer.

Oats.—Phosphoric acid, potash, and nitrogen used singly ranked in the order given in the production of grain and straw. The total yields on plats receiving nitrogen

and phosphoric acid, and phosphoric acid and potash, were almost equally good, while the plats receiving nitrogen and potash gave a smaller total yield and a decidedly smaller yield of grain. Dried blood was more effective than either nitrate of soda or sulphate of ammonia. The application of 48 lbs. of nitrogen per acre resulted in more grain than either a greater or smaller quantity. The yield of straw increased with the quantity of nitrogen applied. Of the different quantities of barnyard manure applied 16,000 lbs. per acre produced the best total yields. Lime used alone diminished the yield of grain but increased the yield of straw. Where 4,000 lbs. of lime was used in addition to 12,000 lbs. of barnyard manure the total yield and especially the yield of straw was increased as compared with the use of the manure alone. Ground limestone gave a decided increase in the yield of straw and a slight increase in the yield of grain. Land plaster was less effective than ground limestone.

Wheat.—The 3 essential elements applied singly ranked in effectiveness in the same order as in the test with oats. In total yield the application of the elements in combinations of 2 ranked as follows: Phosphoric acid and nitrogen, phosphoric acid and potash, and nitrogen and potash. Increasing the quantity of nitrogen increased the total yield. The largest and smallest applications of barnyard manure gave the largest and smallest total yields, respectively, on the manured plats. Lime and manure slightly increased the yield of grain over manure alone. Lime applied alone gave a small increase in total yield as compared with the unfertilized plats. Ground limestone was more effective than either lime or plaster. Of the 3 forms of nitrogen dried blood gave the largest yield of grain and sulphate of ammonia the largest yield of straw.

Timothy and clover.—Phosphoric acid, potash, and nitrogen applied singly ranked in effectiveness in the order given, and where the elements were applied in combinations of 2 the order was as follows: Phosphoric acid and potash, nitrogen and phosphoric acid, and nitrogen and potash. Where the nitrogen of the complete fertilizer was applied in the form of dried blood the largest yield was obtained from an application of 45 lbs. of this element, but where it was applied in the form of nitrate of soda or sulphate of ammonia the use of 24 lbs. gave the highest yield. Barnyard manure gave the best yield on the plat, receiving 16,000 lbs. per acre. An application of 4,000 lbs. of lime to supplement 12,000 lbs. of barnyard manure increased the yield. Lime alone compared with the plats receiving no fertilizers reduced the yield, while ground limestone and plaster each gave a slight increase.

Miscellaneous—Corn removed the largest quantity of nitrogen from the soil, followed by hay, wheat, and oats, in the order given. With respect to the quantity of phosphoric acid and potash removed, the crops stood in the following order: Corn, hay, oats, and wheat. In every instance more nitrogen was removed by the crops than was furnished in the fertilizer, and in every case but one more phosphoric acid was furnished than was removed. Potash, except where applied in the barnyard manure, was also given in excess of the quantity removed in the crops.

In these experiments a mean temperature for the growing season rather below than above the normal was found most favorable to the growth of corn and wheat, and one rather above than below the normal was best for oats and corn. Precipitation rather above than below the normal for the growing season gave the highest yields of corn, wheat, and grass, and when below rather than above the normal the largest yields of oats.

A five-year rotation of crops including clover, H. J. Wheeler and G. E. Adams (*Rhode Island Sta. Rpt. 1902, pp. 305–331*).—The results of an experiment conducted on 5 plats of exhausted soil for the purpose of demonstrating the value of rotation in the renovation of soils are reported at some length. The rotation was as follows: Indian corn on grass sod, potatoes, winter rye, clover, and grass. The 5 different plats introduced into the rotation successively showed the whole course of the rotation in any given year. The work has been in progress for over 5 years and

the rotation is consequently in its second course. Only commercial fertilizers are used in connection with this experiment. The history of each plat is given in detail. The smallest yield of shelled corn, 20.7 bu. per acre, was obtained in 1893, and the largest, 81.43 bu., in 1896. The third year 1.14 tons of corn stover per acre were produced and the fifth year 3.08 tons, being the smallest and largest yields respectively for the first course of the rotation. The minimum and maximum potato crop during the first 5 years was 125.2 and 253.3 bu. for the third and fourth years of the rotation, respectively. A general increase in the yield of potatoes as the rotation progressed was apparent. With rye the yields of grain tended to decrease and of straw to increase. The earlier grass crops were very small, but the use of lime on the land produced a marked improvement. In 1898 the yield of a plat having been limed 2 years before amounted to 4.56 tons per acre. In this rotation 120 lbs. of nitrate of soda per acre were employed as a top-dressing for the grass land, but the authors believe that for a yield of 4 tons per acre about 350 lbs. should have been used. In the second course of the rotation in 1902, after the land had been limed and the top-dressing of the nitrate of soda increased, the second year's hay crop amounted to 3.8 tons and the first year's clover and grass crop to 6.27 tons per acre. The results of different rotation experiments carried on by the station are considered to indicate that in renovating worn-out soils of this character it is probably better to begin the rotation with rye than with Indian corn or potatoes.

Broom corn, C. P. Hartley (*U. S. Dept. Agr., Farmers' Bul. 174, pp. 32, figs. 10*).—This bulletin gives a description of the broom corn plant with directions for the culture of the crop and its preparation for market. Broom-corn smut (*Sphacelotheca sorghi*) is described and a method for its control suggested. Notes are also given on the insect enemies of the plant and statistics of the crop are presented.

The book of corn, H. Myrick (*New York and Chicago: Orange Judd Co., 1903, pp. XVI+368, figs. 99*).—A popular treatise, noting the history of the corn plant, describing the different species, together with different strains and varieties, outlining the breeding and selection of seed corn, presenting rules for judging corn and discussing in general a wide range of subjects pertaining to the culture and uses of the crop.

Corn improvement for Missouri, G. M. Tucker (*Missouri Sta. Bul. 59, pp. 73-91, figs. 5*).—The possibilities of corn improvement are considered and the methods for the work outlined. The uniformity in size of kernel, the percentage of germination, and the number of barren stalks are given as factors influencing the stand. Directions for perfecting the stand are presented. The type of ear with reference to its length and circumstance, butts and tips, and space between the rows. and the type of kernel with reference to the uniformity on the ear and its shape are described. The suggestions for selection are summarized as follows:

"Begin with the whole field or breeding plat, from which select the best plants, according to performance. . . . From these best plants select by the eye and by measurements the best ears. . . . From these best ears select the best kernels. . . . From these best kernels select the few very best for the breeding plat and plant the whole field with the remainder."

Cotton ginning, D. C. Roper (*Twelfth Census United States, Census Bul. 2, pp. 46, maps 13*).—The quantity of cotton ginned from the crops of 1899–1902 is given by States and Territories and by counties together with other data pertaining to this branch of the cotton industry.

Grasses and forage plants in Idaho, L. F. Henderson (*Idaho Sta. Bul. 38, pp. 193-256, figs. 45*).—The grass plats at the station have been left undisturbed to determine how long the different species would sustain themselves. No cultivation was given but the weeds were cut out. A list of 80 species of grasses and leguminous plants which entered into this work is given. The entire list is considered in groups

showing the species well adapted to the Palouse country and those growing well in wet or moist meadows, on rich uplands, and on dry and sandy soil. The species of little or no value are also enumerated. The greater portion of the publication is devoted to the descriptions of the individual species considered. A list of forage plants growing spontaneously in Idaho, and which are known to furnish food to cattle and horses, concludes the bulletin.

Summer forage crops, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1902, pp. 63–68*).—The results of several trials with a mixture of winter wheat and vetch are reported, together with the composition of the green and dried fodder. The yields obtained in 1900 and 1902 were at the rate of 10 and 9.5 tons per acre respectively. The 1901 yield was estimated at 6 to 7 tons per acre. This season the land was seeded with Longfellow corn immediately after the removal of the mixed crop at the end of May. A yield of 17.68 tons of fairly well-eared green fodder per acre was obtained. The total yield of dry matter per acre for the season amounted to 8,622 lbs. The results of digestion trials reported in tables, lead to the conclusion that the mixture of winter wheat and vetch, fed green, is as digestible as either fodder corn or oat and pea fodder. The mixture when used as dry fodder, under normal conditions, is considered as digestible as when fed green.

Corn and soy beans were grown together and were successfully harvested with a corn harvester. Notes are given on the culture of soy beans and cowpeas and on the relative merits of several varieties of these crops.

Range improvement, J. W. BLANKINSHIP (*Montana Sta. Rpt. 1902, pp. 71–75*).—The necessity of range improvement in the State is discussed and the value of 3 species of grasses, *Agropyron spicatum*, *Bouteloua oligostachya*, and *Bulbilis dactyloides*, in connection with this work is pointed out.

The soy bean, G. E. ADAMS (*Rhode Island Sta. Bul. 92, pp. 119–127, figs. 3*).—This bulletin contains a popular account of the soy bean, its uses and culture. In the discussion the results of experiments obtained at the station and elsewhere are restated. For 10 years the Medium Early Green soy bean has produced good crops at the station and has never failed to ripen seed.

Report of the sugar-beet experiments in Ontario, 1902, R. HARCOURT (*Toronto: Ontario Dept. Agr., 1902, pp. 32, figs. 10, map 1*).—Sugar-beet experiments conducted on an extensive scale are described and the factories in operation in Ontario are enumerated. The value of sugar-beet pulp as a stock food is discussed and the composition of limestone rock from different points in the province is shown in a table. The results of culture experiments and fertilizer and distance tests here reported have been noted from another source (E. S. R., 15, p. 36).

The average weight, percentage of sugar, and coefficient of purity of beets harvested in September and October by the different experimenters are shown in tables. In general the later harvested samples were the best in quality.

Progress of the absorption of phosphoric acid by sugar beets, A. GRÉGOIRE (*Bul. Inst. Chim. et Bact. Gembloux, 1903, No. 73, pp. 22–31; L'Ing. Agr. Gembloux, 13 (1903), No. 10, pp. 425–437*).—In these studies it was found that the phosphoric acid content reached 0.78 per cent of the dry substance. The maximum absorption occurred between July 27 and August 24. The phosphoric acid was taken up most rapidly at the beginning of vegetation.

Quality of sweated tobacco produced by different fertilizer treatments, W. FREAR (*Pennsylvania Sta. Rpt. 1902, pp. 34–48*).—These experiments have been previously described (E. S. R., 11, p. 924). A detailed report is here given on the quality of the same crops of Havana leaf for the several years the work was carried on.

An application of cotton-seed meal, sulphate of potash, and dissolved boneblack gave a better yield of uniform and lighter-colored leaf than horse manure. The substitution of linseed meal for cotton-seed meal in this application apparently improved the flavor of the tobacco. The use of horn meal instead of cotton-seed meal and the

partial replacement of cotton-seed meal by nitrate of soda reduced both yield and quality. Sulphate of ammonia as a partial substitute for cotton-seed meal slightly improved the yield and the wrapper qualities of the leaf, but the flavor and the aroma suffered a marked deterioration. Where double carbonate of potash and magnesia was substituted for the sulphate of potash the leaf was more uniform and of better texture and a slightly improved burning quality, without impairing the flavor or aroma. The use of basic slag and the omission of a phosphate from the application resulted in a low yield of poor quality.

"Most commercial tobacco manures contain much of their nitrogen in the form of nitrate of soda or sulphate of ammonia. . . . Such manures are capable of improvement for . . . the Lancaster county limestone clays by reducing the . . . nitrate of soda and sulphate of ammonia to a very small fraction and increasing the quantity of concentrated nitrogenous vegetable material used as a source of nitrogen and humus."

Physical measurements of tobacco leaf from plats differently fertilized, W. Frear and J. A. Fries (*Pennsylvania Sta. Rpt. 1902, pp. 49–74*).—The results of a comparison of the wrapper leaves from the Havana tobacco grown in the course of the fertilizer experiments mentioned in the foregoing abstract are reported in tables and briefly discussed. It was observed that the physical characters of the leaf were much more influenced by the season than by the fertilizer application which in these experiments, in all cases except where horse manure was applied, furnished the same quantities of nitrogen, potash, and phosphoric acid. The variations in total yield and size and weight of single leaf were greatest in the best growing season, while the percentage of rib and the thickness and density of leaf were less subject to seasonal influences.

The use of horse manure resulted in a large and heavy leaf with thick rib and vein, but with low thickness of web and less density than the leaf from any other application. The tobacco grown with cotton-seed meal, sulphate of potash, and dissolved boneblack was smaller in size and weight, but thicker and of greater density of web. Where double carbonate of potash and magnesia were substituted for the sulphate of potash a good yield was obtained and the tobacco had a thin web, was generally of a larger size, and had a thinner vein than the tobacco on adjacent plats. The use of nitrate of soda in place of part of the cotton-seed meal reduced the size of the leaf with a considerable increase in density. Where sulphate of ammonia was substituted for the nitrate of soda the size and weight of the leaf were increased, and the thickness of the vein, but the web was thinner and the density lower.

Distribution of seed wheat, A. K. Risser (*Pennsylvania Sta. Rpt. 1902, pp. 268–270*).—A detailed report by counties is given of the results obtained in a cooperative test of Reliable wheat, a variety distributed by the station. Thirty-five replies were received from 24 counties. The yields reported ranged from 17 to 35 bu. per acre, with an average of 27 bu. The variety proved to be a good yielder, as compared with other sorts, but several experimenters objected to its weak straw and tendency to lodge.

Selection of wheat and corn, E. F. Ladd (*North Dakota Sta. Rpt. 1902, pp. 27–30*).—The selection of wheat was carried on at the station for the purpose of increasing the protein and gluten content. The results obtained during the last 3 years are given in a table without discussion. The corn selected for high nitrogen content in 1901 in nearly every case produced corn of a high nitrogen content in 1902. The physical method of selecting corn of a high nitrogen content was found quite reliable.

Analyses of grasses, flax, and wheat, F. W. Traphagen (*Montana Sta. Rpt. 1902, pp. 58–61, 66, 67*).—The results of analyses based on the air-dried and water-free substance of a list of grasses are tabulated. It is shown "that grasses of the same species, gathered at different periods at different stages of growth, may differ

in composition to a greater degree than grasses of totally different genera, collecte under similar conditions." Analyses of 5 species obtained from alkali districts ar also given. The composition of a sample of Montana-grown flaxseed is given, an its oil content compared with that of flaxseed in other countries. The change i composition of wheat grown from soft-wheat seed without irrigation is pointed ou and an analysis of Wild Goose wheat is reported.

HORTICULTURE.

Culture work at the substations, 1899–1901, C. H. Shinn (*California St Bul. 147, pp. 7–19, 28–35, 41–55, 62–82, figs. 9*).—An account is given of the climati conditions and of the work done at the Foothill, Southern Coast Range, San Joaqui Valley, and Southern California substations with orchard and small fruits, grape nuts, vegetables, and miscellaneous crops. (For the work with field crops see p. 134.

The Foothill Substation (*at Jackson*) (pp. 7–19).—Apples have not done well at thi substation. Pears have done fairly well on mixed granite and slate soil, and Japanes persimmons have been one of the most uniformly successful fruit crops at the sub station. Almonds, apricots, and nectarines have done well in the absence of lat spring frosts. Peaches are well adapted to much of the land about the substation and the most reliable general crop varieties appear to be, in the order of ripening Newhall, Newington Cling, Columbia, Salway, Beer Smock, Henrietta, and Wager The value of plums and prunes is as yet problematical. A number of varieties hav borne fruits, but yields have been low. Of the semitropical fruits grown the fig i the most promising. Olives also do exceptionally well. A good quality of Englis walnuts is grown, but the trees do not always bear heavily and the nuts are not large Nearly all small fruits do well at the substation, but currants need protection fro sunburn. Less water than is usually applied with more thorough cultivation i recommended for these fruits.

Southern Coast Range Substation (*at Paso Robles*) (pp. 28–35, 41–43).—Much of th work here reported with deciduous fruits has been previously noted (E. S. R., 14, p 252). A promising young apple orchard planted in 1897 is now coming into bearing One of the best varieties of apples appears to be Gold Ridge Winter. Notes ar included on the growth of a number of varieties of melons and squashes.

San Joaquin Valley Substation (*at Tulare*) (pp. 44–55).—Frost has killed or seriousl injured many of the semitropical fruits at this substation. Many olives have bee seriously injured. Among those which have proved most hardy are Macrocarpa Manzanillo, Mission, Oblonga, Pendulina, Redding Picholine, and Salonica. Mos species of Eucalyptus have done well at the substation. In the deciduous orchar alkali has been controlled by small applications of gypsum. A large number o varieties of apples have borne considerable quantities of fruit, but none kept beyon November 1. Pears have proved well adapted to alkali soils when not too strong and the success of a large number of varieties is reported. Almonds, apricots, an nectarines all gave poor results. Peaches do well at the substation, with the excep tion of Spanish and southern types. An amended list of the best varieties include among the clings Seller, Grover Cleveland, Chinese, and Oldmixon, and among th freestones Alexander, Oldmixon Free, Elberta, Lovell, Morris White, Muir, Ne Pickett Late, Salway, and Wheatland. Plums and prunes propagated on plum fail on the alkali soils of the substation orchard, but give better results on peac stock. Large crops of American and European sorts are sometimes secured varieties of figs also do well at the substation. One of the best varieties of grape from the standpoint of bearing is the Tinta Val de Peñas.

Southern California Substation (*at Pomona*) (pp. 62–82).—The account of the wor at this substation is prefaced by a brief history of it and an account of the clim and the amounts of irrigation water used for a large number of different crop

Deep-furrow irrigation is advocated for orchards, and a diagram is given showing low this should be carried out and the extent of percolation of irrigation water in lay, loam, and sandy soils from deep and shallow furrows. On sandy-loam soil it is tated that the irrigation furrows should not be more than 4 ft. apart, while on ighter soils 3 ft. apart is better. Apples have proved unsuited to the district. Six varieties appear to be absolutely blight proof. These are Early Ripe, Jonathan, Skinner Seedling, Smith Cider, Rhode Island, and White Astrachan. Pears do poorly. Of a large number of varieties of plums planted in 1891, only 14 varieties have proved worthy of retention. The best of these is Wickson. Almonds are of medium quality, but have borne only 2 good crops in 7 years. Cherries are a failure. Figs grow well at the substation but are practically a failure on account of "fig-sour." The most promising varieties of peaches are southern types. Some notes are given on the relative effects of frosts on a large number of olives. Oranges and lemons are reported as doing well. Notes are given on the relative yields of a number of varieties. Thick-skinned varieties have been least injured by frosts. The results secured with a large number of grapes grafted on different resistant stocks are tabulated.

Fruits, vegetables, flowers, and ornamental plants at the experimental farms in Canada, W. T. Macoun, W. S. Blair, S. A. Bedford, A. Mackay, and T. A. Sharpe (*Canada Expt. Farms Rpts. 1902, pp. 91–110, 120–122, 124–128, 264–277, 303–306, 308–317, 339–349, 373–388, pls. 2*).—Reports in continuation of those previously noted (E. S. R., 14, p. 144) are given on the character, culture, and behavior under different climatic and soil conditions of a large number of fruits, vegetables, flowers, and ornamental plants grown at the experiment stations in Ottawa, Nova Scotia, Manitoba, Northwest Territories, and British Columbia. At the Central Station at Ottawa, W. T. Macoun reports an average profit for 4 years of $121.38 for Wealthy apples set 10 ft. apart in the orchard each way. Twelve new seedling apples of promise are described and 10 seedling plums given names. A list of the best spring flowering perennials is also given. S. A. Bedford describes several species of crabs and crab-apple seedlings that are most promising in Manitoba.

Horticultural department, R. W. Fisher (*Montana Sta. Rpt. 1902, pp. 88–95*).—An outline of the work of the horticultural department during the year with forest and ornamental trees, orchard trees, small fruits, and garden crops. A report on the hardiness of a number of deciduous and evergreen trees which have been grown at the station shows that the elm, oak, white birch, mountain ash, European larch, and the white and green ash are among the hardiest deciduous trees, while among the hardy evergreens are Colorado blue spruce, white fir, red cedar, mountain pine, Douglas spruce, and arbor vitæ.

Of the 64 varieties of apples set in the station orchard in 1895, only 26 are now alive, and of this number only about 8 are worth growing. These are Wealthy, Yellow Transparent, Duchess of Oldenberg, Okabena, Hibernal, Tetofsky, Longfield, and Gideon. Eight of the 10 varieties of crab apples set in 1895 are now alive, and of these the best are Whitney No. 20, Transcendent, Greenwood, Hyslop, and Orange. Out of 30 varieties of plums planted only 2, Moldavka and Yellow Veronesch, are recommended. Three out of 14 varieties of cherries set are now alive. These are Oklanka, Griotte du Nord, and Bessarabian. Flemish Beauty is the only pear which survived out of 16 varieties planted.

Raspberries have been successfully grown at the station when laid down and covered with dirt or straw in the fall for winter protection. Currants have proved one of the easiest crops to grow, being perfectly hardy. Variety tests are noted for string beans, beets, cabbage, and celery.

Report of the assistant in horticulture, A. T. Jordan (*New Jersey Stas. Rpt. 1902, pp. 245–290*).—The work of the station to determine the relative effects of different fertilizers, with and without irrigation, on the early and total yield of varieties

of asparagus, blackberries, raspberries, currants, gooseberries, strawberries, plums, cherries, pears, peaches, and apples has been continued (E. S. R., 14, p. 566), and in addition studies made to determine the value of growing peas, beans, and sweet corn in succession during the same year, and of double cropping with peas and tomatoes. The usual summary of weather conditions is included.

The average results of 5 years' work with asparagus show the Palmetto to be the heaviest yielding of 8 varieties under observation. It yielded 30 per cent heavier than Donald Elmira, which ranked second, and 42 per cent heavier than Conover Colossal, which ranked third. The total yield from the unirrigated plats on the whole has averaged about 3 per cent higher than on the irrigated plats. The top growth, however, averaged 4 per cent greater on the irrigated plats. The best yields have been on plats receiving complete fertilizers. An extra supply of nitrate of soda was not particularly advantageous in these experiments.

With blackberries, Eldorado has proved the most productive sort, for a period of 4 years, followed by Erie and Agawam. Arranging the results secured with irrigation for 4 years, the largest early yield has been obtained on the unirrigated plats, while the total yield has been about 3 per cent larger with irrigation. The use of nitrate of soda has resulted in increased yields on unirrigated plats, but where irrigation was practiced the yields were the lowest obtained. Irrigation has increased the early yield of raspberries 15.3 per cent and the total yield about 5.4 per cent. The use of an extra amount of nitrate of soda has not benefited this crop.

The most prolific currant tested was Red Dutch. The berries, however, are not so large nor do they find so ready a sale as Fay Prolific. A separate account has been kept of a number of individual currant bushes. These have been found to vary greatly in yield, and it is therefore suggested that in propagating currants cuttings be taken only from the most productive plants. The average increase in currants for 5 years, due to irrigation, has been 10.76 per cent, and in gooseberries 3.3 per cent. Both of these fruits have also yielded heavier when manured with 20 tons of barnyard manure per acre than when fertilized with 500 lbs. of complete fertilizer alone or combined with 150 lbs. nitrate of soda additional.

Six varieties of strawberries have been grown for 5 years. Bubach and Glen Mary have proved the heaviest yielding sorts. The use of 500 lbs. of complete fertilizer applied in the spring has resulted in larger yields than the same amount applied with 150 lbs. nitrate of soda additional. The average total yields for 5 years have been greatest on unirrigated plats.

The work of the station with orchard fruits is along the lines of variety testing, irrigation, and fertilizer experiments. Much of the data obtained thus far is reported merely as a matter of record. Plums, cherries, and pears have given on the average slightly increased yields on irrigated plats. Irrigation seemed to delay ripening in the case of the Lombard plum 6 days. On irrigated plats nitrate of soda appears to have been beneficial. Burbank has proved the most productive of several varieties of plums, and Champion the most productive of 6 varieties of peaches.

During the past 7 years the station has grown peas, beans, and sweet corn in succession, followed by crimson clover seeded in the sweet corn as early as possible in August. This rotation has been carried out on a number of plats each differently fertilized. Good crops of peas, beans, and sweet corn have been secured each year, but the crimson clover has not proved satisfactory, making but little growth in the fall and being plowed under too early in spring to make any growth. It is believed that rye would have proved a more satisfactory crop.

The heaviest yields of the different vegetables have been quite uniformly obtained from the plat fertilized with barnyard manure at the rate of 15 tons per acre. Commercial fertilizers in different proportions have resulted in poorer yields. The details of this work are fully tabulated. Doubling the number of rows and the quantity of fertilizer used has not resulted in a proportionate increase in yield. Peas and

tomatoes have been very successfully grown upon the same ground. Liming the soil has not resulted in increased average yields of these crops.

Report of the horticultural division, F. W. CARD and L. P. SPRAGUE (*Rhode Island Sta. Rpt. 1902, pp. 231–262, figs. 9*).—This report includes accounts of experimental work done with flowers, beans, sweet corn, sand cherry, and strawberries. In order to determine whether the red color of flowers may be intensified by feeding sugar to plants, as is asserted in a standard work on plant physiology, experiments were made in growing plants (1) with the addition of sugar to the soil, (2) with the addition of muriate of potash, and (3) with the addition of nitrate of soda. Practically speaking, none of these substances had any influence whatever on the color of the flowers. The work reported with beans is along the line of breeding experiments to develop varieties more resistant to frost and is in continuation of that previously noted (E. S. R., 13, p. 944). A number of detailed records of plants and their progeny subjected to cold are given, but so far no strain of beans has been developed hardier than the varieties commonly grown. The work is being continued.

In a test of the relative merits of board and slate for greenhouse benches as regards heat conduction, the data secured for a period of eighteen days are as follows: Average mean temperature of house, 60° F.; soil temperature of bench over slate, 61°; temperature underneath slate, 62°; temperature of soil over boards, 58°, and temperature underneath boards, 57°. Lettuce was grown in both benches. The average weight of the first crop was 4.13 oz. per plant from the slate bench and 3.85 oz. from the board bench. For the second crop these results were reversed, the average weight per plant being 4.82 oz. for the slate bench and 4.92 oz. for the board bench. It is believed, therefore, that under favorable conditions slate does not promise any great advantage over boards in affording bottom heat. A greater difference might be shown perhaps if all the heat were confined underneath the benches.

An experiment was made with corn to determine whether continued selection of the lowest ear on the stalk for seed would have any greater tendency to increase the number of ears per stalk than selecting the highest ear each time. The experiment was begun in 1899. The relative ear production in 1902 was as follows:

The effect of selecting the highest and lowest ears of corn for seed.

Seed selection.	Proportion of plants with—					
	No ears.	One ear.	Two ears.	Three ears.	Four ears.	Five ears.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
From lowest ear	21.32	48.17	27.72	2.72		
From upper ear	14.38	47.00	32.09	6.28	0.13	0.06

These figures seem to indicate that there is no greater tendency toward increased ear production by selecting the lowest ear for seed than selecting the highest ear. It is believed that the quickest way to increase ear production is to select the best developed seed from the plants producing the largest number of ears, regardless of the point on the stalk from which that seed comes.

The susceptibility of the sand cherry to fruit rot is pointed out as one of the reasons why this fruit is not likely to become useful in the moist climate of the East.

Experiments made to determine (1) the effect of muriate and sulphate of potash upon the firmness, color, and keeping qualities of strawberries, (2) the relative value of different forms of nitrogen for this fruit, and (3) the question whether phosphoric acid in the form of ground bone and floats can be applied to the field before planting strawberries in sufficient quantities and as effectively as annual applications of more readily available forms, are reported in considerable detail. The results of the 2 years' work, which are recorded, are conflicting. No material difference was noted

in the color or firmness of strawberries with the 2 forms of potash. The yield, however, was greater on the sulphate of potash plats.

"In the nitrogen tests sulphate of ammonia has proved best in all cases, with nitrate of soda second in 1901, and dried blood second in 1902. The yield from the plat with no nitrogen drops decidedly the first year, but is better than from the nitrate of soda plat the second year. . . .

"In regard to the third question, the indications so far as they go seem to show that it may be possible to add ground bone, at the time of planting, in sufficient quantities to furnish a supply of phosphoric acid during the fruiting period of the plantation, but that attempting to do the same thing with floats is not likely to prove so satisfactory."

A large number of crosses have been made between different well-known varieties of strawberries, including crosses between Wm. Belt and the wild strawberry. Descriptions of the seedlings and the fruit obtained are given, together with illustrations of the fruit.

Manuring of market-garden crops, B. DYER and F. W. E. SHRIVELL (*Jour. Roy. Hort. Soc.* [*London*], *27* (*1903*), *No. 4, pp. 995–1059, pls. 20.*)—The results of 7 years' work by the authors along the above lines have previously been noted (E. S. R., 14, p. 961). The present account gives the results secured in 1902 and summarizes the whole work for the preceding 8 years. The summaries correspond so closely to those of preceding years that they need not be again repeated. In general the work shows that a small amount of barnyard manure supplemented by commercial fertilizers is likely to be more economical and result in better yields than an excessive use of barnyard manure without commercial fertilizers, or from the use of commercial fertilizers alone without manure.

New experiences with beans, C. L. ALLEN (*Amer. Agr.*, *71* (*1903*), *pp. 476, 477*).—Seven varieties of garden beans were grown in 3 different localities to study methods of culture and find out the increase likely to be obtained from a given amount of seed. Light sandy soil mixed with coarser sand thrown out from a cellar and made fairly rich with stable manure was used in one instance. It was further enriched by 2 applications of 100 lbs. each of nitrate of soda. The soil of this plat was made as fine as possible with plow, harrow, and spade. The second plat was on light turfy loam in fairly good condition for ordinary farm crops. It was enriched in about the same manner as noted for the plat above. This plat was worked with plow and harrow only. The third plat was on low ground about 4 ft. from water. It was enriched with well-rotted stable manure and commercial fertilizers, costing at the rate of about $60 per acre. The soil of this plat was thoroughly pulverized with plow, harrow, spade, and rake. The beans in every case were planted singly 2 ft. apart each way. Shallow cultivation was given after rains, but great care was taken not to go deep enough to injure the roots. The average yield obtained was 168-fold on the first plat, 121-fold on the second plat, and 230-fold on the third plat.

The experiments are interpreted by the author to indicate that for the best results in bean culture the soil should have greater tilth before planting than is usually given, but the cultivator should never be used after the seed is sown except in rare cases, and that 3 qt. of seed per acre is ample. On heavy soils the plants should stand 1½ ft. apart each way.

Experiments in crossing plants, B. D. HALSTED and J. A. KELSEY (*New Jersey Stas. Rpt. 1902, pp. 377–395, pls. 6*).—The report along this line is in continuation of that noted last year (E. S. R., 14, p. 568), with sweet corn, eggplants, tomatoes, salsify, Lima beans, cucumbers, and phloxes. The work for the most part has been with second generation hybrids, and the variations obtained have been exceedingly numerous. The attempt is now being made by further selection to fix the most desirable features of the strains selected. Further crosses in cucumbers were made between the Telegraph and Znaim varieties, and the hybrids obtained are illustrated.

A number of crosses between 24 commercial varieties of *Phlox drummondii* have been made and the different forms illustrated. A paper summing up the results thus far secured in the station breeding experiments (E. S. R., 13, p. 516) is included in the report.

Orchard studies. V. Report on crab apples, W. B. ALWOOD and H. L. PRICE (*Virginia Sta. Bul. 132, pp. 14, figs. 4*).—This bulletin describes 13 varieties of crab apples and gives critical notes on their culture and quality, based on 14 years' work with the fruits at the station. Crab apples will grow on poorer soil than apples, and are of considerable value in making preserves, jelly, and marmalades. They are also believed to deserve a place on the farm as ornamentals, since they bloom profusely and the fruits are very attractive.

Orchard studies. VI. Second report on the cherry orchard, W. B. ALWOOD and H. L. PRICE (*Virginia Sta. Bul. 133, pp. 19–28, figs. 4*).—Notes on the behavior at the station of 20 varieties of cherries. The following varieties are recommended: Coe, Early Purple, Mezel, Rockport, Schmidt, Windsor, Hortense, Olivet, Ostheim, and Montmorency.

The changing of the sex in plants (*Trop. Agr., 22 (1903), No. 11, pp. 789, 790*).—The possibility of changing the sex of the date palm and of the papaw is discussed. About 80 per cent of seedlings of date palms are male. The method of the Arabs in some of the oases in the southern part of Algeria in changing these male plants into bearing trees is to tear off all the leaves from the foot stalks, at 2 or 3 years of age, so that the medial nerve is split in two from the center to the leaf sheaf. It is believed that this tearing process brings about a concentration of the sap movement in the same way as is the case in annular incisions, resulting in an accumulation of sap, "which is more necessary for the vital functions of the female plant than for those of the male." The writer states that it has been his experience that cutting off the terminal buds of papaw trees (*Carica papaya*) as soon as the character of the flower is apparent results in altering that character, inducing the tree to yield good fruit in place of the poor specimens borne by the so-called male trees.

Small fruits in 1901, J. P. PILLSBURY (*Pennsylvania Sta. Rpt. 1902, pp. 415–443*).—The detailed records of variety tests with 62 kinds of strawberries, 31 of raspberries, 25 of blackberries, 8 of currants, and 11 of gooseberries are given, together with brief descriptions of the different varieties in some instances. During the season of 1901 the largest strawberries were produced in matted rows in case of 35 varieties and in hills in case of 22 varieties. The heaviest yields for a period of 5 years have been obtained from the matted rows, and of the varieties tested Crawford, Warfield, Henderson, and See No. 2 stand at the head. The heaviest yielding varieties grown in hills are Warfield, Henderson, Crawford, and See No. 5, in the order named. On an average the increase in yield from matted rows has been about 50 per cent greater than from the hills. The average yield of the Loganberry for 5 years has been 2,976 gm. per 12 plants. The 4 varieties of blackberries averaging highest in production are Eldorado, Snyder, Lovett Best, and Lawton.

Report on cooperative experiments with small fruits, H. L. HUTT (*Ontario Agr. and Expt. Union Rpt. 1902, pp. 25–31*).—Each year the Experimental Union sends out a large number of plants to farmers in different parts of Ontario to be tested. This report contains an account of some of the results obtained up to the present time. The heaviest yielding strawberry in 1902 was Clyde; Van Deman was the earliest and Saunders the latest. Among raspberries, Shaffer has proved the heaviest yielder, while of the black sorts, Hilborn has been the most productive. Blackberries are reported much less hardy than raspberries. Snyder has proved one of the hardiest and, on the whole, given the best results. Victoria has given the best yields of currants tested, and Pearl and Downing lead in productiveness among the gooseberries.

Cranberry culture, L. C. CORBETT (*U. S. Dept. Agr., Farmers' Bul. 176, pp. 20, figs. 12*).—A popular bulletin on the details of cranberry culture in the United States.

Resistant vines and their hybrids, E. H. TWIGHT (*California Sta. Bul. 148, pp. 13, figs. 3*).—General information is given regarding resistant vines and their hybrids. The various species and hybrids are described and their value as stocks in California pointed out.

Effects of grafting; specific reciprocal influence of scion and stock in grapes, L. RAVAZ (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), Nos. 16, pp. 495–504, fig. 1; 17, pp. 514–520, figs. 2*).—This paper, which was read at the International Congress of Agriculture at Rome, in 1903, is also published as a separate. Experiments with a large number of species and varieties of grapes indicate that cuttings made from Vinifera grapes grafted on American stocks are no more resistant to phylloxera than cuttings grown on Vinifera stocks, and that the quality of the Vinifera fruit is not injured by grafting on American stocks for a period of years; neither is the quality of the fruit of American vines improved by grafting on improved varieties of Vinifera grapes. Notes are given on the modifications produced by grafting in the region of the callus, and on the influence of grafting on the nutrition of the vine.

"Headlight," a new early grape of the Delaware group, S. A. BEACH (*Amer. Gard., 24 (1903), No. 442, p. 365*).—The opinion of the author is given on a very early red grape originated by T. V. Munson in 1895. It has been grown at the Geneva Station for 2 years and the author believes it to be of sufficient promise to merit investigation as a very early grape.

Home manufacture and use of unfermented grape juice, G. C. HUSMANN (*U. S. Dept. Agr., Farmers' Bul. 175, pp. 15, figs. 8*).—Popular directions are given for the manufacture of unfermented grape juice in small and large quantities. A few recipes are given for a number of culinary uses of grape juice.

The pests and blights of the tea plant, G. WATT and H. H. MANN (*Calcutta: Supt. Govt. Printing, 1903, pp. 429, pls. 24, figs. 44*).—More than one-third of this book is devoted to tea culture, including such matter as races of the tea plant; seed gardens, and improvement of seed; hoeing, weeding, and tillage generally; drainage of tea gardens; principles of pruning; tea picking, and manuring; thus making the book a very complete treatise on tea culture. The chapters on the insect pests and the fungus diseases of the tea plant discuss these subjects very fully. Other animal pests, such as spiders, mites, nematodes, worms, snails, slugs, millipedes, etc., are also discussed.

Caoutchouc and gutta-percha cultivated in the Dutch East Indies, P. VAN ROMBURGH (*Les plantes a caoutchouc et a gutta-percha cultivées aux Indes Néerlandaises. Batavia, Java: G. Kolff & Co., 1903, pp. 208, pls. 15, map 1*).—This is a report of an exploring trip made with special reference to the caoutchouc and gutta-percha industries of the Dutch East Indies, more particularly the dissemination and culture of these trees. Various species of caoutchouc and gutta-percha cultivated in the Dutch East Indies are described, as are also the methods of producing these substances.

The culture of walnuts in France, J. ARTHAUD-BERTHET (*Ann. Inst. Nat. Agron., 2. ser., 2 (1903), No. 1, pp. 19–144, figs. 8*).—A treatise on walnut culture (*Juglans regia*) in France. The work discusses the botany of walnuts grown in France, classification of varieties, geographical distribution, climate best suited to this species, soils, methods of propagation, culture, manuring, harvesting, and the economic importance of the walnut industry in France, etc.

Shade trees and ornamental vines in Montana, J. W. BLANKINSHIP (*Montana Sta. Rpt. 1902, pp. 75–79*).—Notes on the most reliable and satisfactory shade trees that can be grown in different parts of Montana.

Budding the lilac, L. DANIEL (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 2, pp. 143–145*).—An account is given of some experiments in budding lilacs, in which conclusions are drawn for all grafts as follows: (1) The relative affinity or difference of functional capacities between stock and scion at different periods of the symbiosis plays a very important rôle in the success, duration, and biology of all grafts. (2)

Environment, weather, etc., particularly sudden changes of environment, has a considerable reaction on the whole, a reaction greater than in normal plants. (3) A number of irregularities, like diseases, etc., are the result of defective nutrition resulting from badly assorted grafts.

Flowers for the home garden, F. W. CARD (*Rhode Island Sta. Rpt. 1902, pp. 263–283, pl. 1, figs. 11*).—This is a plea for the home flower garden, with directions for the culture of such hardy plants as sweet peas, pansies, poppies, nasturtiums, phlox, calliopsis, zinnia, asters, cosmos, carrot, gladiolus, dahlias, and certain herbaceous perennials, like columbine and peony. The number of blooms obtained in 9 different sweet-pea mixtures is given. The results indicate that it is better to pay a fair price for a good quality of seed than to buy a cheap mixture.

Children's gardens, EVELYN CECIL (*London and New York: Macmillan Co., 1902, pp. XV+212, pl. 1, figs. 55*).—The kinds of flowers that can be successfully grown in England during each of the four seasons are briefly described, with notes and occasional hints as to methods of culture. The work, while ostensibly written for children, contains but few details, and at the same time is likely to confuse by treating of so large a portion of the plant kingdom.

Experiments with lawn grasses, B. D. HALSTED and J. A. KELSEY (*New Jersey Stas. Rpt. 1902, pp. 395, 396*).—A table is given showing the species of lawn grasses seeded in a number of different plats at the station in the spring of 1896, and the condition and the stand of grasses, in percentages, during the past 7 years. Rhode Island bent, wood meadow, and Kentucky blue grass have proved most satisfactory, in the order named.

FORESTRY.

Forestry at the California stations, C. H. SHINN (*California Sta. Bul. 147, pp. 89–119, figs. 9*).—A progress report is given of the forestry work which has been carried on at the Santa Monica and Chico Forestry substations. These stations were established under the State Board of Forestry in 1887 and transferred to the University of California in 1893. Brief historical statements are given regarding the organization and equipment of the different stations, and data regarding the climate and rainfall are appended. The condition of the different species of trees is given, the principal information being supplemental to that included in previous reports.

At the Santa Monica Station, when taken charge of by the university, there were 44 species of eucalyptus growing, and this number has been extended to include more than 100 species, many of them represented by 50 or more growing specimens. The rate of growth of these different species, their adaptability to their conditions, and value for various purposes are shown. The same factors for acacias, oaks, and other hard-wood trees are given. Among the various plantings undertaken an experiment was carried on to test the drought resistance of different species. All the observations seem to show that some of the tan-bark acacias are among the most drought-resistant trees, and with fairly good cultivation *Acacia decurrens* and *A. mollissima* can be established without any irrigation where there is an annual rainfall of only 10 in.

At the Chico Station the most striking features consist of the large pines, cypresses, sequoias, and other conifers planted in blocks. The size and rate of growth of representatives of these different groups are given. The experience obtained at this substation shows that for general planting in the Sacramento Valley and foothills the yellow pine of the Sierras, redwood, big tree, Monterey pine, and Oregon pine are the best. Among the exotic conifers tested the Deodar cedar and Austrian pine have given the best results.

An account is also given of tree planting on a hilltop at Berkeley. This planting was begun in 1887, and the tract planted comprises about 250 acres and rises to an elevation of 950 ft. This has been planted at various times to eucalyptus, acacias, oaks, Monterey pine, etc. All the trees have been subject to pasture conditions and

have received little or no care. The growth of the different species is shown, from which it appears that *Acacia decurrens*, several species of eucalyptus, and oaks are well established. Land as steep as this tract rents at from 50 cts. to $1 per acre, and is used only for pasturage. From the rate of growth shown in this experiment it would be a much better investment to plant to forest trees for firewood and timber.

Forest conditions in the Northern Sierra Nevada, California, J. B. LEIBERG (*U. S. Geol. Survey, Professional Paper No. 8, pp. 194, pls. 12*).—The region covered by this report is situated in the north-central portion of California and embraces an area of 3,491,100 square miles. Its topography and general characteristics are described, after which a detailed description is given of the forest area. The principal species of trees are enumerated and the range of each indicated. The forest is considered as being represented by different types, each of which is described in detail. The extent of timber cutting, effect of forest fires, grazing, and results of deforestation, as far as the restocking of the burned areas has been observed, are all described.

The forests of Oregon, H. GANNETT (*U. S. Geol. Survey, Professional Paper No. 4, pp. 36, pls. 7*).—A general review is given of the forests of Oregon, being based upon details furnished by special agents of the Geological Survey and from other sources. According to the report the wooded area of Oregon amounts to over 40,000 square miles, about 28,800 of which are covered with merchantable timber. The effect of forest fires in this region is shown, and it is stated that the burned area comprises more than 7 per cent of the entire State, the loss of timber alone, at the present stumpage value, being over $54,000,000. The present total stand of timber is estimated at 213,398,000 M feet B. M. Over 80 per cent of this stand is found west of the crest of the Cascade Mountains. In this region the average stand of timber is not less than 17,700 ft. per acre. The dominant species of timber are red fir, which comprises about 66 per cent of the total; yellow pine, 17 per cent; Sitka spruce and hemlock 5 per cent each, followed by red cedar 2 per cent, and a number of other species comprise 1 per cent or less. A classification is given of the land, and stand of timber by counties, and the total stand is shown in a tabular form.

Forest conditions in the Cascade Range Forest Reserve, Oregon, H. D. LANGILLE, F. G. PLUMMER, ET AL (*U. S. Geol. Survey, Professional Paper No. 9, pp. 298, pls. 41*).—This publication gives a detailed report on different portions of the Cascade Range Forest Reserve, and includes an introduction by H. Gannett, in which the boundaries of the reserve are described and a synopsis given of the general observations made by the special agent. The total area of the reserve is said to be 4,883,588 acres, of which fully 85 per cent is forested. Of the remainder, 8 per cent has been swept by fire, and the balance consists of open country, barren rocky areas, which extend above timber line, and water surface. The stand of timber in this reserve exceeds 50,000,000,000 feet B. M. and is principally represented by red fir, noble fir, hemlock, and yellow pine, a number of other species making up the remainder of the timber. The different portions of the forest range are described, classifications being given of the timbered, burned, cultivated, cut-over, and other areas.

Forest conditions in the Cascade Range, Washington, F. G. PLUMMER (*U. S. Geol. Survey, Professional Paper No. 6, pp. 42, pls. 11*).—A report is given of the forest conditions observed by the author in the Cascade Range, Washington, between the Washington and Mt. Rainier forest reserves. The area covered amounts to about 2,800,000 acres, of which 2,500,000 is naturally timbered, but which has lost 8.4 per cent by fires and 1.64 per cent by logging, thus leaving 2,292,870 acres of timber land, upon which 12,001,510 M feet B. M. is left standing. Lists are given of the principal timber species and their distribution, together with a number of associated species, many of which are not considered of economic value. Attention is called to some of the defects and diseases of timber trees, but in general the timber of this area is free from any serious defects. The effect of grazing on the forests is briefly

indicated and attention called to the fact that in some regions the range is heavily overstocked. Notes are given on the irrigated lands embraced within this area and estimates made regarding the possible extension of irrigation to other parts of this region.

Forest conditions in the Olympic Forest Reserve, Washington, A. DODWELL and T. F. RIXON (*U. S. Geol. Survey, Professional Paper No. 7, pp. 110, pls. 20*).—A general description is given of the location, boundaries, topography, and character of the lands embraced in the Olympic Forest Reserve, which comprises 1,939,000 acres. Taken as a whole, this is said to be the most heavily forested region of the State, and with few exceptions the most heavily forested portion of the country. The timber in this reserve amounts to 60,998,250 M feet B. M., an average stand of about 33,000 feet B. M. per acre. Of the area examined, 83 per cent is covered with merchantable timber, 5 per cent has been burned over, about 0.5 per cent has been logged, while almost 12 per cent is timberless. The species of this region are described, together with the associated trees and shrubs, and a detailed description is given of the different townships embraced within the reserve.

The forests of Washington, H. GANNETT (*U. S. Geol. Survey, Professional Paper No. 5, pp. 38, pl. 1*).—This bulletin is a revision of estimates previously made on the stand of timber in Washington forests. With the exception of the redwood forests of California, the forests of western Washington are the heaviest and most continuous in the United States. The timber is mainly red fir, mingled with spruce, hemlock, and cedar. In giving the revised estimates the author has raised the estimated total stand from 114,778,000 M feet B. M. to over 195,687,966 M feet B. M. The stand of timber in the different counties of the State is indicated and a classification given of the lands of the different counties, comparisons being made between the areas of merchantable timber, timberless areas, and those which have been cut over.

Experiments in tree planting on Sable Island, W. SAUNDERS (*Canada Expt. Farms Rpts. 1902, pp. 55–58*).—In continuation of the previous report (E. S. R., 14, p. 152), an account is given of the condition of trees and shrubs which were planted on Sable Island, off the coast of Nova Scotia, in 1901. Many of the plants were winter-killed, but the survivors made fairly satisfactory growth during the summer. A prolonged drought accompanied by high winds injured many, but on the whole the planting has proved of practical value. A list is given of the varieties of trees and shrubs which have survived the winter and summer conditions.

Forest belts, W. T. MACOUN (*Canada Expt. Farms Rpts. 1902, pp. 122–124*).—A brief account is given on the condition of the various forest belts at Ottawa, which have been previously reported upon (E. S. R., 14, p. 152). During the season covered by the report the trees made favorable growth, and on account of the dense leaf canopy considerable thinning was necessary. The condition of a number of species of trees and shrubs in the arboretum and botanic garden is noted, and it is pointed out that out of 121 trees native in Ottawa more than 100 have proved hardy at this station.

Notes on trees and shrubs, S. A. BEDFORD (*Canada Expt. Farms Rpts. 1902, pp. 306–308*).—The condition of trees and shrubs in the arboretum at the experimental farm in Manitoba is reported upon, from which it appears that most of the species made fairly good growth during the season of 1902. Plantings were made of oak and spruce and the young trees appear to be well established. More than 110,000 trees were distributed during the season and the results so far as reported upon have been entirely satisfactory.

Notes on trees and shrubs, A. MACKAY (*Canada Expt. Farms Rpts. 1902, pp. 345, 346*).—The condition of the trees and shrubs at the Northwest Territories Experimental Farm at Indian Head is reported upon, from which it appears that nearly all the specimens passed the winter without serious injury. Many of the shrubs fruited for the first time and the seed was collected for distribution. As

reported previously, the maple seed was again practically destroyed by a fungus so that seed for distribution had to be obtained from a different locality. Evergreen trees, particularly white and Rocky Mountain spruce and Scotch and mountain pine, made good growth during the season. A list is appended of trees and shrubs that have proved conspicuously successful for the region covered by the report.

Experimental foresty (*Rpt. Govt. Forest Adminstr., 1893–1902; abs. in Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4* (*1903*), *No. 2, pp. 241, 242*).—A brief survey of the activity of the Russian forestry administration for this period.

A primer of forestry, G. PINCHOT (*U. S. Dept. Agr., Farmers' Bul. 173, pp. 47, figs. 33*).—This bulletin is a popularization of a former publication of the Division of Forestry (E. S. R., 11, p. 855). The text has been revised to some extent and many new illustrations provided. It is believed that the new bulletin will prove more useful for general distribution than the previous publication.

SEEDS—WEEDS.

The influence of sterilized soil on seed germination, G. E. STONE and R. E. SMITH (*Massachusetts Sta. Rpt. 1902, pp. 40–42*).—The authors have observed for some time in their study on the influence of sterilized soil on various plant diseases that the seedlings and subsequent growth of plants germinated in sterilized soil were more vigorous than those in soil not so treated. In the present report they give a brief account of experiments to determine the effect of sterilization of the soil on the germination of seed. Old seed of low germinating capacity were selected for the purpose of the investigation, and results of the tests with radish, tomato, cucumber, lettuce, onion, mustard, turnip, and clover seed are given. Two hundred seeds of each kind were used in each experiment, in some instances the experiment being repeated 3 times. While the results can not be considered as conclusive, the preliminary experiment indicates that the germination of lettuce, cucumber, melons, tobacco, etc., is favored in sterilized soil.

Experiments in the germination of corn, B. D. HALSTED and J. A. KELSEY (*New Jersey Stas. Rpt. 1902, pp. 409–412, pl. 1*).—The results of a number of experiments on the germination of corn are given in which an attempt was made to determine some of the factors which might contribute to the production of albino or white seedlings. The seed was germinated in the presence of as little moisture as possible, and was taken from large and small ears for comparison, from different rows in the ear, from different parts of the ear, from stalks which bore more than 1 ear, and from grains produced by close and cross pollination. The germination tests did not give sufficiently marked differences to warrant any conclusion, but it was determined that there was apparently some relation between close fertilization and the production of albino seedlings, the albinos being most abundant in seedlings grown from ears of corn which had been close fertilized.

On the behavior of mutilated seedlings, B. D. HALSTED and J. A. KELSEY (*New Jersey Stas. Rpt. 1902, pp. 412–414, pl. 1*).—This is an abstract of a paper presented before the Society for Plant Morphology and Physiology January 1, 1902, and subsequently published (E. S. R., 14, p. 11).

Tests of the vitality of seeds, 1901–2, W. T. ELLIS (*Canada Expt. Farms Rpts. 1902, pp. 45, 46*).—A report is given of tests of 1,830 samples of seed grain and other seeds which were tested during the season of 1901–2. More than 95 per cent of all the samples were wheat, barley, oats, and peas. A tabular statement is given showing the relative value of the different lots, and additional tables are given in which results of seed tests carried on in different provinces are shown.

Seed testing, J. S. REMINGTON (*Reprint from Jour. Roy. Lancashire Agr. Soc. 1903, pp. 8*).—A discussion is given of the methods of seed testing, together with results of some investigations, and a table which shows the purity, germination, and actual

value of samples of a large number of varieties of field and garden seeds, as well as those of a number of forage plants.

Seed testing of alfalfa and medic, D. FINLAYSON (*Aynsome Agr. Sta., George-over-Sands, Cent. Seed-Testing Lab. Farmers' Bul. 3, pp. 8, pl. 1*).—Illustrated notes are given on some of the impurities found in alfalfa and medic seed, and results of tests for purity and germinative ability of these seeds.

Impurities in farm seeds, G. H. CLARK (*Ontario Agr. and Expt. Union Rpt. 1902, pp. 47–49*).—A discussion of some of the impurities found in farm seeds, particular attention being given to those occurring in the seeds of cereal crops and forage plants. Under the conditions described most of the weed seeds are found in oats, and many of the more troublesome weeds have been distributed with seed oats. Many weed seeds are distributed in timothy, alsike, and red-clover seed, and a table shows the results of a large number of investigations of these seeds and the principal weed seeds found in the samples.

Notes on weeds, J. W. BLANKINSHIP (*Montana Sta. Rpt. 1902, pp. 70, 71*).—Brief notes are given on the occurrence and distribution of the alfalfa dodders (*Cuscuta epithymum* and *C. arvensis*), a native Coreopsis, and the common dandelion. All of these weeds are said to be very troublesome under Montana conditions, and suggestions are given for their repression and warning against their introduction through the use of impure seeds.

Weed notes, B. D. HALSTED and J. A. KELSEY (*New Jersey Stas. Rpt. 1902, pp. 396, 397*).—In continuation of the previous investigations on weeds (E. S. R., 14, p. 578), the authors report on the relative prominence of different species of weeds in a plat of ground which has been abandoned to weed growth for 6 years. The most numerous species in order of individuals are *Rumex acetosella*, *Daucus carota*, *Bromus racemosus*, *Polygonum pennsylvanicum*, *Abutilon abutilon*, and *Chrysanthemum leucanthemum*. A number of other weeds have made their appearance, and at present the weed plat contains about 30 species of plants. Brief notes are given on the occurrence of horse nettle, corn chamomile, ground ivy, and ailanthus, and suggestions for their eradication.

The broom rapes, H. GARMAN (*Kentucky Sta. Bul. 105, pp. 32, pls. 6, figs. 9*).—This bulletin is in continuation of a previous one (E. S. R., 2, p. 22). For 10 years or more the author has been observing broom rapes, and of the 16 species enumerated three (*Orobanche ludoviciana*, *O. minor*, and *O. ramosa*) are known to occur in Kentucky. Branched broom rape (*O. ramosa*) is the best-known species and thus far has not been observed outside the blue-grass region. This species, which is parasitic on hemp, tobacco, tomato, potato, rape, cabbage, and other plants, is described at considerable length, its habits of germination, growth, and parasitism being given in detail. A number of enemies have been noted, among them being several species of aphis, some of which are still under observation. The seed of broom rape are mostly disseminated through sowing with hemp and other seed. The plants may be removed from growing tobacco and seed hemp so as to prevent seeding and further spread. Seeds of broom rape are known to retain their vitality for at least 13 years while lying in the soil. Soaking the seed with strong solutions of copper sulphate kills the broom rape without seriously injuring the hemp seed. Treating with water heated to 140° F. also destroys the broom-rape seed without exerting any hurtful effect on the hemp. The application of gas lime and copperas did not prevent the growth of broom rape, but copper sulphate in the proportion of 1 ton to the acre checked the parasitic growth. This has been considered too costly for field work. Common salt used in the proportion of 2 tons to the acre destroyed both the hemp and broom rape. On this account it can not be used on growing hemp, but if the ground has become badly infested it could be used and after the destruction of the weed some other plant may be cultivated until the injurious effect of the salt disappears.

DISEASES OF PLANTS.

Report of the botanists, G. E. STONE and R. E. SMITH (*Massachusetts Sta. Rpt. 1902, pp. 27–38*).—A review is given of the plant diseases under observation during the season of 1902 and discussions given of some of the more important ones. Among the diseases more extensively described are the cucumber mildew (*Plasmopara cubensis*), muskmelon blight, apple leaf spot due to frost injury, a strawberry disease, plum yellows, etc.

The cucumber mildew, which was first reported at the Massachusetts Station in 1889, has since become very prevalent throughout the Southern and Middle States, and since 1900 has reappeared in Massachusetts, being found on greenhouse cucumbers in different localities. Experiments in spraying for the prevention of this disease have shown but little gain attributed to the use of fungicides. When occurring in fields the fungus does not seem to seriously diminish the yield, but when appearing upon greenhouse cucumbers great damage may be occasioned. The disease is more prevalent upon the early started plants, and on this account the authors recommend starting the plants in October and keeping the atmosphere of the house in as dry condition as possible. By the removal of the affected leaves the disease may be kept in check and where an early crop has been planted spraying with Bordeaux mixture is recommended.

The chief injury to muskmelons reported was from the downy mildew which occurred in connection with the anthracnose and an Alternaria disease. On account of the serious outbreak of the mildew the growing of muskmelons has been almost a complete failure. An experiment has been conducted in cooperation with local growers to test the efficiency of spraying for the prevention of this disease. The details of the work and the results of the experiment are reserved for a future publication.

The apple leaf spot was due to frost injury and resulted in the early defoliation of some of the orchards. Those orchards which were in good condition were less seriously affected than neglected trees grown under unfavorable conditions. No fungus was observed and the spotting of the leaves is attributed to the injury caused by the low temperature occurring during the early part of the season.

The strawberry disease mentioned appears to be a new one. It was first observed in the withering and dying of the fruit stalks, followed by the same effect upon the leaves. An examination of these parts showed no fungus, but the roots were found in all cases to be in poor condition. Further examination showed a fungus growth present in nearly all roots of affected plants, but attempts to obtain cultures in order to determine definitely the organism failed, as did attempted inoculation experiments.

The authors report the occurrence on plums, particularly the Japanese varieties, of a disease very similar to the yellows of the peach. This trouble is characterized by the production of wiry, yellow shoots, just as in peach yellows.

A brief account is given of spraying experiments for the control of the linden leaf spot (*Cercospora microsora*) and elm leaf spot (*Dothidella ulmea*). These trees were sprayed with Bordeaux mixture. The sprayed trees retained their foliage much longer than those not so treated. It is estimated that in the case of linden trees sprayed twice during the season a gain of from 2 to 5 per cent in growth and development would be obtained at an almost insignificant cost.

A brief account is given of the growing of various crops under tent cloth, the experiment being suggested by the success attained in growing Sumatra tobacco. Cucumbers, watermelons, tomatoes, etc., were grown under cloth shade and, so far as the vegetative growth and freedom from disease were concerned, the experiment was very successful; but the plants did not set fruit as well as those grown in the open. This was due probably to a lack of insect visitors.

Experiments in heating soils, G. E. STONE and R. E. SMITH (*Massachusetts Sta. Rpt. 1902, pp. 38–40*).—On account of the widespread interest taken in the problems

of soil sterilization, the authors have conducted a number of experiments to test the efficiency of various methods of steam sterilization. The efficiency of 1 and 2 in. iron pipes, 2-in. colander tin, 2-in. galvanized-iron pipe with different numbers of perforations, and 2-in. tile was investigated. The experiments show that the 2-in. pipe is superior to the 1-in. pipe where the number and size of the perforations are the same, and for all practical purposes perforations ¼ in. in diameter are better than smaller ones. The best results were obtained with a section of Cartter's tubes which contained 4 rows of perforations ¼ in. in diameter. In sterilizing soil there are many factors which must be taken into consideration, among them the pressure and amount of steam supplied, the size of the apparatus, and the amount of earth to be heated.

Notes on some plant diseases and spraying experiments, B. D. Halsted and J. A. Kelsey (*New Jersey Stas. Rpt. 1902, pp. 398–422, pls. 3, figs. 5*).—Notes are given on the club root of turnips in which the authors discuss the possibility of infection through the eating of raw turnips and similar plants. Descriptions are given of the mildew of Lima beans and suggestions for the control of this disease, and notes on the asparagus rust, fungicides and spraying, fungi as related to weather, and a list of species of parasitic fungi observed in a number of localities.

The observations on the asparagus rust seem to indicate that this disease is widely spread, reports having been obtained from many widely separated regions throughout the United States. From the continued experiments at the station the variety Palmetto seems to be most resistant of any under observation, and Argenteuil almost equally so, while Mammoth, Columbian, Colossal, etc., have at least 75 per cent of their plants affected.

The authors note the occurrence of broom rape (*Orobanche ramosa*) as occurring on a coleus plant grown in a pot in the greenhouse. In a previous report this parasite was noted as occurring on tomato, and the present account probably adds a new host plant to the already long list of species known to be subject to attacks of this parasite.

The experiments described with fungicides and spraying include the use of kerosene emulsion as a fungicide in greenhouses, and field trials with soda-Bordeaux mixture. The kerosene emulsion described proved to have considerable value as a fungicide under the conditions of the experiment, as shown upon plats of verbenas, phlox, and other ornamental plants. The field trials with soda-Bordeaux mixture gave negative results, the conditions following the second application being such that further sprayings were discontinued.

Report of the department of botany, H. L. Bolley (*North Dakota Sta. Rpt. 1902, pp. 34–65, pls. 4, figs. 3*).—A detailed report is given of the principal operations conducted by the botanist and his assistant during the year, particular attention being given to the flax wilt, which has already been the subject of a bulletin (E. S. R., 14, p. 55), and a description of a continuous process of treating flaxseed with formaldehyde vapor, which has already been described (E. S. R., 14, p. 983). Notes are also given on water hemlock (*Cicuta maculata*) and water parsnip (*Sium cicutæfolium*). The poisonous properties of these weeds are pointed out and suggestions made for their eradication. Brief outlines are given on the work on plant diseases, soil fungi, and bacteria; plant breeding, forage, and grass studies; economic plant survey of the State, seed-control studies, physiological experiments with trees, and bacteriological analyses.

Results of cooperative experiments in treating for oat smut in 1902, W. Lochhead (*Ontario Agr. and Expt. Union Rpt. 1902, pp. 31–34*).—A brief account is given of the results of treating oats with copper sulphate and with formalin for the prevention of smut in the subsequent crop. Two methods of treatment were adopted. In the first the seed was sprinkled with the solution, and in the second it was immersed for 12 hours in the copper sulphate or for 20 minutes in the formalin solution. Comparing the average number of smutted heads from the different plats,

both treatments greatly reduced the percentage of diseased ones, those treated with formalin being almost entirely free from the smut. The author believes that where the convenience and efficiency of treatment are concerned the formalin is to be preferred above any of the other methods that have been suggested for the prevention of oat smut.

The bacterial disease of the potato, E. MARRE (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 17, pp. 526–528*).—A report is given of investigations relative to the bacterial disease of potatoes due to *Bacillus solanincola*. Inquiries were sent out to a number of correspondents during 1902, and from the replies the author concludes that the disease is influenced by atmospheric conditions, dry, hot weather aiding in its spread. The entrance of the organism to the plant is favored by the presence of leaf-eating and stem-sucking insects. Most of the correspondents reported less disease on plants grown from whole tubers than from cut seed, and marked differences in varietal resistance are noted. Early or very late planting gave the best results, as such plants escaped the dry, hot weather which favored the spread of the disease. However, early and late seeding and resistant varieties can not be absolutely depended upon as means of preventing attacks of this disease. Treating the seed tubers with formalin, corrosive sublimate, and copper sulphate solutions gave no positive relief. Sulphur and ashes dusted over the tubers in the drills before covering was thought by some to be of value, and this treatment will be given further trial.

Potato blight (Cercospora concors), G. LAGERHEIM and G. WAGNER (*K. Landt. Akad. Handl. och Tidskr., 42 (1903), No. 1, pp. 6–13, pls. 2*).—The history of the appearance of this potato disease is discussed at some length. It has been observed during the last 10 years at a number of places in Germany, Bohemia, and Austria. On its appearance in Uphland, Sweden, in August, 1902, it was studied by the authors as to its morphology and mode of development. Spraying with Bordeaux mixture is suggested as the best method of combating the disease, besides burning all the infected plants.—F. W. WOLL.

Potato blight and rot, W. T. MACOUN (*Ontario Agr. and Expt. Union Rpt. 1902, pp. 42–47, maps 2*).—Popular descriptions are given of the early blight (*Alternaria solani*) and the late blight or rot (*Phytophthora infestans*). Cooperative experiments have been carried on in Ontario for the prevention of these diseases, and the average net results show profits ranging from $37.22 to $69.62 as a result of the increased production due to the spraying.

The internal action of copper sulphate in the resistance of potatoes to the potato rot, E. LAURENT (*Compt. Rend. Acad. Sci. Paris, 135 (1902), No. 23, pp. 1040–1042*).—On account of the great sensitiveness of the spores of *Phytophthora infestans* to copper salts, the author has conducted a series of experiments to test the possibility of producing tubers that will not be susceptible to the attacks of this fungus. The experiment was begun in 1901, varieties of potatoes exceptionally subject to disease being grown in pots to the soil of which sulphate of copper was added at the rate of 1 part to 1,000 of soil. During that season the potato rot did not appear, so that the results of the treatment could not be determined. It was continued, however, a second year, and in August the disease appeared in considerable abundance. Tubers were harvested and those of one variety were cut in two, their cut surfaces placed in contact with the leaves of potato carrying the mildew. These were examined after 4 days, and those tubers which had been grown in the pot containing copper did not show any infection, while the check ones were infected in a very decided manner.

An analysis of the tubers grown in the pots showed that they contained 1 part of copper to 20,000, while tubers grown without copper added to the soil did not show the presence of any copper. An attempt was made to protect tubers against the fungus by soaking them for 20 hours in from 2 to 5 per cent solutions of copper sulphate. After this treatment they were washed in water and exposed to leaves carrying the Phytophthora. The parasite developed equally vigorously in all the speci-

mens, showing that this method can not be relied upon to secure immunity from attack.

Spraying potatoes, W. T. Macoun (*Canada Expt. Farms Rpts. 1902, pp. 117–120*).—During the season covered by the report experiments were carried on to compare the value of Bordeaux mixture, either in connection with Paris green or without, and a patented fungicide and insecticide known as Bug Death. The comparative efficiency of the different treatments is shown, from which it appears that Bug Death is not nearly as economical for use as is Bordeaux mixture, with or without Paris green. In 9 out of 11 tests the yield, where Bordeaux mixture and Paris green were sprayed over the plants, was considerably greater than where the other fungicide was used. There is no evidence to show that Bug Death has any value as a plant food, as is claimed, and vines which had received this preparation were no more vigorous than those sprayed with Bordeaux mixture and Paris green.

The effect of black rot on turnips, E. S. Smith (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 29, pp. 20, pls. 14*).—This bulletin consists of a series of photomicrographs, accompanied by an explanatory text, and is in continuation of the previous papers published by the author on this disease (E. S. R., 9, pp. 847, 849). In this paper attention is confined to the action of the parasite on the host plant, the previous discussions treating of the morphology and cultural peculiarities of the parasite. So far as the author is able to determine, the organism causing the black rot is capable of dissolving the cell wall proper, and this action is progressive, as shown by the fact that many of the cell walls observed in the infected portion of the plant are only one-third to one-fourth as thick as the walls of adjacent uninjured cells. The action is probably enzymatic and proceeds rather slowly.

Fungus diseases and other injuries, W. T. Macoun (*Canada Expt. Farms Rpts. 1902, pp. 111, 112*).—Brief notes are given on the occurrence of the sooty fungus or fly-speck fungus of apples, which is caused by *Leptothyrium pomi*, a rusting of apples which is attributed to improper spraying, a serious defoliation of trees, the cause of which was not definitely determined, and the black rot of cabbage. Notes are given on the preparation and use of fungicides and the value of these, particularly Bordeaux mixture, in controlling certain plant diseases.

Report on fungus diseases on cultivated fruits, F. W. Faurot (*Missouri Fruit Sta. Bul. 6, pp. 24, figs. 9*).—Illustrated descriptive notes are given of a number of fungus diseases observed during the season of 1902 as affecting apples, peaches, pears, plums, grapes, blackberries, and raspberries. Directions are given for preventing the occurrence of these diseases, so far as known, together with the results of the author's observations and experiments.

Fungus diseases of the apple, pear, and quince, F. L. Stevens (*North Carolina Sta. Bul. 183, pp. 64–82, figs. 10*).—Popular descriptions are given, with suggestions for prevention, of apple scab, apple rust, ripe rot, apple canker, black rot, and powdery mildew of the apple; fire blight, anthracnose, rust, canker, scab, and leaf spot of pear; and quince rust, fire blight, and fruit spot.

On scab and mildew of fruit trees, and methods of combating these diseases, J. Eriksson (*K. Landt. Akad. Handl. och Tidskr., 42 (1903), No. 1, pp. 53–71, pl. 1, figs. 10*).—The diseases described are apple-tree scab (*Venturia dendritica*), pear-tree scab (*V. pyrina*), and mildew of fruit trees (*Monilia fructigena*). For combating the scab diseases the author recommends immediate removal and destruction of fallen leaves from affected trees, and spraying or washing the bare trees with Bordeaux mixture or copper sulphate solution. In addition to this winter treatment, 2 or 3 sprayings during the spring and summer are advisable. The remedies advocated for combating Monilia are to gather and burn all rotten or dried-up fruit. On trees which have shown indications of disease all dried-up flower clusters are removed before the following spring and the diseased parts are cut off and burned. Affected trees, particularly the young branches, should be sprayed at the beginning

of the winter and early in spring, before the buds open, with a 2 per cent Bordeaux mixture. The ground beneath and around the diseased trees should be strewn quite thickly with lime.—F. W. WOLL.

Crown gall, G. C. BUTZ (*Pennsylvania Sta. Rpt. 1902, pp. 405–414, pl. 1*).—The distribution of the crown gall in Pennsylvania is indicated, and the author states that from 20 to 80 per cent of trees in orchards are frequently affected by this disease. It is said to have first made its appearance about 10 years ago on nursery stock brought from a western nursery, and seems to most seriously affect apples, peaches, and similar stock. The cause of this disease, which has been described in Arizona Bul. 33 (E. S. R., 12, p. 458), is attributed to the fungus *Dendrophagus globosus.*

Under the author's directions experiments with nursery stock were carried on with apple trees to test the efficiency of various treatments for the prevention of crown gall. Healthy trees set in infected lands developed the disease within a year or more. Where healthy trees were planted in infected land and finely powdered sulphate of copper distributed about the roots, no galls were found, but most of the trees had died as the result of a serious drought, and those remaining were so few in number as not to permit of any generalization regarding the efficiency of this treatment. Sulphur used in the same way had no effect in retarding the disease. When the roots of the trees were dipped in Bordeaux mixture there appeared to be some retarding of the development of the galls. Where the galls were cut from the young trees and the trees subsequently planted in clean lands, after a season or two the galls developed, showing that this treatment was of little value except in that it delayed the development of the disease. Cutting out the galls and dipping the trees in Bordeaux mixture, after which the trees were planted in clean soil, did not prevent the redevelopment of a fungus growth.

In conclusion, the author states that the disease is not strictly confined to the crown of the root system, but may develop on the stronger roots a foot or more from the crown. Some investigators, however, consider the galls formed at some distance from the crown as different from the crown gall, but the author believes that they are different manifestations of the same trouble. A list of trees is given upon which crown gall has been found, and while experiments have shown that the organism mentioned above was responsible for the production of galls on the almond, apricot, and peach, it has not been demonstrated that the same organism occurs in the crown galls upon apples, pears, plums, prunes, cherries, raspberries, grapes, English walnuts, and chestnuts.

Studies on the white rot of grapes, G. ISTVÁNFFI (*Ann. L'Inst. Centr. Ampelol., Roy. Hongrois, 2 (1902), pp. 288, pls. 24, figs. 12*).—A monographic study is given of *Coniothyrium diplodiella*, the fungus which is the cause of the white rot of grapes. After giving an historical review of the literature, the author describes the occurrence of the fungus in Hungary in 1901 and the following year. The effect produced upon the different parts of the grape, nearly all of which are subject to attack, are fully described. The fungus is described at length and the results of culture experiments are given. Numerous inoculations were made, different organs of the plant being successfully infected. The effect of fungicides upon the organism is discussed and preventive treatments recommended. According to the author, there are different forms of the fungus which attack different species of grapes as well as upon different parts of the vine, and specific names have been given them. Upon *Vitis vinifera* is found *Coniothyrium diplodiella* upon the fruit, young shoots, and leaves; *C. insitivum* on the canes, and *C. vitis* on the dying branches. On the leaves of *Vitis berlandieri*, *V. cinerea*, and other American species of grapes *C. berlandieri* is found. Accompanying the white rot are said to be a number of other fungi. Among those described are *Colletotrichum vitis* n. sp., *Botrytis cinerea*, *Pestalozzia uvicola*, *Cytospora ampelina*, various species of Capnodium, Verticillum, etc.

Numerous footnote references are given, which constitute a very extensive bibliography of the literature of the subjects treated.

Phthiriosis, a disease of grapes, L. Mangin and P. Viala (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 6, pp. 397–399; Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 10, pp. 316–318; Rev. Vit., 19 (1903), Nos. 481, pp. 269–271; 483, pp. 329–335; 484, pp. 357–363; 485, pp. 385–388, pls. 2, figs. 16*).—An account is given of a disease of grapes which has caused considerable injury in the vineyards of Palestine and adjacent countries. The disease is due to the combined attacks of *Dactylopius vitis* and *Bornetina corium*, n. sp. The attack is made upon the roots, and specimens of all ages show a peculiar thickening of the root which is more or less cylindrical, having when fresh a decided elasticity, but in drying becomes hard and brittle. If these enlargements which surround the root be examined they will show a flocculent mass made up of a mass of insects and the mycelium of the fungus. The root itself will be found to be in various stages of disorganization. The insect punctures the roots, and from the exuding sap is formed a substratum in which the fungus readily develops. In this way a sort of symbiosis is established between the two, resulting in the destruction of the plant. Experiments have been conducted which indicate that the injection of carbon bisulphid about the plants during the early stages of the disease, before the mycelium has made an impenetrable felt about the roots, will destroy the insect. If the treatment be put off too late in the season the Dactylopius within the mass of mycelium will not be reached by the insecticide.

A disease of chestnut, L. Mangin (*Jour. Agr. Prat., n. ser., 5 (1903), No. 9, pp. 278, 279*).—For a number of years the author has had under observation a disease of chestnut trees which seems to be widely distributed throughout France and which has caused the destruction of many trees. Two forms of the disease seem to be recognized, the first of which is due to the weakening of the trees by injury, removal of forest cover, lack of fertility in the soil, etc. The second type, which is the one described, is due to a fungus, and is found in all soils and exposures equally affecting young and old trees. It seems to spread from definite centers, on which account it has been called phylloxera from its resemblance to the spread of that disease in the grape. The aerial parts of the trees seem to be unaffected, but the roots are more or less discolored by the fungus which seems to attack the mycorrhiza, which is symbiotically associated in the growth of the chestnut tree. The parasite consists of a very delicate mycelium which attacks the mycorrhiza, causing its destruction. A study has been made of the fungus, and the author states that it apparently constitutes a new genus associated with Oomyces, and he has given to it the name *Mycelophagus castaneæ*. Although experiments do not seem to have been made, the author recommends the destruction of the parasite by injecting carbon bisulphid about the trees and the destruction of those which show evidence of attack. The use of carbon bisulphid can be recommended only in case of exceedingly valuable trees which are planted in soils where that material can be used to an advantage.

A disease of conifers (*Jour. Bd. Agr. [London], 10 (1903), No. 1, pp. 17–21, pl. 1*).—A description is given of a rather serious disease of coniferous trees, which is caused by attacks of the fungus *Botrytis cinerea*. So far this fungus has been observed occurring on the larch, silver fir, spruce, and sequoia seedlings. The disease has been under observation for 2 years and has proved very destructive to seedlings of larch and Scotch pine. The fungus causes the diseased shoots to curve down or become twisted, the leaves die and separate themselves from the branches, but are frequently prevented from falling by the formation of a web-like mat of mycelium. So far as the observations in England are concerned, this disease is quite abundant in nurseries and seed beds, and particular attention should be given to prevent the growth of weeds which would result in keeping the seedlings damp and shaded. Where the disease is prevalent it is suggested that the seedlings should be sprayed with a mixture called the "violet" mixture. This consists of copper sulphate, 2 lbs.; copper

carbonate, 3 lbs.; potassium permanganate, 3 oz.; soft soap, 8 oz., and rain water, 18 gals. All diseased seedlings should be collected and burned.

A new Bordeaux powder, R. N. BIRD (*Missouri Sta. Bul. 60, pp. 93-103, figs. 5*).—At the request of the department of horticulture the author has made an investigation of a dry form of Bordeaux mixture which could be substituted for the usual formula. The powder devised is composed of 4 lbs. of copper sulphate and 4 lbs. of lime, the lime and copper sulphate each being dissolved or slaked in $2\frac{1}{2}$ gals. of water. Sixty pounds of air-slaked lime is sifted through a fine sieve. The milk of lime and copper sulphate solution are mixed and filtered so that most of the water is removed. The remaining wet material is thoroughly mixed with the 60 lbs. of air-slaked lime, after which the mixture is rubbed through a coarse sieve while still somewhat damp. When perfectly dry it is put through a fine-meshed sieve, and can be applied with any of the usual means for applying powders to plants. This powder contains about $3\frac{1}{3}$ times as much copper per gallon as liquid Bordeaux mixture. In order to reduce it to the usual proportion it should be diluted with about three or four times its bulk of powdered lime or with flour. The results of experiments in which practical tests were made of this powder are to be given in a forthcoming bulletin of the horticultural department of the station.

ENTOMOLOGY.

Report of the entomologist and botanist, J. FLETCHER (*Canada Expt. Farms Rpts. 1902, pp. 169–195, figs. 5*).—The chief enemies of cereal crops during the year were Hessian fly and locusts. The Hessian fly was excessively injurious in 1901, but disappeared almost entirely during the season of 1902. Notes are given on the conditions under which the insect was found during the season, but the cause of the disappearance is not well understood.

Locusts were present in large numbers and did considerable damage in Manitoba. Several remedies were tried, but the best success was had by the use of Criddle mixture, which, as recently modified, consists of 1 part Paris green thoroughly mixed in 60 parts of fresh horse manure, to which 2 lbs. salt is added to a half barrel of the mixture. The mixture is then scattered along the edge of the infested field and serves as a poison bait.

Notes are given on the habits, life history, and injuries of the pea weevil, pea moth, and destructive pea aphis. The remedies suggested against the pea weevil are fumigation, holding over the seed, treating with kerosene, and scalding the seed.

San José scale has been found to be difficult to control, but in the experience of the author trees may be kept in a bearing condition by the use of kerosene emulsion applied twice during the summer, whale-oil soap at the rate of $2\frac{1}{2}$ lbs. to the imperial gallon of water, or by fumigation with hydrocyanic-acid gas. Two new strawberry pests were observed, but no great damage was done by them. These insects are *Mesoleuca truncata* and *Scopelosoma tristigmata.*

A report on the apiary is given by J. Fixter. A test was made of the comparative value of Langstroth, Hedden, and 2 other kinds of hives. The best results were obtained from the Langstroth hive. Experiments in feeding sugar sirup for winter stores showed that bees thus treated passed through the winter in good condition, without the development of dysentery or other diseases. Experiments with brood foundation of different sizes indicated that the best returns were to be had through the use of strips of foundation about 1 in. wide. The question of injury to fruit by bees was tested by means of a number of experiments with peaches, pears, plums, grapes, strawberries, and raspberries. The results obtained confirm those of previous experiments and indicate that bees do not, under ordinary conditions, attack whole fruit of any kind. They do, however, suck the juice from fruit of which the skin has been punctured.

Report of the entomologists, C. H. and H. T. Fernald (*Massachusetts Sta. Rpt. 1902, pp. 45–47*).—During the year considerable attention was given to methods of combating San José scale, as required by the nursery inspection law of the State. The most important injurious insects during the year were brown-tail moth, gypsy moth, San José scale, elm-leaf beetle, etc.

Entomological department, R. A. Cooley (*Montana Sta. Rpt. 1902, pp. 80–87*).—The author presents a list of the more important injurious insects which have been found within the State. Brief notes are also presented on mosquitoes, grasshoppers, plant lice, flea-beetles, cottonwood-leaf beetle, cucumber flea-beetle, mealy bugs, and ants.

Report of the entomologist, J. B. Smith (*New Jersey Stas. Rpt. 1902, pp. 423–593, pls. 17, figs. 11*).—The author discusses miscellaneous outbreaks of injurious insects during the year 1902, including plant lice, fall webworm, strawberry weevil, rose beetles, grain insects, periodical cicada, and oak pruner. Brief mention is made of the present status of imported Mantidæ, cabbage insects, San José scale, and Chinese ladybirds. During the season considerable work was done in the way of inspecting orchards and nurseries. Insecticide experiments were carried on in the entomologist's experimental orchard. Black insecticide soap, used at the rate of 1 lb. in 6 or 7 gals. of water, was of little use as a remedy for San José scale. Agricultural soap also gave unsatisfactory results, while Calcothion proved quite effective. Brief extracts are given from the crop bulletin for the year. The author discusses the appearance of periodical cicada in New Jersey in 1902, together with notes on its distribution, life history, injuries, and measures for repressing it.

General directions are given for fumigating trees, greenhouses, small fruits, and infested buildings, with notes on the advantages and limitations of the method of fumigation. The author discusses also the present distribution of the Chinese ladybird in New Jersey, and states that while no new experiments have been made with crude petroleum at the station, numerous satisfactory reports have been received from fruit growers who have used this remedy.

The author spent considerable time in the investigation of the mosquito nuisance. Notes are given on the habits and life history of the mosquitoes of New Jersey, with special reference to the conditions which are favorable or unfavorable to their spread. Mention is made of fish and other natural enemies of mosquitoes. The marshes around various cities were studied for the purpose of locating breeding grounds of mosquitoes and determining methods of combating the pest. It is urged that drainage or ditching is the method by which extensive breeding areas of mosquitoes can be rendered harmless.

H. P. Johnson presents a report on certain mosquitoes of New Jersey with special reference to malaria. The species studied were *Culex pungens*, *C. sollicitans*, *Anopheles punctipennis*, *A. maculipennis*, and other less important forms. Notes are given on meteorological conditions, breeding habits, and natural enemies of mosquitoes, the duration of larval and adult life, the relative proportion of the sexes, food of the larvæ, biting habits, and the agency of mosquitoes in the transmission of malaria.

Report of the State entomologist, J. B. Smith (*New Jersey State Bd. Agr. Rpt. 1902, pp. 101–108*).—Reference is made to the introduction into this country of *Chilocorus similis*, and the effect of this and related species of ladybirds upon San José scale. Notes are given on the work of State inspection and relationship between the duties of inspection officers and those of investigators. Mention is also made of the injury caused by sinuate pear borer.

Eighteenth report of the State entomologist on injurious and other insects of the State of New York, E. P. Felt (*New York State Mus. Bul., 1902, No. 64, pp. 89–193, pls. 6, figs. 2*).—Notes are given on the habits, life history, and means of combating brown-tail moth. This insect is believed not to occur in the State. The carrot-rust fly (*Psila rosæ*) has been found injuring celery as well as carrots. Notes

are given on the introduction, distribution, and life history of this species. The insect is also described and notes are given on its natural enemies and artifical means of repression. In fighting the insect the author recommends the use of kerosene emulsion, late sowing, rotation of crops, destruction of the insects in stored roots, and fall cultivation. Brief notes are also presented on a number of injurious insects, including tent caterpillar, bud moth, apple-tree bucculatrix, raspberry-cane maggot, clover mite, fall webworm, Hessian fly, pea weevil, elm-leaf beetle, white-marked tussock moth, bollworm, willow curculio, nun moth, walnut caterpillar, birch-tree bucculatrix, periodical cicada, ladybirds, praying mantis, and Chinese praying mantis. A list is given of introduced insects of primary economic importance affecting various cultivated crops. The author summarizes his experimental work in controlling San José scale as follows: Spring applications of crude petroleum emulsion have proved uniformly satisfactory. Whale-oil soap is a valuable insecticide when applied in the fall. Lime-sulphur-salt wash did not give perfectly satisfactory results. A brief account is presented of the voluntary entomological services throughout the State and a list is given of Coleoptera collected at Newport, N. Y., by D. R. Young. As usual in these reports a list is given of the publications of the entomologist during the year.

Proceedings of the Entomological Society of Washington (*Proc. Ent. Soc. Washington, 5 (1903), No. 4, pp. 237-334, pls. 2*).—This number of the proceedings contains the following papers read at meetings of the society: Myrmecosalius, a New Genus in the Ceropalidæ, by W. H. Ashmead; Neuropteroid Insects from Arizona and Note on *Ceria willistonii*, by N. Banks; Notes on the Orthoptera of Bermuda, with the description of a New Species, by A. N. Caudell; The Genera of the Dipterous Family Empididæ, with Notes and New Species, by D. W. Coquillett; Myrmeleonidæ from Arizona; and the Odonata Collected by Messrs. Schwartz and Barber in Arizona and New Mexico, by R. P. Currie; Notes on *Crambus offectalis* and Allied Forms (*Eretria neomexicana*); New North American Lepidoptera, with Notes on Larvæ; A Note on *Pyrausta ochosalis;* Note on a Wrongly Identified Species of Tortricidæ (*Phthinolophus indentanus*); and a Review of the North American Species of the Lepidopterous Family Anthroceridæ, by H. G. Dyar; On the Cicindelidæ of Southern Venezuela, by W. Horn; A Letter from Cuba, by E. A. Schwarz; A Revision of the Boreal-American Species of Nonagria, by J. B. Smith.

Government entomologist's report, E. E. GREEN (*Roy. Bot. Gard. Ceylon Adminstr. Rpts. 1902, pt. 4, pp. 11-14*).—Descriptive and economic notes are given on *Xyleborus fornicatus*, *Capua coffearia*, *Helopeltis antonii*, and *Heterusia cingala*, all of which are injurious to tea plants. Brief notes are also presented on insects injurious to cacao, rice, and cardamoms, together with an account of mosquitoes, white ants, acetylene trap, fumigating apparatus, scale insects, sericulture, lac insects, etc.

Insect enemies of the apple, pear, and quince, with methods of treatment, F. SHERMAN, JR. (*North Carolina Sta. Bul. 183, pp. 45-63, figs. 11*).—Economic and biological notes on woolly aphis, round-headed apple-tree borer, flat-headed apple-tree borer, fruit bark beetle, scurfy scale, oyster-shell bark louse, San José scale, apple aphis, apple-tree tent caterpillar, fall webworm, codling moth, plum curculio, and pear-leaf blister mite.

Orchard studies. IV. Remedial measures against San José scale, W. B. ALWOOD (*Virginia Sta. Bul. 131, pp. 149-169, figs. 2*).—A brief account is presented of the appearance, habits, and means of combating San José scale. The remedies which have proved most successful in various localities are discussed. These include lye wash, soap washes, kerosene, crude petroleum, kerosene emulsion, and lime-sulphur-salt wash. Brief notes are also given on the natural enemies of the San José scale.

Insect pests of sugar cane, S. M. HADI (*The sugar industry of the United Provinces of Agra and Oudh. Allahabad: Frank Luker, 1902, pp. 45-51*).—White ants are reported as attacking sugar cane during the stage of germination and later. They appear in large numbers when the soil is dry. The young plant after germination

s eaten at the root and is rapidly destroyed. The preventive measures adopted by the natives consist in steeping the cuttings in a solution of the pounded leaves of *Adhatoda vasica*, in mustard cake, or in a solution of asafetida and common salt. An account is given of the life history of the sugar-cane borer and the usual remedies are recommended. Considerable injury is also reported from *Hieroglyphus furcifer*, plant lice, and a plant bug.

Observations on hymenopterous parasites of certain Fulgoridæ, O. H. SWEZEY (*Ohio State Univ. Bul., 7. ser., No. 23, pp. 8, pls. 2; reprint from Ohio Nat., 3 (1903), pp. 444–452*).—Brief notes on the habits and life history of *Dryinus ormenidis*, *Labeo typhlocybæ*, *L. longitarsis*, *Cheiloneurus swezeyi*, and *Gonatopus bicolor*.

The potato moth, W. W. FROGGATT (*Agr. Gaz. New South Wales, 14 (1903), No. 4, pp. 321–326, pl. 1*).—A brief account of the distribution, appearance, life history, and injuries caused by this insect. A number of complaints have been made concerning the damage caused by this species in various parts of New South Wales. The methods recommended for controlling the insect are largely preventive, such as the destruction of food plants in the fall and keeping the insect out of storerooms.

Turnip and cabbage aphis, C. FULLER (*Agr. Jour. and Min. Rec., 6 (1903), No. 9, pp. 295, 296, fig. 1*).—This insect is reported as doing considerable damage to cabbage and related crops. In controlling the cabbage aphis the author recommends the use of kerosene emulsion, which may be sprayed with a knapsack sprayer, and the use of nicotin sheep dip.

The larva and pupa of the apple-bud borer (Steganoptycha pyricolana), E. D. SANDERSON (*Canad. Ent., 35 (1903), No. 6, pp. 158–161, figs. 5*).—Descriptive and anatomical notes, especially of the mouth parts of this species.

Bryobia ribis, R. VON HANSTEIN (*Sitzber. Gesell. Naturf. Freunde Berlin, 1902, No. 6, pp. 128–136*).—This species is reported as injurious to currants, and notes are given on its life history and anatomy.

Tortrix pilleriana, J. DUFOUR (*Chron. Agr. Canton Vaud, 16 (1903), No. 11, pp. 307–311*).—Notes are given on a number of insecticide applications which were made for the purpose of destroying this pest. These remedies included black soap, oil of colza, tobacco decoction, etc. The substances were for the most part applied hot. Good results were obtained wherever the temperature of the insecticide could be carefully regulated.

Precocious development of pupal and imaginal organs in lepidopterous caterpillars, H. KOLBE (*Sitzber. Gesell. Naturf. Freunde Berlin, 1902, No. 7–8, pp. 158–166*).—Anatomical notes on *Dendrolimus pini*.

Cicadas and their habits, W. W. FROGGATT (*Agr. Gaz. New South Wales, 14 (1903), No. 4, pp. 334–341, figs. 8*).—Brief notes on the habits and life history of cicadas in general, and a detailed biological and economic account of *Cyclochila australasiæ* and *Thopa saccata*.

Galls and insects producing them, III, IV, and V, M. T. COOK (*Ohio State Univ. Bul., 7. ser., No. 20, pp. 419–436, pls. 6*).—The author investigated the histology of a number of lateral bud galls and stem galls and also studied the development of these structures. It was found that bud galls vary considerably, according to the kind of insect to which they are due. Stem galls are much less variable. A comparison is made between galls caused by mites, plant lice, Psyllidæ, Cecidomyia, Cynipidæ, and other insects.

The more important insect remedies for the month of June, H. A. SURFACE (*Pennsylvania State Dept. Agr. Mo. Bul. Div. Zool., 1 (1903), No. 2, pp. 8–16, pls. 2*).—Attention is called to the desirability of maintaining a good state of cultivation, using fertilizers, killing weeds, destroying badly infested plants and rubbish, in order to make specific remedial measures more effective. Brief directions are given with regard to the choice and application of remedies in combating insects injurious to fruit trees, field crops, small fruits, ornamental plants, and garden crops.

Experiments to test the value of Bug Death as compared with Paris green and Bordeaux and Paris green on potatoes, R. ROBERTSON (*Canada Expt. Farms Rpts. 1902, pp. 250, 251*).—The largest yield of potatoes was obtained from plants treated with Bug Death; but the cost per acre for a treatment of this insecticide was $8.40 for 2 applications, while 2 sprayings with Paris green cost only $1.15 per acre.

Chemistry of insecticides and fungicides, F. T. SHUTT (*Canada Expt. Farms Rpts. 1902, pp. 151–154*).—The author presents results of analyses of potassium cyanid, lime-sulphur-salt wash, and Bug Death. One sample of a substance labeled potassium cyanid was found to contain no potash; it proved to be sodium cyanid, from which apparently a larger quantity of hydrocyanic-acid gas could be obtained than from potassium cyanid. An experiment was made in adding potash to the California wash for the purpose of enhancing the value of this insecticide. The results indicated that the wash may be more apt to clog in the nozzle after the addition of potash, if the mixture is allowed to cool before spraying. An analysis of Bug Death indicated that this substance is chiefly an impure zinc oxid, and it is believed that the material can not act as a fertilizer, as is claimed, but may exercise a slight fungicidal action.

Notes on spraying and spray machinery, F. W. FAUROT and J. T. STINSON (*Missouri Fruit Sta. Bul. 5, pp. 24, pls. 7*).—The author discusses the subjects of insecticides and fungicides with special reference to their defects and the conditions of effectiveness. Measurements were made of the skin of a number of common varieties of apples for the purpose of determining whether the thickness of the skin was in any way connected with the degree of injury sometimes produced by Bordeaux mixture. No connection was found between these 2 factors. Detailed notes were given on the preparation of insecticides and fungicides and on the construction and management of spraying machinery. The bulletin includes a spray calendar in the form of a folio.

Pleasure and profit in honey production, D. E. LYON (*New Jersey State Bd. Agr. Rpt. 1902, pp. 295–306*).—A popular account of the biology of the honeybee and of practical methods for managing it with profit.

An original honey extracter, BLONDET (*Rev. Internat. Apicult., 25 (1903), No. 5, pp. 92, 93, fig. 1*).—A description of the advantages secured by the author in a simple form of honey extracter.

Ripe and unripe honey, F. T. SHUTT (*Canada Expt. Farms Rpts. 1902, pp. 163, 164*).—Analyses of capped and uncapped honey, which are taken as being equivalent to ripe and unripe honey, indicate that the honey from fully capped comb contains from 4 to 5 per cent less water than that from partly or entirely uncapped comb. The differences in moisture content observed in different samples of honey kept in bottles with glass stoppers and those covered with cheese cloth were exceedingly slight. Honey from uncapped or partly capped comb was found to possess poor keeping qualities and fermented more readily than mature honey.

Treatment of foul brood by means of eucalyptus, J. COMTAT (*Rev. Internat. Apicult., 25 (1903), No. 5, pp. 95, 96*).—Experiments were made with essence of eucalyptus as a remedy for foul brood. This substance was used in a number of ways, but without marked success, except when added in the form of a slightly alcoholic essence to the sirup used for feeding the bees in the spring.

FOODS—NUTRITION.

Dietary studies of groups, especially in public institutions, C. F. LANGWORTHY (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 387–410*).—The general problems which should be considered in providing a diet for large numbers fed under uniform conditions, as in public institutions, are discussed, and experimental data, which have to do with the feeding of armies, schools, hospitals, and other institutions and groups, summarized.

Canadian bakers' strong flour, F. T. Shutt (*Canada Expt. Farms Rpts. 1902, p. 160–162*).—Analyses of 4 samples of flour are reported and discussed.

Micro-organisms of the fermentation of black bread, Budinov (*Vyestnik Imp. Russ. Obsh. Akklimat. Zhiv. i Rast. Bakt. Agron. Stantz., No. 9, pp. 17–35; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 1, p. 116*).—The author studied the yeasts present in 2 samples of sour rye bread. Only one bacterium (*B. mesentericus pani viscosi II*) was found to be common to both samples, but representatives of the following 3 groups of micro-organisms were identified: (1) Peptonizing bacteria which turn the dough from thick to a more plastic state; (2) yeast which cause the dough to rise; and (3) lactic or acetic bacteria on which the sour taste and smell of the black bread depend.

The cultivation of the isolated organisms on sterilized dough was unsuccessful, owing to the difficulty of obtaining sterilized flour. It was found that the complete sterilization of the flour required a half hour's heating in an autoclave under 2 atmospheres pressure, but in this treatment the flour bakes together, darkens, acquires a specific odor and becomes unsuited to the preparation of dough and the cultivation of micro-organisms. The action of ether during 2 weeks does not sterilize the flour, and while formaldehyde vapor apparently acts better, the experiments with this have not been concluded. The author has begun the study of an anaerobic flora of yeast preparations.—P. FIREMAN.

ANIMAL PRODUCTION.

Analyses of feeding stuffs, E. F. Ladd (*North Dakota Sta. Rpt. 1902, pp. 21–27*).—Analyses are reported of hay from different sorts of millet, pigeon grass, red clover, timothy, and brome grass; of fodder from corn planted at different thickness and on different dates; of a number of varieties of millet seed and emmer, barley, corn, oats, and the following forage crops: Millet and oats, barley and oats, emmer, yellow Canadian field peas, white Russian oats, lupine grass peas, field peas and oats, Manshury barley, German millet, Japanese barnyard millet, and corn. Several varieties of wheat, and a sample of macaroni wheat flour, were also analyzed, the gluten and gliadin content being determined in addition to ordinary constituents.

Cattle-feed inspection, J. B. Lindsey (*Massachusetts Sta. Rpt. 1902, pp. 52–54*).—Notes are given on the extent of adulteration of feeding stuffs in the State during the year, and mention is made of new feeds placed on the market.

Fodders and feeding stuffs, F. T. Shutt (*Canada Expt. Farms Rpts. 1902, pp. 139–151*).—Analyses are reported of corn and clover silage, corn, clover, and sunflower silage, awnless brome hay (*Bromus inermis*), field brome hay (*Bromus arvensis*), upland and lowland hay, sedge hay (*Spartina juncea*), barley, oil cake meal, cocoanut cake, cotton-seed meal, gluten meals, corn oil cake, corn bran, wheat bran, calf meal, and mixed cattle feeds.

The author also analyzed a number of samples of mangel-wurzels, Sweedish turnips and sugar beets, reporting the average weight of root, dry matter and sugar in juice.

Methods of steer feeding, G. C. Watson and A. K. Risser (*Pennsylvania Sta. Rpt. 1902, pp. 271–279*).—In cooperation with the Pennsylvania State Department of Agriculture the comparative merits of fattening steers in pens and stalls was studied with 3 lots containing 5 animals each, the tests being a continuation of earlier work (E. S. R., 13, p. 880; 14, p. 684). After a preliminary period of 1 week the test began November 14 and continued 10 weeks. Lot 1 was fed in a large stall equivalent to 5 small ones. The steers in lots 2 and 3 each occupied small stalls. Lots 1 and 2 were supplied with water by means of automatic watering basins, while lot 3 was watered in a yard. The average daily gain per steer was 1.99 lbs. for the lot fed in large stalls and 1.49 and 1.52 lbs. for those fed in small stalls. Practically the same amounts of hay and straw were consumed by the 3 lots, but the amount of grain eaten

per pound of gain was 8.6 lbs. for the lot in the large stalls as compared with 11.2 and 11.09 lbs. for the lots in the small stalls. Less time was required for attendance when the steers were kept in the large stalls (79.5 hours) than when they were watered in small stalls (87 hours) or turned out to water (91.3 hours).

Considering this and the former tests the following general deductions were drawn: "While the gain was practically the same for an equal amount of food consumed, it was apparently in favor of the steers running loose in pens. The difference in the economy of food consumed is too slight to warrant a very definite conclusion, but the difference in time required for attendance is decidedly marked. With the use of the same amount of bedding and much less labor, the steers in the pens were kept cleaner than it was possible to keep those in the stalls."

Experiments with steers, R. ROBERTSON, S. A. BEDFORD, and A. MACKAY (*Canada Expt. Farms Rpts. 1902, pp. 253–260, 298–300, 351–354*).—In continuation of earlier work (E. S. R., 14, p. 178) the advisability of dehorning fully grown steers when fed loose or tied in stalls was tested at the Maritime Provinces Farm with 3 lots, each containing 4 3-year-olds. All were fed hay, roots, silage, and mixed meals for 5 months in the winter. The average gain of the dehorned steers fed in box stalls was 356 lbs. per head; of the dehorned steers tied in stalls 313 lbs., and of those fed in stalls but not dehorned 315 lbs.

Heavy and light steers for fattening were compared, using 2 lots of 4 animals each, averaging respectively 1,200 and 1,000 lbs. per head. In 5 months (December to May) the heavy steers made an average gain of 356 lbs. each and the lighter steers of 344 lbs. each. The cost of the feed was the same for both lots, "making a difference [in profit] in favor of the heavy steers of $5.01 per steer."

As in earlier work (E. S. R., 14, p. 178) limited and full rations were tested for a year with 2 lots of 5 calves each. Both lots were fed in the winter grain with roots and hay or hay and straw and were pastured in the summer, the lot fed the liberal ration receiving considerably more grain than the other and for a greater part of the time. The steers fed the full ration averaged 490 lbs. in weight at the beginning of the trial and made an average daily gain of 1.13 lbs. at a cost of 5.63 cts. per lb. Those fed the limited growing ration weighed at the beginning 392 lbs. on an average and gained 0.83 lbs. per head per day, the cost of a pound of gain being 3.99 cts.

In a second test under much the same general conditions 5 calves averaging 191 lbs. each fed a full fattening ration for 198 days gained 1.64 lbs. per head per day, the cost of a pound of gain being 4.38 cts., and 5 calves averaging 121 lbs. each in weight made in the same time on a limited growing ration an average daily gain of 1.35 lbs., the cost of a pound of gain being 2.55 cts.

At the Manitoba Farm spelt straw was compared with hay made from brome grass (*Bromus inermis*) and from western rye grass (*Agropyron tenerum*) as coarse fodder for steers, these being fed in each case with an equal quantity of Swedish turnips and from 6 to 11 lbs. of mixed grain. The 4 steers fed brome-grass hay gained in the 16 weeks of the test a total of 675 lbs. The same number fed the western rye-grass hay gained 660 lbs. and 3 steers fed spelt straw gained 355 lbs. The average profit per steer for the 3 lots was about $19.80.

A comparison is also reported from the Indian Head Farm of western rye grass, cut straw, and brome grass, using 3 lots of 5 steers each weighing not far from 1,130 lbs. In every case with 14 lbs. of the coarse fodder tested was fed 16 lbs. of silage together with mixed grain. In the 16 weeks of the test the steers fed western rye-grass hay gained 830 lbs. at a profit of $11.23 per head. Those fed cut straw gained 1,040 lbs. at a profit of $17.21, and those fed brome-grass hay gained 910 lbs., the average profit being $11.74.

Cattle: Beef production, J. H. GRISDALE (*Canada Expt. Farms Rpts. 1902, pp. 62, 63, 72–80*).—The station herd and Canadian cattle-feeding problems are briefly discussed, and in continuation of earlier work (E. S. R., 14, p. 178) several feeding tests are reported. Using 3 lots of 9 steers each, the relative merits of different

ethods of handling steers were studied. The steers in lot 1 were not dehorned and ere tied in stalls, each animal having 56 sq. ft. floor space. Lots 2 and 3 were ehorned and were kept loose, having 84 and 38 sq. ft. of floor space per steer, espectively. The average live weight of the steers at the beginning was not far om 1,200 lbs. and all were fed meal, silage, roots and hay for 186 days. Lot 1 (tied p) made an average daily gain of 1.65 lbs. per head at a cost of 6.22 cts. per lb. Lot (large space) gained 1.77 lbs. at a cost of 6.02 cts. per head, and lot 3 (smaller space) ained 1.86 lbs. at a cost of 5.41 cts. per lb.

The influence of the age on the cost of beef production was tested with 3-year-olds, -year-olds, yearlings, and calves, the first 3 lots containing 9 animals each and the ast 5. During the trial (180 days for the calves and 186 days for the others) all the nimals were fed meal, silage, roots, and hay. The 3-year-olds made an average aily gain of 1.65 lbs. each at a cost of 6.22 cts. per lb. The 2-year-olds gained 1.67 os. at 5.7 cts., the yearlings 1.85 lbs. at 4.65 cts., and the calves 2.14 lbs. at 3.6 cts. er lb. "In daily gain and cost of production there is a quite remarkable gradation n favor of the younger classes."

Under practically the same conditions as in earlier work (E. S. R., 14, p. 178) the elative merits of light and heavy rations were tested with 2 lots of 5 yearlings each, veraging 443 and 405 lbs., respectively, and 2 lots of 6 calves each, averaging 111 nd 113 lbs. each. In 1 year the yearlings fed the heavy ration made an average aily gain of 1.76 lbs. at an average cost of 4.33 cts. per lb., and those fed the light ation 1.15 lbs. at 3.37 cts. In 200 days the calves on the heavy ration gained on an verage 1.45 lbs. per head per day at a cost of 3.7 cts. per lb. and those on the light ation 1.33 lbs. at 2.96 cts. per lb.

Flesh and fat in beef, D. H. OTIS (*Kansas Sta. Bul. 118, pp. 185-212, figs. 17*).—For the purposes of class demonstration a large fat steer 38 months old weighing 1,790 bs., a prime steer 24 months old weighing 1,240 lbs., a poor thin cow of the sort known as a "canner" weighing 975 lbs., a "baby beef" heifer weighing 775 lbs., nd a mature grade bull were judged by an expert. All but the latter were slaughered and cut up, the dressed weight ranging from 41 per cent in the case of the thin cow to 66.5 per cent of the live weight in the case of the large fat steer. The tallow of the latter constituted 6.7 per cent of the carcass and that of the prime steer 5.5 per ent. The various cuts from the different animals were compared and discussed at ength, a veal calf being included in this part of the work to make the comparison more complete. The fat on both of the steers was pronounced of fine quality and not tallowy. Baby beef loin was free from waste fat and while not as juicy and possibly lacking the flavor of the 2 steers, the meat was tender and every portion of he carcass could be used. The cooked meat prepared in several ways was judged by a number of persons, the fat steer, the prime steer, and the baby beef ranging as regards flavor in the order mentioned when broiled or roasted. When boiled the baby beef ranked first, the prime steer second, and the fat steer third. "However, each sample if served upon the home table would be classed as excellent." The samples of boiled and roasted meat were weighed before and after cooking, but the data obtained are considered insufficient for general deductions.

Division of animal nutrition, H. P. ARMSBY (*Pennsylvania Sta. Rpt. 1902, pp. 280, 281*).—Brief statements are made regarding the work of the past year which had to do with the construction and calibration of the respiration calorimeter designed for experiments with animals, which has been built in cooperation with the Bureau of Animal Industry of this Department. The author notes that in a check experiment in which 729.9 cc. of alcohol was burned in the respiration chamber, the carbon dioxid and heat measured agreed very closely with the theoretical amounts. It is calculated that this quantity of alcohol would furnish 1,023.19 gm. carbon dioxid and 3,844 calories of energy. The amounts measured by the calorimeter were 1,023.60 gm. carbon dioxid and 3,829 calories.

"It will be seen that the errors were less than one-half per cent, a degree of accu racy which compares favorably with the most exact laboratory methods. Th results for the water produced were not so satisfactory, but the source of this erro has been apparently discovered and it is anticipated that later tests will give mor satisfactory results."

Sheep, J. H. GRISDALE and R. ROBERTSON (*Canada Expt. Farms Rpts. 1902, pp. 8 261*).—Brief notes regarding the sheep kept at the Central and Maritime Province Experimental Farms.

Sheep, W. H. DALRYMPLE (*Louisiana Stas. Bul. 74, 2, ser., pp. 197–216, figs. 11*).– The importance of improved breeds is urged, the principal breeds of sheep ar described, and sheep raising is discussed with special reference to local condition the experience of the station in raising sheep and the cultivation of different cro suited to their needs being briefly cited.

Digestion experiments with sheep, J. B. LINDSEY ET AL. (*Massachusetts St Rpt. 1902, pp. 82–101*).—This gives in tabular form the results of 185 trials with 7 feeding stuffs made at the station during the period from 1894 to 1902. The coeff cients of digestibility have been published from time to time in the reports of th station. The influence of drying and curing on digestibility was studied with whea sand vetch, and barnyard millet. The curing process apparently did not affect th digestibility of the wheat and vetch, while it noticeably decreased that of barnyar millet.

The pentosans, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1902, pp. 69–81*).—Th author reviews the literature relating to the determination and digestibility of pe tosans, and reports in tabular form the experiments on this subject which have bee made with sheep at the station, the principal data obtained being summarized in th following table:

Digestibility of pentosans and other constituents in experiments with sheep.

Feed stuff.	Pento-sans in feed.	Digestibility.				
		Protein.	Fat.	Nitrogen-free extract.	Crude fiber.	Pento-sans.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cen*
English hay, average 6 tests	21.28	59.73	49.49	60.39	61.03	[a] 62.
Meadow or swale hay	18.25	33.88	43.60	46.03	32.97	28.
Barnyard millet hay	23.35	63.67	46.34	51.58	61.59	60.
Black grass, average 2 tests	25.08	58.58	43.58	52.69	58.92	55.
Fox grass, average 3 tests	26.77	59.67	35.61	52.79	53.02	48.
Branch grass, average 2 tests	26.28	56.97	34.06	49.76	54.33	49.
Cove mixture (black grass and redtop)	22.24	47.92	40.33	53.19	59.68	53.
Salt mixture (fox grass and branch grass)	24.09	41.72	27.90	52.28	57.51	48.
Flat sage (*Spartina stricta maritima*)	23.82	51.77	36.14	55.05	60.42	58.
Buffalo gluten feed, average 2 tests	16.93	86.04	87.29	84.16	66.02	82.
New process linseed meal	13.21	87.24	91.01	85.51	61.23	88.
Old process linseed meal	13.24	88.79	88.59	77.55	57.02	83.
Corn cobs	30.35	17.38	50.11	60.04	65.33	63.
Dried brewers' grains	23.77	79.26	91.11	57.83	52.57	56.
Wheat bran, average 2 tests	26.08	79.08	68.07	70.40	39.93	63.
Atlas meal	12.76	72.80	91.24	84.45	105.70	90.
Peanut feed	20.69	70.56	89.68	49.05	11.68	40.
Soy-bean meal	5.18	90.05	85.02	72.17	50.42	64.

[a] Five tests only.

The conclusion is drawn "that the pentosans are as digestible as any of the oth fodder groups (except in the presence of excessive incrusting substance), and th the digested material is practically utilized in the animal organism to the same degr as the other carbohydrates."

Swine, J. H. GRISDALE, R. ROBERTSON, S. A. BEDFORD, and A. MACKAY (*Cana Expt. Farms Rpts. 1902, pp. 80–81, 260–261, 300–302, 354*).—At the Maritime Pro inces Farm the relative merits of feeding in pastures and pens was studied with

lots, each containing 10 pigs 2 to 4 months old, weighing not far from 50 lbs. each. Both lots were fed a ration of 3 lbs. of buckwheat, shorts, and wheat bran with 5 lbs. of skim milk. In each case 3 of the pigs were fed for 85 days, 3 for 102, and the remainder for 120 days. The average daily gain of the pigs fed in pens ranged from 1.01 to 1.34 lbs., and those fed in pasture from 1.13 to 1.3 lbs. per head.

At the Manitoba Experimental Farm the value of lamb's quarter seed (*Chenopodium album*) as part of a ration was studied. This material was boiled, mixed with chopped oats, barley, and wheat screenings, 2:1:1, and fed wet for 76 days to a lot of 2 crossed breed Tamworth pigs. They weighed together when purchased 337 lbs. and gained 221 lbs., the estimated profit being $5.04. Two similar pigs fed the grain ration without lamb's quarter seed gained 230 lbs., the estimated profit being $4.22. "It would appear that lamb's quarter seed has a limited value as food for pigs."

In a test covering 82 days the feeding value of roots (potatoes and turnips, 2:1) as part of a ration was studied with 2 lots of 2 pigs each, averaging less than 100 lbs. in weight. The roots were boiled, mashed and mixed with ground barley, oats, and wheat screenings. The pigs fed this mixture gained 201 lbs.; and the 2 fed the same grain ration but no roots gained 195 lbs. The estimated profit in the 2 cases was $3.78 and $4.37.

"It would appear from this test that potatoes and turnips can be used to replace a portion of the grain ration but they are worth less than 20 cts. per bushel for that purpose."

Profitable pig feeding, G. W. WATERS (*Missouri State Bd. Agr. Mo. Bul., 2 (1903), No. 12, pp. 4–20, figs. 7*).—The possibility of feeding pigs profitably is discussed on the basis of experiment station work, and a number of tests at the Missouri Station are briefly quoted on the comparative value of blue grass, red clover, alfalfa, and rape as pasturage. In each case 6 pigs averaging about 40 lbs. in weight at the beginning of the trial were fed for a period of 90 days. One lot made an average daily gain of 0.71 lb. per pig on corn and blue grass, consuming 5.2 lbs. grain per pound of gain. On corn and green clover the second lot made an average daily gain of 0.87 lb. per pig, requiring 4.29 lbs. of grain per pound of gain. On corn and green alfalfa the average daily gain was 0.95 lb., and on corn meal and rape 0.78 lb., the grain required per pound of gain in the 2 cases being 3.97 and 4.82 lbs., respectively. For purposes of comparison, a lot of pigs was fed corn and skim milk and gained 1.81 lbs. per head per day, on an average, requiring 2.44 lbs. of grain per pound of gain.

In the author's opinion these experiments emphasize the value of supplementing a corn ration. It is further pointed out that when clover hay, alfalfa and skim milk were used cheaper and more rapid gains were made. The importance of different forage crops is discussed.

The swine industry in Missouri (*Missouri State Bd. Agr. Mo. Bul., 2 (1903), No. 12, pp. 3, 4*).—Statistics are given of the pig industry in Missouri as compared with other States.

The production of firm bacon, J. H. GRISDALE (*Ontario Agr. and Expt. Union Rpt. 1902, pp. 41, 42*).—A general discussion, based on the work of the Canadian experiment stations. Feeding pigs too rapidly "feeding off," that is, marketing pigs before maturity, and feeding any ration not conducive to health the author believes will cause soft bacon. As regards feeding, "corn fed with a small proportion of skim milk or whey gives much better results [than corn only]. After the skim milk or whey constitutes 10 or 15 per cent of the dry matter of the ration, the proportion does not appear to greatly matter. . . . A small proportion of corn with the cereals, oats or barley, or with peas, does not appear to have a very injurious effect. Barley is unsurpassed as a feed for the production of firm bacon. Oats, also, are most excellent. Peas produce good results, and, mixed with other grains, are exceedingly valuable.

In conclusion, skim milk or whey are almost infallible guarantees of firm pork. The cereals and peas properly fed constitute an almost faultless ration. Corn may be fed, but must have some counteracting food along with it, or it will give bad results."

Horses, J. H. GRISDALE, R. ROBERTSON, and A. MACKAY (*Canada Expt. Farms Rpts. 1902, pp. 61-63, 252, 355.*)—Brief statements are made regarding the horses kept at the Canada experimental farms. On an average the cost of feed per horse per day was at the Central Experimental Farm 27.33 cts. and the cost of care 8 cts. additional. In a test made at the same place of the relative value of mixed grains fed with hay chopped into pieces about half an inch long, 7 horses, weighing about 1,400 lbs. each, gained, on an average 83 lbs. per head in 91 days on a daily grain ration of 17.33 lbs. ground oats. Three similar horses fed 18 lbs. per head daily of a mixture of equal parts of ground oats and barley made an average daily gain of 70 lbs. per head in the same time, and 3 horses fed 17 lbs. per head of ground oats and barley, 2:1, gained 52 lbs. each. "All the horses continued in good health during the experiment and so far as could be judged any one of the grain or meal rations was as good as another."

Experiments in chicken fattening, F. T. SHUTT (*Canada Expt. Farms Rpts. 1902, pp. 218-230, pl. 1*).—The food requirements of poultry are briefly discussed and a number of feeding tests reported. The relative gains made by different breeds on a ration of ground oats, ground barley, and meat meal (4 : 3 : 1) with sufficient skim milk to make a mash, and supplemented by whole wheat in the evening was studied with Barred and White Plymouth Rocks, Faverolles, Silver Gray Dorkings, Buff Orpington, Rhode Island Reds, White Indian Game, White Wyandottes, and Plymouth Rock × Light Brahma crosses. The number of chickens ranged from 4 to 6 per lot. In the 6 weeks of the test the average gains in weight ranged from 1 lb. 8 oz. with the White Indian Games to 3 lbs. and 2 oz. with the Plymouth Rock × Light Brahma crosses, the cost of a pound of gain ranging from 3.7 cts. with the cross-breed chickens to 4.7 cts. with Rhode Island Reds.

Unground and finely ground grain were tested with 2 lots of 6 Barred Plymouth Rock chickens 12 weeks old, weighing about 3.25 lbs. each at the beginning of the test, the feeding stuffs used being the same as mentioned above. The chickens fed the grain whole made an average gain of 1 lb. 10.5 oz. per head in the 6 weeks of the test, the cost of a pound of gain being 7.1 cts. Similar values for the chickens fed the grain finely ground were 2.12 lbs. and 5.6 cts. In this and the experiments described below the chickens were killed and dressed at the close of the trial and the proportion of edible and nonedible parts was ascertained and the flesh was cooked and its quality judged. As regards the effects of whole and ground grain, the birds fed the latter when dressed were plumper, slightly yellower, of better appearance "and were also considered to furnish on cooking the juicier or richer meat, due evidently to a marked (though not excessive) deposition of fat in the tissues."

The comparative merits of skim milk and water for wetting feed were studied with 2 lots each containing 3 Rhode Island Reds and 3 Orpingtons, weighing not far from 2 lbs. each, and 2 lots each containing 6 Barred Plymouth Rocks, averaging not far from 3.5 lbs. each. The ration was made up of ground oats, barley, and meat meal 4:3:1. In the 6 weeks of the test the Rhode Island Reds and Orpingtons fed the ration wet with skim milk made an average gain of 2 lbs 2 oz. per chicken while those fed the ration wet with water gained 1 lb. 13 oz., the cost of the pound of gain in the 2 cases being 4.7 cts. and 5 cts. The gains made by the Plymouth Rocks on the skim milk ration averaged 2 lbs. 10 oz. per head, the cost of a pound of gain being 5.7 cts. Similar values for the chickens fed the ration mixed with water were 1 lb. 15 oz. and 6.7 cts. It is stated that the chickens fed the ration wet with milk were decidedly better in appearance, being plumper and yellower when dressed, and more juicy and better flavored when cooked.

In continuation of earlier work (E. S. R., 14, p. 180) the relative merits of feeding chickens in pens and crates was studied with 2 lots of 6 Silver Grey Dorking pullets and 2 lots containing the same number of Barred Plymouth Rock cockerels, the former weighing about 2 lbs. and the latter between 3 and 4 lbs. each at the beginning of the trial. The ground oats, ground barley, and meat meal mixture wet with skim milk mentioned above were fed. The trial covered 4 weeks with the pullets and 6 weeks with the cockerels. The pullets fed in pens gained on an average 1 lb. 9 oz., and those fed in crates 1 lb. 6 oz. each; the cockerels fed in pens 3 lbs. 1.2 oz., and those fed in crates 2 lbs. and 7 oz., the cost of a pound of gain being, respectively, 3.3, 4.5, 5.7, and 6.8 cts. "All the birds were excellent table fowl, but the pen-fed presented the finer appearance as to color and size. Though it was difficult for some of those who tested the dressed meat to note any difference as regards juiciness, the majority considered the pen-fed fowl as the better in this respect."

Gluten meal and clover meal were tested with 2 lots, each containing 6 Barred Plymouth Rock cockerels weighing not far from 3 lbs. per head on an average. In 6 weeks the birds fed ground oats and gluten meal wet with skim milk made an average gain of 2 lbs. 9 oz. per head, at a cost of 4.6 cts. per pound. The cockerels fed ground oats, ground clover, and meat meal, gained 2 lbs. 3 oz., the cost of a pound of gain being 6.6 cts. The chickens fed the gluten meal were better filled out, of better color and finer appearance when dressed than the others, and their flesh was considered juicier and more delicate.

According to the author the gluten-meal ration "has given such satisfactory results from every standpoint that it merits further investigation. Gluten meal has shown itself with other classes of farm stock an easily digested, concentrated food of great value, and we are encouraged in further work with poultry to experiment with it in varying proportions with other meals. The indications are that it will prove a profitable flesh-producing food in chicken fattening."

Taking into account all the tests in which such data were recorded, the proportions of different materials removed in dressing and drawing the 72 chickens of different breeds, calculated on the basis of the weights of the chickens as killed, was as follows: Dressed and drawn carcass, not including the giblets, 66.4; giblets, 5.5; head and feet, 11.2; feathers, 8.3, and entrails, 8.5 per cent.

Poultry experiments, W. P. BROOKS and H. M. THOMSON (*Massachusetts Sta. Rpt. 1902, pp. 153–155*).—A brief summary is given of the results of feeding experiments with poultry during the year. Several feeding stuffs were compared in rations having different nutritive ratios. The more important results are stated as follows:

"In the comparison of wheat with corn, where beef scraps are the source of animal food, the egg production has been good and nearly equal on the 2 rations, although the hens receiving the wheat ration have been somewhat the most productive.

"In the comparison of wheat with corn, with milk albumin as the source of animal food, the egg production has been less satisfactory, and the hens which have received the corn ration have been the more productive.

"In the comparison of buckwheat and corn, with milk albumin as the source of animal food, the egg yield has been rather small, with the advantage decidedly in favor of the corn."

In the comparative tests of wheat and corn for several years the results have not been entirely consistent.

Report of the poultry manager, A. G. GILBERT (*Canada Expt. Farms Rpts. 1902, pp. 203–216, pl. 1, figs. 2*).—The conditions of success in poultry raising, early market types, and other problems are discussed and statements made regarding the progress of the station poultry. In order to ascertain the effect of close confinement, as compared with an abundance of fresh air, on the strength of germs and the number

and vitality of the chicks, a record was kept of the eggs set and chickens hatched from a number of lots of hens which were closely confined in a warm house during the winter, as compared with those which were allowed to run in cold, fresh air.

According to the author, the results showed that "the chicks from the eggs of hens which had voluntary run during winter proved strong and lived, while the chicks from the closely confined died, with the exception of 2, which did not make satisfactory growth. . . . Germs evidently became strong at 12 or 15 days after the hens had a run outside. This will answer a question often asked as to when the eggs of hens closely confined become strong. . . . Results from eggs put into an incubator during early springtime were very similar to those obtained from eggs under hens at the same period. There was a large and discouraging number of chickens dead in the shell, at or about the pipping stage. This great mortality in fully developed chickens almost ready to leave the shell has been and is the subject of much discussion. . . . Investigation into and discussion of the subject, up to the present time seem to warrant the call for 'fresh air and more of it for breeding stock and incubators.'"

Figures are given showing the gains made by the station chickens in 3 months. The weight of cockerels ranged from 3 lbs. 2 oz. in the case of White Wyandottes and Faverolles to 5 lbs. 1 oz. in the case of second cross Light Brahma × Barred Plymouth Rocks. The effect of early penning up of fowls was shown by the fact that 70 kept in a poultry house with a run during the month of November laid 192 eggs, while during the same time 147 hens and pullets allowed to run at large in a field laid 132 eggs. "The advantage is apparently with the penned fowls."

Brief statements are also made regarding the rations fed the station poultry, the eggs laid during the year, and during the months when prices were highest.

Subdepartment of poultry report, H. C. GARDINER (*Montana Sta. Rpt. 1902, pp. 96–100*).—According to the experience of the station, poultry houses may profitably be heated, an average temperature of 45–50° F. being regarded as most satisfactory. Little artificial heat is required in a properly constructed house while the sun is shining. "The most successful method of heating poultry buildings, and the only practical method for poultry plants, is a hot-water pipe system, but for the average building a small stove serves the purpose admirably."

The advantages of shade for poultry in summer are discussed. In the experience of the station, Mammoth Russian sunflower is very satisfactory for this purpose. The plant makes a large growth, affords abundant shade and also protection from hawks, while the mature heads are a useful feed. The need of green forage for poultry is also spoken of, clover being recommended for permanent pasturage and oats for early forage.

In the experience of the station Brown Leghorns are the most satisfactory breed for raising under local conditions. The results of 3 years' experimenting shows that the large combs and wattles, which are a disadvantage in a northern climate, may be greatly diminished in size by care, breeding, and selection.

Cooperative poultry experiments. The yearly record of three flocks, H. H. WING (*New York Cornell Sta. Bul. 211, pp. 261–279, fig. 1*).—With 3 of the flocks included in a test previously reported (E. S. R., 14, p. 486) the station has continued cooperative poultry experiments in order to secure data covering one year. The 3 flocks contained on an average from 290 to 509 birds, exclusive of males. In the year from December 1, 1901, to November 30, 1902, which includes the 3 months of the earlier test, the average daily egg production for the 3 flocks representing 1,250 fowls was 34.7 eggs per 100 fowls. The total yearly production per hen averaged 129.1 eggs, the average cost of food per dozen eggs was 9.2 cts., the cost of feeding a hen for the year 99.6 cts., and the average selling price of the eggs 21.4 cts. per dozen. "The average value of the eggs at market rates exceeded the cost of food by $1.31 per hen. Forty-four per cent of the total value of product was required for food."

Poultry experiments, C. CURTICE (*Rhode Island Sta. Rpt. 1902, pp. 333–373, pls. 7*).—Changes which have been made in the location of the poultry houses and in the plans for poultry work are described, and experiments with different kinds of incubators under a variety of conditions are reported, part of the experiments being made in connection with the regular work of students at the agricultural college.

In some of the tests differences were observed in the percentage of eggs hatched in different tiers of incubators, and this point was further studied to determine the effect of inside and outside temperature. It was found that the temperature inside the different tiers of incubators varied much less than the outside temperature. In some cases the largest hatch was obtained in an upper tier, in others in the lower, but in the author's opinion the increase in the percentage of eggs hatched could be directly attributed to more heat. The data obtained in the experiments, he believes, "show that too little heat arrests development. There seems to be no indication that an increase of heat to the amount used in these experiments kills the chicks in the later stages. The conditions found indicate that the majority exhausted their vitality in reaching the particular stage where death ensued, and that more heat favored further advancement."

The author states that, considering the year's work as a whole, only moderate success was obtained as regards the proportion of eggs hatched. "As a rule, the low percentage of efficiency in incubating eggs in winter has been ascribed to the condition of the winter egg and the hen; that is to say, it is claimed that the winter embryos have less vitality than the spring embryos. The winter experiments show, however, that, while no entire lot of hatches was extra good in any month, there were some in all of the months that were good, and in fact much better than the average for any month. This indicates that the hatching is at greater fault than the eggs. In other words, until more uniformity is obtained in handling machines of the same make, set in the same room at the same time, we must consider the weather and incubator conditions before complaining of the eggs."

Various problems connected with poultry hatching are discussed, and brief notes given regarding the broods tested and the post-mortem examination of chicks which died within 2 or 3 weeks after hatching. Some experiments have been begun for the study of "blackhead" in turkeys, and it is proposed to continue the work.

Poultry, R. ROBERTSON, S. A. BEDFORD, and A. MACKAY (*Canada Expt. Farms Rpts. 1902, pp. 261, 262, 302, 355*).—Brief statements regarding the poultry kept at 3 of the Canadian experimental farms. At the station for the Maritime Provinces a large percentage of the chicks hatched with incubators and under a hen died at the pipping stage, especially in the case of the early hatches.

Report of cooperative experiments in poultry work, W. R. GRAHAM (*Ontario Agr. and Expt. Union Rpt. 1902, pp. 37–39*).—A brief report with discussion of cooperative experiments in hatching eggs with incubators.

The preservation of eggs, F. T. SHUTT (*Canada Expt. Farms Rpts. 1902, pp. 216–218*).—The relative merits of different methods of preserving eggs was tested in continuation of previous work (E. S. R., 14, p. 180), the materials used being saturated limewater, with and without common salt; sodium silicate (water glass), common salt, permanganate of potash, calcium chlorid, and magnesium chlorid. As in former years, the best results were obtained with the saturated limewater.

"This fifth season's work with egg preservatives furnishes further corroboratory evidence of the value of limewater. Of the solutions experimented with, it has proved the most satisfactory. It is certainly equal to water glass in effectiveness and is to be preferred to this much advertised preservative on the grounds of economy and ease of preparation. . . . The solubility of lime at ordinary temperatures is 1 part in 700 parts of water. Such a solution would be termed saturated limewater. Translated into pounds and gallons, this means 1 lb. of lime is sufficient

to saturate 70 gals. of water. However, owing to impurities in commercial lime, it is well to use more than is called for in this statement. It may not, however, be necessary, if good, freshly burnt quicklime can be obtained, to employ as much as was at first recommended, namely, 2 to 3 lbs. to 5 gals. of water."

Further experiments with thoroughbred geese, T. H. TAYLOR, Jr. (*Rhode Island Sta. Rpt. 1902, pp. 374-378*).—Experiments with geese made in 1901 in continuation of earlier work (E. S. R., 10, p. 990) are reported, Embden, Toulouse, African, Brown China, and White China breeds being compared. Brief statements are made regarding rations fed the geese. The egg production ranged from 5.75 per bird with the White China to 22.25 with the Toulouse, averaging 13.3 for all the breeds. The percentage of fertile eggs ranged from 12 with the Embden to 50 with the Toulouse, and the percentage of fertile eggs which hatched ranged from 31 with the Toulouse to 75 with the Brown China. After hatching, the goslings were fed at first fine cracked corn and bran moistened with hot water, and were allowed access to tender grass; when this was not available such green feed as cabbage, green rye, or lettuce was substituted. After 2 weeks they were given a mixture of equal parts of coarser cracked corn, ground oats, and bran, and after 8 weeks the oats were omitted and the amount of cracked corn increased. Twenty-three of the 25 goslings hatched lived to reach the age of 10 weeks, at which the birds were considered fit for market. The average weight then ranged from 4.75 with the Embden to 7.50 lbs. with the White Chinas.

"Under the circumstances the experiment indicates that the preference should be given to the Africans, as they seem to have done the best when the numbers averaged are considered. This, too, is in line with the popular opinion among those who raise thoroughbred geese for market. The Africans are generally acknowledged to be the quickest growing of any of the thoroughbred geese."

Experimental studies in oyster propagation, 1902, J. NELSON (*New Jersey Stas. Rpt. 1902, pp. 331-369, pl. 1, figs. 6*).—Continuing work previously reported (E. S. R., 14, p. 602), special attention was paid to the early development of the oyster embryo, one of the principal objects being to ascertain whether varieties of oysters differed in their developmental viability. The failure of fertilized eggs to develop as far as the shell stage, which was observed in most of the lots experimented with earlier, was attributed to one of the three following causes, namely, that the proper variety of oysters was not used, that the eggs were not properly handled, or that they were not in a proper stage of maturity. The experimental studies which were carried on do not, in the author's opinion, warrant final deductions, yet considerable information has been secured.

"First of all we found that native seed is not superior in developmental vitality to oyster seed imported from distant localities. Contrary to expectation, southern plants were found to equal or possibly to exceed native seed in developmental constitution. We found that the successful viability is not confined to any one variety of seed.

"Next, we found that the most careful handling of the eggs did not seem to secure the desired viability in the great majority of the experiments. In those experiments that showed the desired viability no especial care was taken.

"Thirdly, we worked with eggs of the very choicest appearance and as mature as possible, using both those that were just about to be spawned out and those that remained after the oyster had begun spawning.

"Apparently, as a result of careful selection in this regard, we obtained a higher percentage of viability during the season just past than during any previous season. This result is in harmony with our fundamental dictum, viz, that the success of oyster development depends on the inherent vitality of the eggs. Nevertheless, there are some puzzling features connected with the results of our experiments, and it seems as if it would be necessary to make a careful study of natural spawning on natural beds to clear up these matters."

DAIRY FARMING—DAIRYING.

Feeding dairy cows, D. W. MAY (*Kentucky Sta. Bul. 106, pp. 45–79, pls. 3*).—This is a general discussion of the principles involved in the feeding of dairy cows, including observations and results of experiments at the station and a review of considerable literature on the subject, references to which are given. Some of the results at the station may be noted. A nutritive ratio of from 1:5 to 1:6 has given the best results. Animals of the station herd scoring highest have been the largest and most economical producers of milk and butter.

The records of the herd for 4 years show an average decrease of about 5 per cent of milk and 3 per cent of butter per month during the first 4 months of the lactation period and an average decrease of 8.1 per cent of milk and 7.4 per cent of butter per month during the first 8 months. Data are given showing the decreased yield following irregular milking and other unusual conditions incident to the exhibition of cows at local fairs. Considerable variations in the character of the feed were followed by only small monthly variations in the fat content of the milk. Exposure of 18 cows to a very heavy rain for 2 hours in December caused a decrease in the yield of milk of 24.4 and 12.5 lbs., respectively, on the 2 days following. Exposure of cows to storms in summer had very little effect upon the yield of milk.

Cows receiving heavy rations of grain, silage, and clover hay in April showed a marked increase in yield upon being turned on rye pasture. Feeding grain to cows on pasture was unsatisfactory, 60 lbs. of grain being required to gain 2.9 lbs. of milk during the first week and 5.2 lbs. the second week. Silage was fed to cows turned on pasture in the spring with good results. The addition of sugar beets to a ration containing silage was found to be unprofitable. Experiments to determine the amount of grain that should be fed indicated that no hard and fast rule can be given. Bran gave slightly better results than shorts in comparative tests. The addition of linseed meal to a ration including bran and corn in the spring profitably increased the yield of butter. In the summer the increased yield was not sufficient to pay for the additional cost. Cotton-seed meal gave better results than bran when fed to cows on pasture. Cotton-seed meal was also profitably substituted for a part of the corn ration. Germ meal was compared with corn-and-cob meal, with results which, while somewhat conflicting, seemed to favor the germ meal.

The influence of a variety in the rations of dairy cows, H. HAYWARD (*Pennsylvania Sta. Rpt. 1902, pp. 314–320*).—Eight cows were fed a uniform grain ration for a period of 40 days, when they were divided into 2 lots, one lot being fed the same ration for a second period of 40 days and the other lot practically the same amount and kind of food but arranged in 2 rations alternating every 5 days. During a third period both lots were fed the control ration. Detailed data are given as regards the food consumed and the milk, fat, and solids-not-fat produced, and the following conclusions are drawn tentatively from the results obtained: "A variety in the ration of a dairy cow as used in this experiment has no influence upon the amount of milk produced nor upon its composition. A constant, palatable ration may be fed with less trouble, perhaps more cheaply, and with better results than one which is being constantly varied."

The influence of the nutritive ratio upon the economy of milk and butter production, H. HAYWARD (*Pennsylvania Sta. Rpt. 1902, pp. 321–396*).—The work here reported in detail consisted of 3 experiments, the first being made in 1896 and the last completed in 1899. Ten cows arranged in pairs and thus constituting 2 lots were used in each experiment, which was divided into 5 periods of about 40 days each. During the first and last periods all the cows, and during the intervening periods the 5 cows constituting lot 1 or the control lot, were fed a uniform ration. The other 5 cows, during periods 2, 3, and 4, received rations having varying nutritive ratios. In the first 2 experiments the digestible matter in the grain consumed

was computed from average analyses of feeding stuffs. In the third experiment th feeding stuffs were analyzed. The following table sumarizes some of the data for th three experiments:

Influence of the nutritive ratio upon milk production.

	Lot.	Nutritive ratio.	Total digestible nutrients consumed.	Daily yield of milk.	Daily yield of fat.	Daily yield of solids-not-fat.	Fat content of milk.	Cost of ration.	Profit from milk.	Protein eaten per pound of milk
Experiment I:			*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Per ct.*	*Cents.*	*Cents.*	*Lbs.*

Period 3	1	1:6.50	14.87	14.74	.690	1.250	4.76	19.8	2.3	.12
	2	1:11.3	16.58	14.28	.690	1.230	4.83	19.1	2.3	.07
Period 4	1	1:6.40	14.55	11.74	.600	1.090	5.07	19.8	— 2.2	.15
	2	1:8.30	15.85	13.02	.650	1.130	4.96	19.8	— .3	.10
Period 5	1	1:6.20	14.43	10.89	.520	.960	4.77	19.8	— 3.5	.16
	2	1:6.30	15.67	12.94	.650	1.160	5.05	20.1	— .7	.14

The author draws the following conclusions tentatively: "The nutritive ratio between the limits of 1:3.4 and 1:11.3 had no effect upon the quantity or quality o milk production. One and three-tenths pounds of computed digestible protein wa sufficient for a 1,000 lb. cow in full milk, the other conditions necessary to her wel fare being met. Within certain limits the quantity, digestibility, and palatability of the food, and its effect upon the animal's general system was of more importanc than the relative amount of digestible protein and carbohydrates the ration con tained. The individuality of the cows experimented upon is an important factor t be reckoned with in investigations of this kind. The term 'balanced ration' is very indefinite one and may be misleading."

Report of the assistant in dairy husbandry, C. B. LANE (*New Jersey Stas. Rpt 1902, pp. 291–327, pls. 9*).—Notes are given on the 12 kinds of forage crops grown for the dairy herd during the year, data as to yield, cost of production, etc., bein tabulated. The average yield of alfalfa for 5 years was 19.32 tons of green forage equivalent to 4.83 tons of hay per acre. The average cost of production was $26.5 per acre. Disking alfalfa proved beneficial. Of the several varieties of corn grown for forage the best yields were made by Monmouth White. Data are also given i tabular form for the different soiling crop rotations which have been practiced at th station. Conditions affecting the value of forage crops, such as stage of maturity palatability, influence upon the flavor of milk, etc., are briefly discussed.

During the period from May 1 to November 1, when soiling crops were fed, th average yield of the herd for 6 years was 3,457 lbs. of milk and 173.8 lbs. of butter

and during the other 6 months of the year, when silage was fed, the average yield was 3,050 lbs. of milk and 156 lbs. of butter. The use of nitrate of soda at the rate of 150 to 160 lbs. per acre was found to be profitable in the case of rye, wheat, and barnyard millet, and slightly unprofitable in the case of barley sown very late in the season. Liming proved beneficial in all the tests made.

Data concerning the fertilizing elements contained in the feeding stuffs purchased and in the milk produced by the dairy herd showed a decided gain to the farm during the 6 years in which dairying in relation to soil exhaustion has been studied.

Four cases of milk fever, with 3 recoveries following the Schmidt treatment, are reported.

The average cost of milk production for 6 years was 2.39 cts. per quart, which includes food, labor, and interest on and decrease in the value of the herd.

A monthly record of 22 cows for the year ended April 1, 1902, is given. The average yield of milk per cow was 6,671.1 lbs. and the average fat content of the milk was 4.22 per cent. The waste in handling and delivering milk during the year was 2 per cent, as compared with 10.8 per cent in 1897.

Dairy herd records, J. H. Grisdale and R. Robertson (*Canada Expt. Farms Rpts. 1902, pp. 63–72, 252, 253*).—Records for one year are given of 26 cows at the Central Experimental Farm and 22 cows at the Experimental Farm for the Maritime Provinces.

Tests of pure-bred cows, J. B. Lindsey (*Massachusetts Sta. Rpt. 1902, pp. 57–60*).—Seven-day tests of 10 Jersey cows are reported. Of the 133.38 lbs. of fat produced by the 10 cows, 128.59 lbs., or 96.41 per cent, was recovered in the manufactured butter. Analyses of 16 samples of the butter showed the following average composition: Water 14.03 per cent, fat 82.88 per cent, salt 2.45 per cent, curd 0.74 per cent.

Milking experiments, J. H. Grisdale (*Canada Expt. Farms Rpts. 1902, p. 70*).—Four experiments to determine the effect upon the yield and quality of milk of milking cows at unequal intervals are briefly summarized. The results are considered as indicating that—

"(1) Slight inequalities in the intervals between milkings do not affect the average percentage of fat in the daily yield of milk, nor the average daily yield of milk.

"(2) Very considerable inequalities in the intervals between milkings would appear to affect slightly both the quantity and quality of the milk produced, the quantity being reduced and the quality somewhat inferior. The amount of butter fat in 100 lbs. of milk seemed to be reduced by about 3½ per cent.

"(3) Very considerable inequalities in the intervals between milkings affected the amount of milk and the percentage of fat in the milk at the different milkings. The amount of milk after the long interval was much greater than that yielded after the short interval, but the percentage of butter fat in the milk after the long period was much lower than the percentage of fat in the milk after the short interval.

"(4) On the whole, it would appear that inequalities in the intervals between milkings need arouse no anxiety as to their effect upon the quantity or quality of the product, provided no considerable sudden changes are made."

The bacterial contamination of milk, F. C. Harrison (*Rev. Gén. Lait, 2 (1903), Nos. 20, pp. 457–463; 21, pp. 481–489; 22, pp. 510–519; 23, pp. 538–546*).—The author discusses the infection of milk by bacteria contained in the udder and contamination from the exterior of the animal, from the milker, from the air of the stable, and from dairy utensils, reviewing considerable literature to which references are appended, and reporting briefly the results of experiments conducted by himself. The experiments relating to the bacterial flora of freshly drawn milk have been noted from another source (E. S. R., 14, p. 907).

In the author's experience the use of a milking machine greatly increased the bacterial content of the milk. The purification of milk by centrifugal separation was investigated. The bacterial content of the cream and skim milk mixed after separation was greater than that of the milk before separation in 21 out of 30 experiments.

The number of liquefying bacteria was largely increased by separation. The results tend to show that this method of purification, so far as bacteria are concerned, is ineffectual.

From 12,000 to 42,000 bacteria per minute were deposited in a 12-in. pail during bedding, while only 400 to 2,000 were deposited per minute 1 hour after this operation. From 215,000 to 806,000 bacteria per cubic centimeter were found in the washings of cans poorly cleaned, from 15,000 to 93,000 in the washings of cans washed in tepid water and then scalded, and from 300 to 1,800 in the washings of cans washed in tepid water and then steamed for 5 minutes.

Bacteria in normal milk and their relation to the ripening of cheese, E. von Freudenreich and J. Thöni (*Landw. Jahrb. Schweiz, 17 (1903), No. 3, pp. 234–246; Ann. Agr. Suisse, 4 (1903), No. 4, pp. 215–229; Rev. Gén. Lait, 2 (1903), Nos. 11, pp. 241–247; 12, pp. 271–280*).—Studies were made of the milk of 15 cows to determine the number and species of the bacteria present. The milking was done with the utmost care to prevent contamination, and gelatin plate cultures were made immediately, one drop of the milk from each quarter of the udder being used in separate cultures. Whey-agar stab cultures were also made for the purpose of determining the presence or absence of lactic-acid bacteria.

The experiments were made in March, 1902, and repeated in April. As regards the total number of bacteria great variations were observed with the different cows and with the different quarters of the udder of the same cow. The species consisted practically of micrococci and a nonliquefying Bacterium. Lactic-acid bacteria were invariably absent. The micrococci consisted of both liquefying and nonliquefying forms, of which the nonliquefying seemed on the whole to predominate. As the nonliquefying micrococci as well as the nonliquefying Bacterium disappear early in cheese, these organisms were not studied. The liquefying micrococci were grouped according to their morphological and cultural characters into 4 types, some of which included several varieties. The different forms are described, as is also a rapidly liquefying Bacterium isolated from cheese.

Numerous small experimental cheeses were made in order to study the influence of the different liquefying organisms. The milk used for this purpose was obtained with great care and contained on an average 104 bacteria per cubic centimeter. Bacteriological and chemical examinations were made of the cheeses 7 days after making and again at the end of 5 or 6 months. As in earlier experiments, cheeses made without the addition of cultures showed almost no ripening. The best results were obtained by the use of a liquefying micrococcus isolated from Emmenthaler cheese and closely resembling a micrococcus isolated in one or two instances from milk. The results with the micrococcus isolated from milk were favorable as regards the taste of the cheese, and a further study is to be made of this organism. The other organisms isolated from milk rendered the casein soluble to a greater or less extent, but the cheeses inoculated with them did not undergo normal ripening.

The micrococcus isolated from cheese is believed to be the only one of importance in the ripening of Emmenthaler cheese, and the rôle here played is that of rendering the casein soluble, making it more assimilable to the lactic-acid bacteria which later predominate and which are the principal agents in cheese ripening.

The presence of bacteria in the cow's udder, E. von Freudenreich (*Landw. Jahrb. Schweiz, 17 (1903), No. 3, pp. 201–222; Ann. Agr. Suisse, 4 (1903), No. 4, pp. 185–206; Rev. Gén. Lait, 2 (1903), Nos. 16, pp. 361–370; 17, pp. 385–394; 18, pp. 40[illegible]–417*).—Following a review of the literature of this subject bacteriological examinations of the udders of 15 cows are reported. Gelatin cultures were made, using portions of glandular tissue from each half of the udder, pieces of mucous membrane from each milk cistern, and in some cases milk obtained from the milk ducts or the glandular tissue. The material for inoculation was obtained in most cases immediately after the death of the animal and with great care to prevent contamination

Bacteria were found in cultures from each of the udders examined. The possibility of air contamination as accounting for this result was excluded by a series of control experiments in which pieces of sterilized paper were used in place of the animal tissue, the results showing no infection, and by the conditions and results of the experiments as a whole. The number of bacteria varied greatly in the different udders and was highest in the two which were not examined until the morning following the evening on which the animals died, showing marked bacterial development overnight. Plates exposed for from 10 to 45 minutes to the air of the laboratory, in which the examinations were made, developed only 10 to 50 colonies, showing an insufficient number in the air to account for the results. The cultures did not show the diversity of forms to be expected from air contamination. Moreover, it was necessary to heat the gelatin to 37° C. in order to secure the liquefaction of the gelatin and the penetration of the tissues in order to obtain a strong inoculation, which would not have been the case had the bacteria been confined solely to the exterior of the piece of tissue.

The bacteria found were almost always liquefying and nonliquefying micrococci. Occasionally, however, a nonliquefying Bacterium was present, and in 2 instances other species, believed to be due to accidental infection, were met with. In 3 cases portions of the udder showed morbid changes, cultures from which, contrary to expectation, showed a low content of bacteria. In the udders of 3 cows, which had not been milked for several weeks, fewer bacteria were present than usual. The bacteria were apparently incapable of indefinite multiplication in the udder.

The source of the bacteria in the udder was studied. *Bacillus prodigiosus* injected into the teat of a goat was recovered in the milk during the 8 days following. Three days after a second injection the goat was killed and the bacillus was found in the glandular tissue. *B. fluorescens* similarly injected was not recovered. While not so numerous as in the mammary gland, bacteria were also found in the normal kidney and spleen, indicating an infection through the blood. The evidence so far obtained is not considered sufficient to decide whether the infection of the mammary gland is hematogenous or results from an invasion by way of the milk ducts. It is suggested that perhaps the infection is produced in both ways.

Studies concerning the so-called germicidal action of milk, H. W. Conn and W. A. Stocking (*Rev. Gén. Lait, 2 (1903), Nos. 12, pp. 265–271; 13, pp. 298–304*).—The authors do not consider that the decrease frequently observed in the total number of bacteria in milk during the first few hours after milking is due to a germicidal action possessed by the milk, but believe that certain species of bacteria, finding milk an unsuitable medium for growth, disappear more or less rapidly, and that when such species are more numerous than those finding milk a suitable medium a decrease in the total number of bacteria may result. Evidence is presented in support of this view, to which reference has previously been made (E. S. R., 14, p. 533).

The physical constitution of the fat globules of milk, M. Beau (*Rev. Gén. Lait, 2 (1903), Nos. 15, pp. 341–350; 16, pp. 372–378; 17, pp. 395–399; 18, pp. 417–424; 19, pp. 441–448*).—This is an exposition of the different theories which have been advanced, the evidence in support of each being reviewed in detail.

Contribution to the study of churning, M. Henseval and L. Marcos (*Rev. Gén. Lait, 2 (1903), Nos. 20, pp. 463–469; 21, pp. 489–499; 22, pp. 519–524*).—The theory of churning is discussed and experiments relating to the influence of temperature and rapidity of churning, richness of cream, acidity, and pasteurization are reported. The temperature and number of revolutions were varied in churning 3 lots of the same cream. With 60 revolutions and an initial temperature of 11° C. the time required for churning was 58 minutes and the final temperature was 14.2°. With the same number of revolutions and an initial temperature of 14° the time required was 34 minutes and the final temperature was 15.2°. With 80 revolutions and an initial temperature of 10° the time required was 62 minutes and the final

temperature was 13.5°. The number of revolutions per minute is therefore shown to be an important factor in churning, a high number compensating to a certain extent for a low temperature.

Two churning experiments were made with cream containing different percentages of fat. The loss of fat in the buttermilk from rich cream was greater than that in the buttermilk from cream less concentrated. Taking into account, however, the difference in the volume of milk furnishing the cream, the results are stated to be more favorable to the rich cream. Less time was required in churning the rich cream. When sweet cream was used the butter from rich cream was considered superior in quality, but when ripened cream was churned the results were reversed.

In churning experiments with sweet cream pasteurization increased the yield of butter by increasing its water content, the loss of fat being, however, somewhat greater than that from unpasteurized cream. Pasteurization notably decreased the time required for churning. The butter from pasteurized cream was considered better as regards quality and keeping properties. Ripened cream as compared with sweet cream churned more exhaustively and in less time.

The percentage of water in Canadian creamery butter, F. T. Shutt (*Canada Expt. Farms Rpts. 1902, pp. 164, 165*).—This is a summary of the report previously noted (E. S. R., 14, p. 908).

Execution of the dairy law, J. B. Lindsey (*Massachusetts Sta. Rpt. 1902, pp. 54–56*).—Of the 2,344 pieces of glassware tested during 1902, 56 pieces or, 2.4 per cent, were found incorrect. The limits of error allowed in testing are given. The inspection of Babcock machines in 1901 showed 20 machines to be in good condition, 11 to be in need of repairs, and 9 to be entirely unfit for satisfactory work. The inspection in 1902, while not completed, showed a marked improvement.

VETERINARY SCIENCE AND PRACTICE.

Proceedings of the American Veterinary Medical Association for 1902 (*St. Paul: Pioneer Press Co., pp. 346, pl. 1, figs. 9*).—The thirty-ninth meeting of the association was held in Minneapolis, Minn., September 2–5, 1902. A number of papers were read at the various sessions of the association. The majority of these papers have already been noted (E. S. R., 14, pp. 200–202). The other papers will be briefly referred to in this connection.

The pathogenesis of equine pneumonic emphysema, A. H. Baker (pp. 155–158).—This disease is said to be on the increase in both the eastern and western portions of the country. The majority of cases are due to faulty dietetics. The results of the disease may vary from slight injury to total uselessness of the horse. In the treatment of the disease the author recommends that attention be given to securing clean hay and grain.

The care and Comfort of domestic animals under varying conditions, E. A. A. Grange (pp. 206–211).—Attention is called to a number of unfavorable conditions to which driving and draft horses are subjected through neglect. It is urged that trained veterinarians should undertake investigations on various problems connected with the proper care and protection of animals from rain and excessive cold or heat as well as any other unfavorable conditions.

Equine periodic ophthalmia, M. Jacob (pp. 212–216).—The author made a study of this disease with special reference to the extent of its distribution, the age at which horses and mules are most frequently affected, the nature of the disease, and the line of treatment. The disease was found to be most prevalent in April, and it is believed that it is transmitted in the food, water, soil, and possibly in the air. This form of opthalmia is most prevalent in Tennessee and Kentucky. It appears that the left eye is more frequently affected than the right. The best results in treatment were obtained from the use of Lugol's solution.

A pathological and symptomatic treatment of parturient paralysis, R. P. Lyman (pp. 234–242).—Detailed notes are given on the clinical symptoms and treatment of 18 cases of this disease. The author discusses briefly the etiology of this disease and the nature of treatments which have been generally recommended. In a number of cases hypodermic injections of strychnin in doses of $\frac{1}{8}$ gr. were given every 2 hours, with excellent results. The strychnin treatment may be combined, or not, with Schmidt's treatment, according to circumstances. The results obtained by the use of strychnin were so satisfactory that the author feels justified in continuing it.

The legitimate field of the American Veterinary Medical Association, R. R. Bell (pp. 243–248).—A brief discussion of the nature of the papers to be read and the other work to be performed at the meetings of the association. The author believes that the papers should be on as wide a variety of subjects as possible in order to make the meetings of interest to all veterinarians, and that clinics should be held in connection with each meeting.

Parasitic ictero-hematuria of sheep, M. E. Knowles (pp. 277–281).—The author briefly discusses the nature and symptoms of this disease, which has been reported as existing in the Deer Lodge Valley since 1891, and which appears to be of considerable economic importance in that locality. In connection with this paper a portion of an article by V. Babes on the same subject was also presented.

Annual report for 1901 of the principal of the Royal Veterinary College, J. McFadyean (*Jour. Roy. Agr. Soc. England, 63 (1902), pp. 248–266*).—The number of cases of rabies in England gradually diminished until the disease appeared to be exterminated in 1900. In 1902, however, a few cases occurred, which seems to indicate that rabies still exists in England, although within restricted limits. During the year 647 outbreaks of anthrax occurred. Glanders prevailed to a considerably increased extent, there being 1,350 outbreaks, with only 2,332 cases. The causes of the increase in glanders infection have not been carefully worked out. The latest outbreak of foot-and-mouth disease was stamped out during the year 1901. Experiments with intravenous injections of corrosive sublimate showed that this remedy is of no value in cases of foot-and-mouth disease of the malignant type.

Hog cholera appeared during the season to a greater degree than for several years, 3,140 outbreaks being reported. The author summarizes his investigations of this disease as follows: Every pig which is susceptible to cholera is capable of spreading the disease; the disease may also be carried from place to place in the excrement of infected pigs or upon other materials which have come in contact with such pigs. It is recommended that all pigs which have been exposed should be quarantined for some time on account of the fact that decided symptoms may not appear at once.

Notes are given on the prevalence of tuberculosis, the sterilization of tuberculous milk, and the immunization of cattle against tuberculosis. Experiments in producing immunity against tuberculosis have been made by the author on 3 cattle, 1 being treated with tubercle bacilli from the liver of a fowl, the second from the liver of a tuberculous pheasant, while the third case was tuberculous at the beginning of the experiment. These experiments indicated that a high degree of immunity against tuberculosis could be conferred on cattle. The immunity was not absolute and the author does not claim that his experiments foreshadow a practical method of vaccinating cattle on a large scale against tuberculosis.

Differential diagnosis of certain pathogenic bacteria, W. Omeliansky (*Centbl. Bakt. u. Par., 1. Abt., 34 (1903), No. 1, Orig., pp. 1–6*).—The author describes technical methods by which a number of pathogenic organisms, including anthrax and diphtheria bacilli, can be differentiated through the use of alkaline reactions and a number of fatty acids, especially formic acid.

Further investigations of Klein's pathogenic yeast, E. Cohn (*Centbl. Bakt. u. Par. 1., Abt., 33 (1903), No. 9, Orig., pp. 688–696, pls. 2*).—The author continued his studies of this organism, which has been shown to be exceedingly pathogenic for

mice and other experimental animals, including dogs. Detailed notes are given on the stainability of the yeast and on the nucleus, capsule and other morphological features of this organism. The yeast produces very different effects on different animal tissues. In the liver of mice the yeast cells were found quite unattended by pathological processes, while in the lungs of the same animals the inflammatory processes were quite conspicuous and tissue destruction was well marked in the alimentary tract of guinea pigs. Quite frequently also granulation tumors were produced. Experiments were made to determine the possibility of immunizing mice against the yeast. Mice which were treated with hypodermic injections of serum obtained from inoculated animals were later inoculated with virulent cultures; in some cases the progress of the disease was slightly delayed, but the immunizing effects were not marked in any case. No agglutinin or precipitin appeared to be developed in the immune serum.

A new acid-fast Streptothrix pathogenic to man and animals, C. Birt and W. B. Leishman (*Jour. Hyg.* [*Cambridge*], *2* (*1902*), *No. 2, pp. 120–128, pl. 1*).—The organism studied by the authors was isolated from a human patient, and during the further studies devoted to it many inoculations were made in experimental animals. It was found to be fatal to guinea pigs when inoculated in the peritoneum, within a period of from 5 to 6 weeks. Notes are given for the purpose of furnishing a differential diagnosis between this and related species.

The absorption of tetanus toxin, V. Morax and A. Marie (*Ann. Inst. Pasteur, 17* (*1903*), *No. 5, pp. 335–342*).—The authors previously noted the affinity of nerve tissue for the toxin of tetanus. Further experiments were made for the purpose of testing the absorption of this toxin by nerve fibers of different function. During these experiments dogs, ponies, and monkeys were used. It was found that the motor, sensory, and vasomotor fibers of the spinal nerves are equally concerned in the absorption of the tetanus toxin. The amount of toxin absorbed by different kinds of nerve fibers in different portions of the body depends somewhat upon the blood circulation and upon the distance of the part in question from the point of inoculation.

The heredity of albinism, W. E. Castle and G. M. Allen (*Proc. Amer. Acad. Arts and Sci., 38* (*1903*), *No. 21, pp. 601–622*).—A number of experiments were made in the investigation of the subject in the zoological laboratory of Harvard University. The experimental animals were mice, guinea pigs, and rabbits. The authors conclude as a result of their experiments that complete albinism behaves as a recessive character, and therefore occurs in accordance with Mendel's law.

Report on animal diseases, H. Mitchell (*New Jersey State Bd. Agr. Rpt. 1902, pp. 171–174*).—A brief account of anthrax, glanders, rabies, and tuberculosis, showing the number and location of cases of these diseases.

Inspection of cattle in Argentina (*U. S. Consular Rpts., 72* (*1903*), *No. 27[illegible], pp. 124, 125*).—Brief notes on the terms of a convention with Uruguay with regard to sanitary inspection of live stock.

Dangers of eating meat from abattoirs and means of avoiding them, E. M. Serrano (*Gac. Med. Zool., 26* (*1902*), *No. 3–7, Sup., pp. 72*).—A series of lectures delivered at the Spanish Hygienic Society. Dangerous meat is divided into 4 classes, viz, meat infested with bacteria or parasites, meat which has undergone alterations and is unusually susceptible to putrefaction, meat which has undergone alterations so as to render it repulsive, and viscera which exhibit bacterial or parasitic lesions which are transmissible to man. Notes are given on the most approved methods of inspecting the meat for the purpose of detecting these various dangerous conditions.

The virulence of tubercle bacilli in pure cultures from tuberculous foci in man, E. Krompecher and K. Zimmermann (*Centbl. Bakt. u. Par., 1. Abt., 33* (*1903*), *No. 8, Orig., pp. 580–607*).—The recent literature bearing on this subject is critically discussed in connection with a short bibliography. The author's experiments were

undertaken for the purpose of studying the variations in virulence in tubercle bacilli of human origin. It was found in making pure cultures from this material that success was to be expected only in cases where the tubercle bacilli were not associated with other organisms. In cases of mixed infection the other organisms appear to check the development of the tubercle bacilli. In 86 per cent of cases of surgical tuberculosis in man success was had in cultivating the bacilli from the material thus obtained. It was found that from material which contained but very few isolated tubercle bacilli cultures could easily be made on a 5 per cent glycerin-potato medium. This method proved a more successful test for the presence of tubercle bacilli than inoculation experiments with animals. The variations in color of different cultures from yellowish to red or blackish brown are considered as due largely to the composition of the medium rather than to the differences in virulence of the bacilli. Great differences are observed in the development of the disease in rabbits of the same weight inoculated with equal doses. These differences are ascribed strictly to variations in individual susceptibility. Generalized tuberculosis was produced in rabbits within from 30 to 40 days after intravenous inoculation with from 0.25 to 10 mg. of material obtained from pure cultures of human origin. The authors call attention to the danger of ascribing the differences in the lesions found in different animals to differences in virulence of the bacilli concerned. It is believed to be safer to ascribe this phenomena to differences in individual resisting power and susceptibility. Tubercle bacilli which were subjected to the action of iodoform were found not to lose their virulence to any appreciable extent.

A method of testing the agglutination of tubercle bacilli, A. Köppen (*Centbl. Bakt. u. Par., 34 (1903), No. 1, Orig., pp. 6–13*).—Some of the more important literature on this subject is briefly criticised. The author argues that great care should be exercised in preparing sera for testing agglutination, in order that one may be sure that the result is a true agglutination and not a mere chemical precipitation.

Report of commission on tuberculosis in animals, F. Dye (*New Jersey State Bd. Agr. Rpt. 1902, pp. 161–168*).—The State has increased the amount of appropriation for carrying on the work of suppressing tuberculosis. The commission appointed for this purpose is investigating dairy herds and other herds in which outbreaks of tuberculosis are reported. The average indemnity price paid for diseased cattle was $22.79. Notes are also given on the application of the tuberculin test.

Combating tuberculosis in Denmark, E. Power (*Jour. Agr. Prat., n. ser., 5 (1903), No. 18, pp. 574–576*).—The system of governmental control of bovine tuberculosis in Denmark has been gradually perfected since 1893, and the many beneficial results which have been brought about by this system are briefly described by the author.

Tuberculosis and the use of tuberculin, W. Robertson (*Agr. Jour. Cape Good Hope, 23 (1903), No. 5, pp. 528–539, pls. 2*).—The author mentions the animals which are most susceptible to tuberculosis and briefly describes the natural channels of infection with this disease in cattle. Notes are also given on the symptoms and pathological lesions, and on the comparative frequency of the invasion of different parts and organs of the body. The nature of tuberculin is discussed, and directions are given for making tuberculin tests and for keeping herds of cattle free from tuberculosis.

The occurrence of tubercle bacilli in the milk of reacting cows, O. Stenström (*Ztschr. Thiermed., 6 (1902), No. 4, pp. 241–257*).—In experiments reported in this paper the author sought to determine the stage which tuberculosis must reach in cattle before the milk becomes infectious. Some of the cows from which the milk was obtained were affected with latent tuberculosis, while others were diseased to such an extent as to present clinical symptoms. None, however, were affected with the mammary form of the disease. Rabbits and guinea pigs were used for the experimental animals. In all 83 inoculations were made with the milk from these

cows, and in not a single case did the milk prove to be virulent. The author states, however, that in spite of the fact that all of these experiments and the majority of those of other investigators tend to show that the milk of tuberculous cows not affected with the mammary form is not virulent, tubercle bacilli occur from time to time in the milk of such cows. It is suggested that the chief means by which tubercle bacilli gain entrance to milk is from uncleanliness in milking and from the failure to detect mammary tuberculosis.

Observations on abortion and tuberculosis in cattle, J. Nelson (*New Jersey Stas. Rpt. 1902, pp. 370–374*).—Notes are given on the temperature reactions and post-mortem findings in a number of tuberculous cows which were slaughtered during the year. Some of these animals had been subjected to 20 injections of tuberculin, but this treatment, while perhaps prolonging the course of the disease, did not prevent its slow development.

Do Koch's recent assertions justify a change of attitude toward bovine tuberculosis? Dammann (*Jahrb. Deut. Landw. Gesell., 17 (1902), pp. 34–44*).—The author reviews in a critical manner the literature relating to the controversy concerning the unity or duality of the tubercle bacillus. It is concluded from this discussion that the dual nature of tubercle bacillus is not demonstrated and that sanitary precautions should therefore be strictly observed in dealing with the meat and milk of tuberculous animals.

Remarks on Veszpremi's "Differences in virulence of different cultures of tubercle bacilli," K. Vagedes (*Centbl. Bakt. u. Par. 1. Abt., 33 (1903), No. 9, Orig., pp. 679, 680*).—A controversial article in which it is pointed out that while the results claimed by the 2 investigators differ to some extent, they agree in indicating that tubercle bacilli of different origin may exhibit considerable differences in virulence.

The prospects for the prevention of Texas fever and the tsetse-fly disease, R. Endlich (*Tropenpflanzer, 6 (1902), No. 6, pp. 269–285*).—The author presents a brief critical account of the work thus far accomplished in connection with the study and prevention of Texas fever in the United States and elsewhere. Notes are also given on the work of Koch and other authors in the control of tsetse-fly disease.

The prevention of the tsetse-fly disease and its economic importance, Schilling (*Tropenpflanzer, 6 (1902), No. 12, pp. 616–625*).—Attention was called to the great need of draft oxen and horses in the Togo District of South Africa and to the rudimentary condition of soil cultivation. The prevalence of the tsetse-fly disease is believed to be of great importance in determining the backward state of agricultural science in that country and the problem of its eradication is shown to be of great importance.

Directions for using vaccine for the prevention of blackleg in cattle, L. L. Lewis (*Oklahoma Sta. Bul. 57, pp. 15, figs. 3*).—The Oklahoma Station has been distributing vaccine to farmers for a number of years, the total number of doses being about 278,000. The vaccine is distributed free upon application of any stock raiser. Suggestions are given regarding the methods of vaccinating animals and a brief discussion is presented on the symptoms of blackleg. It has been found best to vaccinate young animals at least twice, and 3 times if they are vaccinated before 6 months of age. Vaccination of young calves does not furnish protection for any great period.

Notes on an outbreak of cattle plague in Shanghai and its limitation by the gall immunization of Koch, A. Stanley (*Jour. Hyg. [Cambridge], 2 (1902), No. 1, pp. 43–46*).—An outbreak of this disease occurred in Shanghai and spread from herd to herd despite the efforts of the police to control it. It was therefore resolved to apply Koch's method of immunization with gall. Gall bladders of cattle just dead of the disease were removed under antiseptic conditions and bile obtained from them was inoculated into the dewlap of healthy cattle in doses of 20 cc. During these experiments 68 cattle were injected with gall. In all, 11 of these animals died, but only 1 under conditions which precluded an infection previous to the vaccina-

ion. The method is regarded as inexpensive and easily applied and also as of great fficiency.

Sulphate of iron as a preventive of foot-and-mouth disease, G. TEISANU *Jour. Agr. Prat., n. ser., 5 (1903), No. 17, p. 538).*—This remedy was used as a wash n preventing a contagion of foot-and-mouth disease during an outbreak of this plague. The animals thus treated did not develop the disease.

Tympanites, E. RUHVEDEL (*Jour. Khediv. Agr. Soc. and School Agr., 4 (1902), No. 5, pp. 189, 190*).—Brief notes on tympanites as caused by feeding on berseem and other related plants. The usual remedies for this affection are recommended.

Tests of fly preventives, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1902, pp. 61–63*).—A test was made of a number of proprietary remedies for keeping flies away from cattle and horses. These remedies included Sure Thing, Cattle Comfort, Stop Fly, Norwood Sanitary Fluid, Flylene, Shoo Fly, Eli Fly Chaser, Eureka, Rippley's Fly Remover, and Cypher's Anti-Fly Paste. The results obtained from the use of these remedies on cattle and horses indicate that while a number of the preparations are quite efficient in keeping the flies away from the animals, the cost is so great as to be almost prohibitive.

Some diseases of sheep, T. W. CAVE (*Jour. Southeast. Agr. Col. Wye, 1903, No. 12, pp. 86–95*).—Notes on a number of bacterial and parasitic diseases, including tetanus, gid, and tapeworms, together with an account of blackleg, which is referred to in parts of England under the term "struck." Attention is called to the desirability of exercising antiseptic precautions in the prevention of tetanus. For reducing the prevalence of gid it is necessary to destroy the heads of infested sheep in order that they may not be eaten by dogs.

Heartwater in sheep and goats, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 22 (1903), No. 4, pp. 838–843*).—A method of vaccination against this disease was devised by Dr. Purvis, and the veterinary department of Cape Colony was questioned regarding the value of this system of vaccination. A test by the department indicated that the method was no more efficacious than that in use by the department veterinarians. Notes are given on the special facts which have been demonstrated in connection with the etiology and treatment of this disease.

Scab in sheep, D. E. SALMON and C. W. STILES (*U. S. Dept. Agr., Farmers' Bul. 159, pp. 48, figs. 17*).—A condensed form of Bulletin 21, revised, of the Bureau of Animal Industry (E. S. R., 10, p. 793).

Some of our commoner local internal parasitic diseases of sheep, W. H. DALRYMPLE (*Louisiana Stas. Bul. 74, 2. ser., pp. 216–231, figs. 2*).—The sheep botfly sometimes occurs in such large numbers as to cause a great irritation and loss of flesh. The author found 42 larvæ of this insect in a single sheep. Notes are given on the adult and larval condition of the insect and on the symptoms produced by its presence in the nasal passages of the sheep. The remedies recommended are largely preventive and include smearing tar or fish oil upon the nose of the sheep, together with the destruction of the heads of infested sheep after slaughter. A brief account is also given of *Tænia expansa*—the common tapeworm of sheep—and on the stomach worm (*Strongylus contortus*). The author discusses the habits and life history of these species.

Especial attention was devoted to a study of the nodular disease of sheep, due to the presence of *Œsophagostoma columbianum* in the walls of the intestines. These worms are so protected by their position that direct remedies are of little avail. The only means of checking their spread is found in the adoption of preventive measures. Experiments were made for the purpose of determining whether pastures may be readily infected by the presence of sheep infested with this parasitic worm. It was found that sheep affected with nodular disease, when placed on a clean pasture, readily infected this land with the parasites which cause the disease. Healthy lambs when allowed to graze upon such land soon became affected from this exposure.

Brief suggestions are made with regard to a practical method by which healthy lambs may be obtained from diseased ewes.

Parturient paresis in sows and its treatment according to Schmidt's method, K. Egeberg (*Norsk. Vet. Tidsskr., 15 (1903), No. 1, pp. 29, 30*).—The author describes the symptoms observed in cases of this disease in sows. In one instance a test was made of the recent method of treatment, which consists in pumping air into the udder. The symptoms were relieved within a short time and complete recovery took place.

Mal de caderas, M. Elmassian and E. Migone (*Ann. Inst. Pasteur, 17 (1903), No. 4, pp. 241–267, figs. 4*).—This disease is due to the presence in the blood of the protozoan organism known as *Trypanosoma equina*. This organism is described in detail and notes are given on the most approved methods for fixing, staining, and studying it. Mal de caderas occurs in a number of clinical forms, the more common of which runs a tolerably rapid course. The disease also occurs in chronic and paralytic forms.

Notes are given on the symptoms that are characteristic of these different forms and upon the pathological lesions which are produced during the progress of the disease. The liver, spleen, and pancreas become much injected and swollen, while the lymphatic system is not affected. In addition to the horse, mule, and ass, which are most susceptible to the disease, a number of other animals may be infected, and the susceptibility of these animals varies from that observed in monkeys to the absolute refractoriness of birds. Aside from the horse tribe, the susceptible animals are as follows: Monkey, white and gray mice, white rat, capibara, guinea pig, rabbit, dog, sheep, cattle, pig.

A study of the disease of South American horses known by the name of mal de caderas, J. Lignières (*Contribution à l'étude de la trypanosomose des équidés Sud-Americains connue sous le nom de "mal de cadera." Buenos Aires: 1902, Coni Brothers, pp. 120, pls. 3*).—The author reviews in a critical manner the literature relating to this disease. Notes are given on the microscopical structure of *Trypanosoma elmassiani*, which is the causative organism of the disease. The author discusses also the method of multiplication of this organism, its abnormal forms, and the effect of various sera in agglutinating it.

In a long series of experiments it was found that agglutination of the pathogenic organism of mal de caderas could be brought about by the sera of normal sheep, pigs, rabbits, and horses, but more effectively by the sera of cattle, sheep, dogs, and cats affected with mal de caderas. As a rule agglutination took place immediately, and then became more pronounced by a gradual process. The organism of mal de caderas when subjected to a temperature of 53° C. for 5 minutes or 45° for 8 minutes was killed. It withstood a temperature of 44° C. for 5 minutes, but was destroyed by the same temperature when applied for a period of 15 minutes. Subjection to a temperature of −20° for 5 minutes destroyed a considerable percentage of the trypanosoma.

Experiments were also made with a number of antiseptic substances, such as carbolic acid, lysol, boric acid, corrosive sublimate, and permanganate of potash. In general the antiseptics had the effect of causing agglutination. This process was most pronounced after the use of potassium permanganate. An extensive series of inoculation experiments showed that a large number of animals are susceptible to this disease. The susceptible animals according to the author's experiments, mentioned in the order of their susceptibility, include white mouse, white rat, gray mouse, gray rat, dog, horse, rabbit, cat, sheep, cattle, dog, pigeon, duck, domestic fowl, and frog. The method of infection by this disease has not been determined. The author suggests the possibility of the organism being carried by *Stomoxys calcitrans*. The blood of infected animals when taken from the stomach of this species of fly was found to contain the organism of mal de caderas in a virulent condition.

Horse sickness, investigation, H. W. PITCHFORD (*Agr. Jour. and Min. Rec., 6 (1903), No. 8, pp. 249–257*).—The author continues an account of his studies on the etiology of South African horse sickness. It is believed that some flying insect, probably a mosquito, is the carrier of infection. Horses kept in stables in which smudges were maintained appeared to be protected against the disease, and the author interprets this fact as due to the effect of smoke upon mosquitoes.

Notes on the mallein test, G. FEIST (*Fortschr. Vet. Hyg., 1 (1903), No. 1, pp. 30–33*).—Attention is called to the difficulties experienced by official veterinarians in satisfying the minds of horse owners as to the diagnosis of glanders. Notes are given on 286 cases in which the mallein test was made; among these horses 26 reacted and were found to be glanderous upon post-mortem examination. In the author's experience no case was observed in which a glanderous horse failed to react, and no reaction was produced in horses which were not glanderous.

The pathological importance of botfly larvæ in the stomach of horses, E. PERRONCITO (*Fortschr. Vet. Hyg., 1 (1903), No. 1, pp. 40–43*).—A number of cases have been reported in the literature of this subject in which the stomach wall was more or less injured by the presence of botfly larvæ. The author believes that the attacks of these insects brings about greater susceptibility to colic and infectious diseases.

Insects which may aid in the spread of surra, J. C. KONINGSBERGER (*Teysmannia, 13 (1902), No. 6, pp. 314–322*).—On account of the resemblance in symptoms of surra and nagana the author believes that the former disease may be conveyed in Java by some species of fly, as nagana is transmitted by the tsetse fly in South Africa. Descriptions are given of several species of biting and sucking insects which might be suspected of being carriers of surra.—H. M. PIETERS.

Natural immunity of dogs and chickens to anthrax, A. PETTERSSON (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 8, pp. 613–626*).—During the author's experiments on this subject it was found that the serum obtained from chickens possessed essentially the same resisting powers toward anthrax as that obtained from dogs. The dog, however, is preferred in experiments of this sort for various reasons.

A number of experiments were made by the auther for the purpose of determining the properties of dog serum, especially in its reactions toward anthrax bacilli and with regard to the stimulating effect upon the dog serum of serum from rabbits previously treated with dog serum. It was found that rabbits which were treated with the serum of dogs developed substances antagonistic to both the amboceptor and the complement. Cytolytic immune bodies were produced by previous treatment of the animals with cellular secretions.

Rabies in South Africa, A. LOIR (*Ann. Inst. Pasteur, 17 (1903), No. 4, pp. 298–302*).—The author presents a brief description of an outbreak of rabies which occurred in Rhodesia. On account of the seriousness of the outbreak as observed by the author it was recommended that all dogs be muzzled and that all suspected dogs and other animals be killed. As a result of the investigation 80,000 dogs were killed. A number of experiments were made on rabbits for the purpose of determining the virulence of rabies virus as obtained from various cases.

Antirabies vaccine at the Pasteur Institute in 1902, E. VIALA (*Ann. Inst. Pasteur, 17 (1903), No. 5, pp. 365–368*).—A table is given showing the number of persons treated and the mortality in these cases from 1886 to 1902, inclusive. The author discusses briefly also the history of the rabid animals concerned in these cases.

The histology of rabies corpuscles in the peripheral nerve ganglia, V. F. OTTE (*Ucher. Zapiski Kazan. Vet. Inst., 20 (1903), Nos. 2, pp. 237–245; 3, pp. 388–404, pl. 1*).—The microscopical structure of these corpuscles was carefully studied by the author and is described in detail.

An explanation of the occurrence of distemper among cats in the government of Kazan, in connection with the distribution of cultures of mouse typhus, A. N. ALEKASYEEV (*Uchen. Zapiski Kazan Vet. Inst., 20 (1903), Nos. 2, pp. 128–210; 3, pp. 251–314*).—The author made an exhaustive study of a number of outbreaks of distemper among cats which occurred coincidently with the distribution of mouse typhus cultures in the Province of Kazan. The literature of the subject is critically reviewed in connection with a brief bibliography. It is believed as a result of the author's studies that cats may be affected with a disease resembling distemper in all respects and may die as a result of eating mice which are infected with typhus. As a rule, however, it is believed that the distribution of mouse typhus cultures and the occurrence of distemper in cats are merely coincident and are not associated as the result of an infection of one animal by another. A number of organisms were isolated from cats which were affected with distemper.

The need of legislation relative to diseases of domestic animals, H. B. McDOWELL (*Delaware State Bd. Agr. Rpt., n. ser., 1901–2, pp. 43–49*).—Attention is called to the necessity of further legislation, especially in the control of anthrax and tuberculosis. It is said that at present the conditions are very favorable for the spread of anthrax in Delaware, on account of neglect of precautions which could easily be taken.

First aids to injured and sick animals, H. B. McDOWELL (*Delaware State Bd. Agr. Rpt., n. ser., 1901–2, pp. 57–63*).—Brief notes on simple remedies which may be applied by stock raisers in assisting the work of veterinarians in the treatment of wounds, bruised shoulders, colic, scratches, and laminitis.

The veterinary pharmacopœia and manual of comparative therapy, G., C., and A. GRESSWELL (*London: Baillière, Tindall & Cox, 1903, 2. ed., pp. XIII+457*).—In this edition numerous alterations and additions have been made for the purpose of incorporating material to represent the later discoveries in the field of veterinary medicine and therapeutics. A discussion of the various drugs is arranged in an alphabetical manner and involves an account of the composition, characteristics, therapeutics, and doses.

Disinfecting value of certain formaldehyde preparations, K. KOKUBO (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 7, Orig., pp. 568–571*).—A comparative test was made of carbolic acid, old and new Septoforma, and formalin soap in the destruction of anthrax spores, *Staphylococcus aureus*, Streptococcus, and typhoid bacilli. Anthrax spores were found to be alive after exposure for 95 days to a 1 per cent carbolic acid solution and were killed by exposure for 25 days to a 3 per cent solution. When exposed to a 10 per cent formalin soap the anthrax spores lived but a few hours.

Panaceas in veterinary medicine, E. THIERRY (*Jour. Agr. Prat., n. ser., 5 (1903), No. 9, pp. 290, 291*).—Notes are presented on a number of remedies which have been recommended as capable of producing great curative effects in a large variety of diseases. The author believes that none of these remedies are as effective as represented.

Animal parasites of man, M. BRAUN (*Die thierischen Parasiten des Menschen. Würzburg: A. Stuber, 1903, 3. ed., pp. 360, figs. 272*).—This volume constitutes a handbook on the animal parasites of man and is intended for the use of students and physicians. It includes a general discussion of parasites and their life histories, together with special accounts of the various parasites belonging to different orders and families of animals which have been observed in or upon man under parasitic conditions.

AGRICULTURAL ENGINEERING.

Review of irrigation investigations for 1902, E. MEAD (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 359–385, pls. 6*).—The causes of the recent rise in value of irrigated lands and water rights and the need of enactment of better irrigation laws are discussed; the purpose and scope of the irrigation investigations

of this Office are explained; and the results obtained in studies relating to irrigation laws and institutions and to the duty of water are briefly summarized. The practical bearing and influence of the work are also pointed out.

Special attention is given to a discussion of losses by seepage and of drainage as a necessary accompaniment of irrigation; the importance of developing inquiries along other lines of agricultural engineering, including investigations relating to the pumping of water for farm uses and to farm buildings and machinery; the water-right problems of the arid region; and irrigation in the humid sections of the United States and in the insular possessions. A list of 7 publications issued during the year is appended.

The drainage work has proceeded far enough to show that drainage in connection with irrigation presents some very different problems from those encountered in such work in humid regions and that to be effective different methods must be followed; for example, the drains must be placed at a greater depth.

As regards irrigation in the humid portion of the United States, the report says: "There are few sections in the United States where at some time during the growing season a drought of greater or less severity is not experienced each year, and where the application of water, if for a brief period only, would not secure largely increased yields. It remains to be determined, however, whether this kind of irrigation will pay. The number of farmers who are establishing experimental irrigation plants is already large, and the advice given by this Department during the last season affected the expenditure of several hundred thousand dollars. . . . In addition to this general assistance, systematic studies of the possibilities of irrigation in the humid portions of the United States are now being carried on in Wisconsin, Missouri, and New Jersey in cooperation with the State agricultural experiment stations of those States. The results in 1901 were all in favor of irrigation because the season was dry. The results in 1902 were less favorable because the season was wet."

Irrigation, C. H. SHINN (*California Sta. Bul. 147, pp. 65–71, figs. 4*).—The amounts of water used on a large number of fruits and other plants at the Southern California substation are reported. The amount applied during the 18 months from September, 1897, to April, 1899, including 15.1 in. of rainfall, was on the average for all crops a little over 25 in. Irrigation of oranges by means of deep and shallow furrows was tested, with results decidedly favoring the use of deep furrows. (See also E. S. R., 13, p. 952.)

Irrigation, W. J. ALLEN (*Agr. Gaz. New South Wales, 14 (1903), No. 6, pp. 538–545, figs. 8*).—Practical information regarding the construction of water channels, the leveling of land, and the application of water to different crops is given. Some results of the use of irrigation in different parts of New South Wales are also reported.

The amount of water used in field irrigation, S. FORTIER (*Montana Sta. Rpt. 1902, pp. 113–116*).—This is a brief summary of observations made in cooperation with this Office and already published in detail in the bulletins of the Office.

Pumping for irrigation from wells, J. J. VERNON and F. E. LESTER (*New Mexico Sta. Bul. 45, pp. 67, figs. 36*).—This bulletin records the results of experiments in pumping water for irrigation at the station farm. "The conditions existing in the Mesilla Valley, where the experiment station is located, are probably fairly typical of those to be found throughout the greater part of the valley of the Rio Grande. . . .

"The various strata found throughout the valley consist of layers of soil, sand, and gravel, of varying degrees of coarseness, with occasional layers of hardpan or clay. Sand evidently forms the greater part of the strata in the valley and in many parts extends to the surface, although usually covered by a layer of sediment and rich soil varying in thickness from a few inches to many feet. It seems to be generally true that most of the valley is underlaid at a reasonable depth with gravel beds sufficiently thick to procure from them by means of slotted strainers an ample water supply. In the Mesilla Valley a gravel bed is usually found at from 20 to 80 ft. in depth, although

there is no certainty as to the depth at which it will be found or the thickness of the stratum. . . .

"Throughout the whole length of the valley proper water will be found at a depth of from 4 or 5 ft. to 20 or 30 ft., depending upon the height of the ground above the level of the river bed. This water appears to be generally of a good and fairly uniform quality throughout the valley, though near to the foothills the quality is an uncertain thing. In the matter of quantity it seems to be more a matter of providing means for making the water available than any question as to the underflow."

The open well is considered in most respects preferable to the pipe, but under present conditions is too expensive.

Methods of sinking wells, installing pumps and strainers, and operating pumps are explained. The results of comparative tests of 8 pumps of various types (centrifugal and rotary) and sizes and of 4 kinds of fuel (cottonwood, tornillo, and coal) are reported. Data regarding pumping plants in New Mexico and other States are given.

Summarizing the results of studies and observations, the authors state that—

"An ample quantity of water for irrigating purposes exists throughout the Rio Grande Valley in southern New Mexico at a comparative shallow depth.

"This water, termed the underflow, can be easily made available by sinking pipe wells, with slotted strainers, into the gravel strata at comparatively low cost.

"The station at Mesilla Park sank an experimental well 6 in. in diameter and 48 ft. deep from which was pumped a continuous stream of over 1,000 gals. a minute.

"From this well it was found possible, using a 20-horsepower steam engine with tornillo wood as fuel, to irrigate average land 3 in. deep at a maximum cost of from 51 cts. to 64 cts. an acre, according to the pump used. This estimate is for short runs; for long runs this cost will probably be reduced, a point to be determined later. . . .

"A study of the relative conditions existing in New Mexico and other States shows that in the Rio Grande Valley in southern New Mexico at least the conditions are unusually favorable for the successful and economical operation of pumping plants as a means of supplying water for irrigating purposes."

Contributions to the study of drainage and irrigation, E. Risler and G. Wery (*Ann. Inst. Nat. Agron., 2. ser., 2 (1903), No. 1, pp. 5–18*).—This article discusses the consumption of water by plants and the relation between the distribution of rainfall in different parts of France and the water requirements of plants.

Discharge of the principal rivers of Montana, J. S. Baker (*Montana Sta. Rpt. 1902, pp. 117–131*).—A tabular record of stream measurements made in cooperation with the U. S. Geological Survey.

The resistance of road vehicles to traction, A. Binnie et al. (*Rpt. British Assoc. Adv. Sci., 1902, pp. 314–349, pls. 4, figs. 4*).—This is the report of the committee appointed to consider this subject. It reviews the investigations of Corréze and Manès (1832), Coriolis (1835), Morin (1837–1842), Dupuit, Edmund Leahy (1847), Charié-Marsaines, A. Michelin (1896), W. C. Unwin (1897), H. S. Hele-Shaw (1897), and I. O. Baker (1902), and describes the apparatus and methods used and results obtained in some tests made by the committee.

The experiments undertaken were intended "to determine the relation between the tractive effort and the following, viz, load, diameter of wheel, width and section of tire, hardness of tire (in the case of pneumatics), effect of springs, and velocity for every type of road under all circumstances, and any other relations that may be suggested during the progress of the work."

The special dynamometer apparatus used in the tests is described in detail. It consists of a castor frame in which can be mounted the wheel to be experimented on, a system of levers for transmitting to a small plunger the pull exerted on the wheel, and a recording pressure-gauge for registering the same, together with a recording tachometer.

"In performing an experiment a given type of wheel is mounted in the frame and a run made over a piece of road of the desired type. Since the 2 graphs are side

by side, the relation between tractive force and velocity can be seen at every point of the run, and from those portions of the graph where the velocity is constant and of the required value a mean tractive effort can be obtained. After a number of experiments have been performed curves can be plotted and empirical formulæ deduced for the various relations.

"As the dynamometer has only been completed such a short time, the trials are as yet only preliminary. The general results, however, tend to confirm those of previous investigators."

A text-book on roads and pavements, F. P. SPALDING (*New York: John Wiley & Sons; London: Chapman & Hall, Ltd., 1903, pp. VIII + 235, figs. 44*).—This is the second revised and enlarged edition of this work.

Highway construction in Wisconsin, E. R. BUCKLEY (*Wisconsin Geol. and Nat. Hist. Survey Bul. 10, 1903, Economic ser. 6, pp. XVI + 339, pls. 106*).—It is stated that the information contained in this bulletin "is intended primarily for those interested in the construction and maintenance of streets in cities, towns, and villages in Wisconsin, although a great part of the report is equally applicable in the principles of street construction and maintenance to rural districts. An attempt has been made to discuss impartially the different pavements, hoping to furnish unbiased and reliable information as to their merits." Data are given as to methods and cost of construction and maintenance, sources, quality, and methods of testing materials used in highway construction, and durability of different kinds of highways. Satisfactory results were obtained from abrasion tests, in which the Duval abraiding machine was used. The results of the tests of the cementing power of the finely ground stone as determined by the Page method were very discordant and unsatisfactory.

Machine threshing and seed grains, M. RINGELMANN (*Jour. Agr. Prat., n. ser., 6 (1903), No. 28, pp. 42, 43*).—The injury to seed grain in threshing is briefly discussed.

The comparative value of different forms of power in agriculture, H. HOLLDACK (*Fühlings Landw. Ztg., 52 (1903), Nos. 12, pp. 416–420; 13, pp. 458–465, figs. 2*).—A general discussion.

Modern silage methods (*Salem, Ohio: The Silver Mfg. Co., 1903, pp. 199, figs. 30*).—A summary of information regarding the construction of silos and the preparation and use of silage.

MISCELLANEOUS.

Annual Report of the Office of Experiment Stations, 1902 (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 547, pls. 48, figs. 2*).—This contains a report on the work and expenditures of the agricultural experiment stations in the United States for the fiscal year ended June 30, 1902, including a review of the work of this Office; summarized accounts of the meetings of the Association of American Agricultural Colleges and Experiment Stations and the American Association of Farmers' Institute Workers held in 1902; a list of the publications issued by this Office and the experiment stations during the calendar year 1902; Federal legislation, regulations, and rulings affecting agricultural colleges and experiment stations; annual reports of the experiment stations in Alaska, Hawaii, and Porto Rico; a review of irrigation investigations for 1902; and several articles relating to nutrition investigations, agricultural education, and cooperative experiments. Parts of this report are abstracted elsewhere in this issue.

Annual Report of Idaho Station, 1902 (*Idaho Sta. Rpt. 1902, pp. 24*).—This includes the organization list of the station, reports of the director and heads of departments, a summary of meteorological observations noted elsewhere, and a financial statement for the fiscal year ended June 30, 1902.

Fifteenth Annual Report of Massachusetts Station, 1902 (*Massachusetts Sta. Rpt. 1902, pp. 163*).—This includes a list of the officers of the station, an outline of the more important work undertaken, a financial statement for the fiscal year ended June 30, 1902, and departmental reports, parts of which are noted elsewhere.

Ninth Annual Report of Montana Station, 1902 (*Montana Sta. Rpt. 1902, pp. 131*).—This contains the organization list of the station, a financial statement for the fiscal year ended June 30, 1902, a report of the director discussing agricultural conditions in the State and reviewing the work of the station, and departmental reports for the year ended November 30, 1902, parts of which are noted elsewhere.

Annual Report of New Jersey Stations, 1902 (*New Jersey Stas. Rpt. 1902, pp. XVII+593*).—This includes the organization lists of the stations; a financial statement of the State station for the year ended October 31, 1902, and of the college station for the fiscal year ended June 30, 1902; a report of the director reviewing the different lines of station work; and reports of the chemists, assistant in soil chemistry and bacteriology, assistant in horticulture, assistant in dairy husbandry, biologist, botanist, and entomologist. Reprints of Bulletins 160 of the station on Feeding Stuffs (E. S. R., 14, p. 380) and 163 on Fertilizers (E. S. R., 14, p. 749) are included in the report of the chemists.

Thirteenth Annual Report of North Dakota Station, 1902 (*North Dakota Sta. Rpt. 1902, pp. 128*).—This includes the organization list of the station, a brief report of the director, reports of the heads of the different departments including the results of experimental work noted elsewhere, a summary of Bulletin 53 of the station on Food Adulteration (E. S. R., 14, p. 892), and a financial statement for the fiscal year ended June 30, 1902.

Annual Report of Pennsylvania Station, 1902 (*Pennsylvania Sta. Rpt. 1902, pp. 483*).—This includes the organization list of the station; a financial statement for the fiscal year ended June 30, 1902; a report of the director reviewing station work during the year and discussing the needs and future of the station; and departmental reports containing in addition to accounts of the different lines of work several articles noted elsewhere in this issue. The following articles in essentially the same form or abridged have already been noted from other sources: Pennsylvania sugar beets in 1901 (E. S. R., 14, p. 141), errors in manure sampling and analysis (E. S. R., 14, p. 938), effects of fermentation upon the chemical composition of cider and vinegar (E. S. R., 14, p. 1027), changes in the composition of milk during its delivery (E. S. R., 14, p. 489), available energy of timothy hay (E. S. R., 14, p. 993), combustible gases excreted by cattle (E. S. R., 14, p. 994), rearing of calves on milk substitutes (E. S. R., 14, p. 479), and weeds in general—two newcomers into Pennsylvania (E. S. R., 14, p. 52).

Fifteenth Annual Report of Rhode Island Station, 1902 (*Rhode Island Sta. Rpt. 1902, pp. 203–412+VIII*).—This contains a brief biographical sketch of the late Joseph A. Tillinghast, a report of the director on the different lines of station work, reports of divisions and articles abstracted elsewhere, a financial statement for the fiscal year ended June 30, 1902, acknowledgments, and a complete list of the publications of the station since its organization.

Farmers' institutes in the United States, D. J. Crosby (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 461–480*).—A general survey is given of the institute movement in the United States and of the work and appropriations in each of the different States during the year.

Farmers' institute bulletin, 1902 (*Mississippi Sta. Bul. 80, pp. 59, figs. 15*).—This is a summary account of the round-up farmers' institute held at the college in August, 1902. Some of the subjects discussed were as follows: The Relation of the Experiment Station to Mississippi Farmers, and The Functions of Live Stock on the Farm, by W. L. Hutchinson; Raising Beef Cattle for Profit in Mississippi, by E. R. Lloyd; Farm Drainage, by J. W. Fox; The Relation of the United States Department of Agriculture to the Farmer, by C. B. Smith; Commercial Horticulture in Mississippi, by A. B. McKay; Dairying in Mississippi, by J. S. Moore; The Breeding and Development of Dairy Cows, by Ada F. Howie; Some Diseases of Farm Animals and How to Treat Them, by J. C. Roberts; What Chemistry Has Done for the Farmer, by W. R. Perkins; and Mississippi Agriculture as Viewed by an Outsider, by H. E. Stockbridge.

Some features of recent progress in agricultural education, A. C. TRUE (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 417–459, pls. 2*).—This article presents some of the main features of recent advancement in agricultural teaching and methods in this country. An account is given of the 4 weeks' graduate school of agriculture held at the Ohio State University in July, 1902. A paper was read by the author at that meeting showing that agriculture at the present time is as truly a science as is that of geology, geography, or medicine. The educational values of courses in agriculture are discussed at some length and concrete examples given of present courses in agriculture in colleges, secondary agricultural schools, and town high schools.

The improvement of education in rural schools, J. W. ROBERTSON (*Ontario Agr. and Expt. Union Rpt. 1902, pp. 78–84*).—A general discussion of this subject.

Cooperation between experiment stations and farmers (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 491–540, pls. 5, fig. 1*).—In this account an attempt is made to bring out the origin and history of the movement for cooperation between the experiment stations and farmers; the present status of the movement, including details as to the extent and character of different phases of the work; and the value of cooperative experiments to the station or college, the farmers, and to agricultural science.

As typical of this work examples in the Southern States, Middle West, and Northern States and Canada are cited. Southern work is illustrated concretely by the cooperative experiments conducted by the Alabama Station, which are reviewed in detail by J. F. Duggar. Cooperative work in the West is illustrated by experiments carried out under the direction of the Illinois Station and reported by E. Davenport. In the North the cooperative work done in New York State by the college of agriculture of Cornell University is selected for illustration, the work being described by J. L. Stone; and Canadian work is reported by C. A. Zavitz, of the Ontario Agricultural College.

Cooperative work between farmers and stations has been found to furnish ready means for distributing and testing improved varieties of seeds and plants throughout the country, and for bringing the agricultural colleges and experiment stations into close and mutually helpful relations with the farming communities. Besides it is a valuable training for the farmers themselves in systematic and accurate work.

"Popular" editions of station bulletins, F. H. HALL (*U. S. Dept. Agr., Office of Experiment Stations Rpt. 1902, pp. 481–489*).—The author shows that simple condensed summaries of station work are much in favor with farmers in New York, and that where stations publish more than 10 bulletins averaging 30 pages each in the year enough can be saved on printing to pay the expenses of an expert editor.

Crop Reporter (*U. S. Dept. Agr., Bureau of Statistics Crop Reporter, Vol. 5, Nos. 1, pp. 1–8; 2, pp. 9–16; 3, pp. 17–24*).—These numbers, for May, June, and July, 1903, contain the usual statistical information on the condition of crops in the United States and foreign countries.

Agricultural statistics of Ireland, 1902 (*Dublin: Dept. Agr. and Tech. Instr., 1903, pp. XLIX+165, dgms. 3, map 1*).

Agriculture for beginners, C. W. BURKETT, F. L. STEVENS, and D. H. HILL (*Boston and London: Ginn & Co., 1903, pp. XII+267, pl. 1, figs. 215*).—The authors believe that the theory and practice of agriculture can and should be taught in the public schools, and they have prepared a suitable text-book for this purpose. They "see no difference between teaching the child the fundamental principles of farming and teaching the same child the fundamental truths of arithmetic, geography, or grammar." The book is written in a pleasing manner and is well illustrated. The subjects treated have been carefully and appropriately selected. Chapters are devoted to the soil; the soil and the plant; the plant; how to raise a fruit tree; the diseases of plants; orchard, garden and field insects; farm crops; domestic animals, and farm dairying. The book is a valuable addition to the facilities for teaching the elements of agriculture.

NOTES.

Alaska Stations.—H. P. Nielsen, of Kansas, who has been in charge of the Kenai Experiment Station since April 1, 1899, has resigned, his resignation to take effect November 1. He will be succeeded by P. H. Ross, a graduate of the Kansas Agricultural College, who has been Mr. Nielsen's assistant the past summer. W. L. Neal, who has been assistant to the superintendent of the Copper River Station the past summer, has also resigned, his resignation to take effect November 1.

Arizona University.—President F. Y. Adams severed his connection with the university during the summer, and has been succeeded by Kendrick C. Babcock, Ph.D., assistant professor of American history at the University of California.

California Station.—The poultry station authorized by the last legislature has been established in the vicinity of Petaluma, Sonoma County, and H. O. Woodworth, of the New York State Experiment Station, placed in charge. V. A. Moore, of the Veterinary College at Cornell University, spent some weeks in California during the past summer investigating the pathology of poultry diseases for the station. Warren T. Clarke, the field entomologist of the station, has been appointed assistant superintendent of university extension in agriculture or farmers' institutes. This will not, however, take him entirely from active work in investigations in entomology. W. H. Volck has been appointed temporary assistant field entomologist in the codling moth investigation. Santa Cruz County has made an additional appropriation of $150, thus making the total appropriation for this investigation from Santa Cruz and Monterey counties $2,750. Several rooms are being added to the third story of the agricultural building to provide for the fertilizer control work.

Connecticut College and Storrs Station.—B. B. Turner, Ph. D., recently instructor in chemistry at Cornell University, has entered upon his duties as chemist to the college and station, vice C. A. Meserve, who has resigned to accept another position. A small laboratory has been fitted up for the station in the chemical building. The college has revised its course of instruction somewhat and hereafter will not give a degree to the four-year students who have entered the college from the grammar schools, but a diploma instead, two years' additional work being required for the bachelor degree.

Delaware Station.—Clayton O. Smith has been appointed assistant in bacteriology.

Hawaii Station.—A tract of about 100 acres of land in Kona, on the island of Hawaii, is to be turned over to the use of the station for the purpose of making experiments in tobacco culture. One crop of tobacco has been grown under shade at Honolulu and has been sent to this country for fermenting. The crop made a satisfactory growth but its quality is not yet known.

Illinois College and Station.—The following new appointments have been made for the ensuing year: Joseph W. Hart, formerly of the South Carolina College and Station and recently superintendent of the Kingston Dairy School, has become chief assistant in dairy manufactures in the station and instructor in dairy manufactures in the college; Cassius C. Hayden and Herbert A. Hopper, assistants in dairy husbandry in both college and station; and Carl E. Lee, assistant in dairy husbandry in the station. Louis D. Hall has succeeded E. B. Forbes, who has gone to Missouri, as instructor in beef cattle; William Dietrich, a graduate of the University of Wisconsin, has been appointed assistant in swine husbandry in the station and instructor in

e college; Edwin S. Good, assistant in animal husbandry in the station; and ufus C. Obrecht, assistant in horse husbandry in both college and station. lbert N. Hume, a graduate of Purdue University, succeeds Dwight S. Dalby as structor in farm crops. Clifford Willis has been appointed assistant in soil physics both college and station, and James H. Pettit, formerly assistant in chemistry, has ecome assistant in soil analysis in the station and in soil fertility in the college. urt A. Schroeder and Ira O. Schaub have also been added to the chemical force of e station, and James T. Barrett has become assistant in botany in the station.

Iowa College and Station.—C. J. Zintheo, recently of the North Dakota College, as entered upon his duties as professor of farm mechanics in the college. This ork has recently been organized as a branch of the agronomy department of the ivision of agriculture, and is intended to cover instruction in all kinds of farm achinery and appliances, including land drainage, rural telephones, farm water upply, and the various means of obtaining power for operating farm machinery, ich as electric motors, gasoline engines, steam engines, water power, and wind ower. A four-story fire-proof building, 60 by 100 ft., is now being erected as a boratory for conducting this work. J. J. Repp has resigned as veterinarian and rofessor of pathology and therapeutics, and has been succeeded by Carl W. Gay. I. Jacob, of Knoxville, Tenn., a graduate of the Pennsylvania Veterinary College, as been elected to the chair of veterinary medicine and sanitary science. W. H. tevenson has been advanced to the head of the department of soils and A. T. Erwin as become associate professor of horticulture. G. I. Christie has been appointed ssistant in soils, and Wayne Dinsmore assistant in animal husbandry.

Kansas College and Station.—The college has commenced the erection of a commodi-us auditorium, for which an appropriation of $40,000 was made by the last legis-ature of the State. A building to be used exclusively by the dairy department is lso being erected at a cost of $15,000, which will contain class rooms as well as uarters for dairy manufacturing. Oscar Erf, instructor in dairy husbandry in the Jniversity of Illinois, now occupies the chair of dairying and animal husbandry, and R. J. Kinzer, formerly superintendent of the Iowa College farm, has been elected ssistant in the animal husbandry work in the college. F. D. Coburn, William Hunter, J. M. Satterthwaite, and S. J. Stewart, of the board of regents, have retired nd are succeeded by C. E. Friend, of Soldier; R. J. Brock of Manhattan; J. W. Berry of Jewell; and J. O. Tulloss of Sedan.

Maine University and Station.—W. N. Spring has been appointed professor of for-stry; Edith M. Patch, of the University of Minnesota, entomologist to the station, nd S. C. Dinsmore, a graduate of the university, assistant chemist to the station. V. D. Hurd, a graduate of the Michigan Agricultural College, and during the past ummer agricultural demonstrator for the Rhode Island College, has become pro-essor of agronomy, and will have charge of the college farm.

Massachusetts College and Station.—George A. Drew, assistant horticulturist, esigned early in September to accept a position as superintendent of a large estate n Greenwich, Conn. He is succeeded by George O. Greene, recently assistant orticulturist at the Kansas College and Station.

Minnesota College.—F. D. Tucker, who for several years past has occupied the osition of principal of the school of agriculture, has resigned to become president of Memorial University, Mason City, Iowa.

Missouri University and Station.—E. H. Favor has been appointed assistant in orticulture at the university and station. W. L. Howard has been promoted to he position of instructor in horticulture, and Robert J. Foster has been appointed nstructor in veterinary science.

Montana College and Station.—F. W. Traphagen has resigned to accept the chair of metallurgy and assaying in the State School of Mines, at Golden, Colo.

New Hampshire College and Station.—The inauguration of President W. D. Gibbs and the formal dedication of the new agricultural building occurred October 28. The dedicatory address was delivered by Dr. A. C. True, of this Office. E. L. Shaw, formerly assistant in agriculture at the Missouri Station, has been appointed assistant professor of animal husbandry in the college, and F. W. Taylor, of the Bureau of Soils, professor of agronomy. Percy A. Campbell has been appointed superintendent of the college farm. Herbert H. Lamson, bacteriologist, has resigned to become professor of natural science in the State Normal School at Plymouth.

New Mexico College and Station.—R. F. Hare, formerly assistant professor of chemistry, has been elected professor of chemistry in the college and chemist to the station. The 22-horsepower oil-burning engine recently installed for pumping water for irrigation has proved quite satisfactory. The preliminary runs showed a cost of 30 cts. for irrigating an acre 3 in. deep, using crude oil at 5⅜ cts. per gallon, as compared with 70 cts. per acre with wood and $1.30 with coal, the same pump being used in each case. Contrary to the prevalent belief that Irish potatoes could not be grown in this locality, several varieties in a test this season produced quite well.

New York State Station.—Victor H. Lowe, until recently entomologist to the station, died August 27, at Fort Collins, Colo., where he had gone in the hope of recovering his health. In his death the station loses a very successful and enthusiastic worker, thoroughly imbued with the spirit of scientific investigation, and alive to the importance of economic entomology in agricultural and horticultural practice. His work was marked by thoroughness and its practical nature, and he was one of the most popular of the New York State Institute speakers. Mr. Lowe was a graduate of the Michigan Agricultural College in the class of '91, and was appointed to a position in entomology in the New York State Station in 1893, rising to the head of the department in a few years. His chief investigations at the station were on the army worm, case bearers, nursery stock pests, plant lice, cottonwood-leaf beetle on willows, raspberry sawfly, tent caterpillars, the cankerworm, and San José scale, while considerable study was given to the matter of spraying with crude petroleum, with kerosene, and with lime, sulphur and salt mixture, and to the devising of a convenient box fumigator for small orchard trees. Mr. Lowe is succeeded at the station by P. J. Parrott, of the Ohio Station, formerly an assistant at the Geneva Station. Martin J. Prucha, formerly assistant to H. W. Conn, of Wesleyan University, has been appointed assistant bacteriologist, and E. B. Hart has been promoted to the position of associate chemist. The construction of a horse barn has just been commenced, and the contracts let for fire protection. The latter include a chemical engine, a 15,000-gal. tank on a 100-ft. tower, hydrants, and 1,000 ft. of hose with 3 carts.

North Carolina College.—The following appointments in the chemical department of the college are noted from *Science:* William G. Morrison, M. A. (Virginia), instructor in chemistry; Robert W. Page, B. S. (Columbia), instructor of analytic chemistry and metallurgy; Albert A. Haskell, B. S. (Massachusetts Institute of Technology), instructor in dyeing; O. M. Gardner, B. S. (North Carolina College), instructor in chemistry.

Ohio College and Station.—Friend Whittlesey, of the board of control, died September 13. F. A. Derthick, master of the State Grange, has been appointed to succeed him.

Oklahoma College and Station.—E. H. Riley, a graduate of the Minnesota School of Agriculture and of the University of Minnesota, has been appointed assistant in animal husbandry in the college and station, succeeding R. C. Obrecht.

Rhode Island Station.—J. W. Hutchins, of the Michigan Agricultural College, has been appointed agricultural demonstrator to succeed W. D. Hurd, who, as mentioned above, has gone to the Maine College and Station. This officer, provided for by State appropriation, has proved a most satisfactory experiment. The demonstra

or has gone out to the farmers in response to calls, and during the summer months there were more calls for his services than could be met. He was frequently called upon to visit 4 or 5 farmers in a single day to give advice and demonstrations in spraying, the treatment of soils, and other practical questions. He carried the work of the station directly to the farmers, and also brought the farmers into closer touch with the college by explaining the opportunities which it afforded for agricultural instruction. The work of this officer was the more important from the fact that the State has no organized farmers' institutes. The station has obtained results indicating that ignited alumina phosphate is of little or no value to most crops when used upon a very acid soil. This substance shows a high percentage of reverted phosphoric acid, and is said to be used quite extensively in certain ready mixed commercial fertilizers, upon which account these results are rendered particularly valuable.

South Carolina College and Station.—O. M. Watson, poultryman, has resigned, and the division has been temporarily discontinued. C. O. Upton, chief of the dairy and live stock division, has resigned. An appropriation of $40,000 has been made for the erection of a central agricultural building. Thirty-two local institutes were held during July and August, with an aggregate attendance of 8,690. Attendance on the State institute held at the college is estimated at 1,500. The interest in the institutes is rapidly increasing.

Texas College and Station.—John A. Craig, formerly of the Wisconsin and Iowa colleges and stations, but for several years not connected with station work, has been elected director of the station and lecturer on animal husbandry. G. S. Fraps, Ph. D., of the North Carolina College and Station, has been elected assistant chemist to the station. B. C. Pittuck has resigned to become adjunct professor of agriculture at Louisiana State University.

Virginia Station.—J. B. McBryde has been appointed assistant chemist, and W. A. P. Moncure, assistant mycologist.

Washington Station.—R. E. Snodgrass, assistant entomologist, has resigned.

West Virginia University and Station.—Dr. A. C. True, of this Office, delivered an address at the convocation at the opening of the university September 23 on the subject of The Place of Agriculture in the University. Preparation is being made for more extensive work in dairy instruction, the legislature having appropriated $5,000 for that purpose. Rooms are being fitted up in the basement of one of the university buildings, and plans are being considered with reference to the formation of a herd. Walton K. Brainard, a graduate of the Michigan Agricultural College, has been placed in charge of the dairy work, and short courses will be offered during the coming winter. S. W. Fletcher, horticulturist, has resigned to accept a position at Cornell University in charge of the extension work.

Wyoming University.—Charles W. Lewis, M. S., D. D., formerly president of Moore's Hill College in Indiana, has succeeded E. E. Smiley as president.

New Agricultural College in Japan.—A new agricultural college, the third in that country, was opened at Morioka, Japan, in April last. The director of the new college is Professor Tamari, a graduate of the Michigan Agricultural College. The interest in agricultur l education in Japan is said to be quite widespread.

Experiment Station for Rhodesia.—The government of Rhodesia has established an experiment station about two miles from Salisbury, the capital town. The work at present will be conducted by the staff of the agricultural department, under the direction of E. Ross Townsend, secretary. This year about 100 acres were planted to grains, corn, Kafir corn, sorghum, cotton, tobacco, hemp, flax, cowpeas, and other leguminous plants. Special attention will be given to the breeding of disease-resistant plants, and work will also be carried on in the study of animal diseases. The work at the station will be supplemented by cooperative experiments with the farmers of the country. The agricultural department is about to establish an agricultural journal as an official organ and for the dissemination of information.

Agricultural Education in Jamaica.—In an article on this subject *Agricultural News* describes the attention which has been given to agriculture in the training of teachers for the elementary schools as a preliminary to the introduction of agricultural instruction in schools of that grade. Since 1900, 4 courses of lectures for teachers have been held, each lasting about 4 weeks, and including considerable practical work at the Hope Gardens. Nearly 200 of the Jamaica teachers in charge of schools have now attended such courses of instruction. Agriculture also occupies a prominent place in the curriculum of the training colleges, regular instruction being given in that subject during the 2 or 3 years that the students are in residence, together with considerable practical work. For a year past opportunities have been given at the government laboratory for young men intending to become planters or farmers to obtain an education in agricultural science as related to tropical agriculture. The course lasts for 2 years, and at its close a diploma may be granted by the board of agriculture. In addition to the above agencies there are 2 traveling instructors who give their whole time to lectures and demonstrations among the small settlers, as well as 3 local instructors under the agricultural society.

School Garden Exhibit.—What was probably the largest exhibit of this kind ever held in this country was made at the School of Horticulture at Hartford September 18. There were 150 individual exhibits, made by the boys and girls who have been working in the gardens and teachers who have been taking the course in gardening this year. The exhibits consisted of a long list of vegetables and several kinds of flowers. Prizes were awarded for the best-kept gardens, the best kept notebooks, and the best exhibit of products grown. An attractive feature of the afternoon was the hoeing contest, participated in by the second and third year pupils. Although the ground was very heavy with recent rains, this contest showed very good results. Flax and hemp, especially the former, were shown in all stages of their development, from the seed to the finished cloth, two flax-spinning wheels and a loom being in operation. The experimental plats of the school showed a great variety of field crops and vegetables, medicinal herbs, nursery stock, flowers, etc., and a series of fertilizer experiments on vegetables. In the evening there was an outdoor exhibition of magic-lantern slides, showing school gardens throughout the United States and in several foreign countries.

This year the school has had 120 boys and girls from the public schools, 27 from the Watkinson Farm School, and a class of 22 teachers from the Hartford public schools. The teachers commenced February 14, working every Saturday morning, beginning with greenhouse work and concluding with a garden 10 by 30 ft. for each teacher. Much interest has been displayed in the work.

Meeting of the American Pomological Society.—The twenty-eighth biennial meeting of the American Pomological Society was held in Boston, September 10–12. About 200 members were present, and the meeting was an enthusiastic and successful one. The sessions were held in the new Horticultural Hall of the Massachusetts Horticultural Society, where there was put on exhibition an extensive display of fruits representing all sections of the United States and Canada.

In his opening address President C. L. Watrous urged the desirability of experiments in cross pollination and the growing of seedling fruits in order that new varieties adapted to particular localities might be obtained. He favored a Federal law securing to originators of fruits exclusive right to their productions for a series of years, and also a law to control the shipping of nursery stock between States and foreign countries as a means for the better control of fungus and insect pests.

Prof. L. H. Bailey delivered an address on The Attitude of the Schools to Country Life. He pointed out that our present school system originated with the universities, and the ladder of learning was thus let down from above. The agricultural colleges are not filling quite the place it was expected they would. They have developed agricultural literature, established agricultural science, and raised the tone of farm

fe, but they do not reach the mass of people who live in the country. He urged he teaching in school of the things that men are interested in. The kindergarten as declared the most important thing that has come into our educational system. he vital factor in the teacher should be love and sympathy for the child, not the iving of information. The natural way to give agricultural education was believed be through the schools rather than by bulletins. The gist of the bulletins should e embodied in the text-book. Some statistics were quoted to show that as pupils the country schools grow older a smaller proportion affirm a desire to make a living by some phase of agriculture. One of the reasons for this would seem to be that he majority of the teachers in the country schools come from the city, and, consciously or unconsciously, attract the child's mind cityward. The announcement as made that it is proposed to establish a model country school building and rounds at Ithaca, under the auspices of Cornell University, at a cost of $1,000 to 1,500, to be supplied with pupils from the town, and to serve as a means for the etter training of teachers in agriculture.

In a paper on the Relation of Cold Storage to Commercial Orcharding, G. Harold Powell, of this Department, stated that cold storage is likely to have its greatest nfluence on the development of commercial apple growing. Quick-ripening fruits ike the peach, summer pears, and small fruits are not generally adapted to cold-torage treatment. They ripen in hot weather, and the end of their life is quickly eached unless ripening is checked by immediate storage. Even then they can be eld back only for a limited time. They rapidly lose their delicate aroma and lavor, and when placed on the market often deteriorate before reaching the con-umer. If summer fruits are stored, success demands that they be well ripened and hysically perfect when put in cold storage. They must be placed in small pack-ges, stored immediately after packing, and must be kept as cool as possible after emoving from storage and sold at once. Under these conditions berries may be tored a week, peaches 2 weeks, and Bartlett pears a month or longer if there is a lemand for the fruit. Refrigeration is likely to prove of special importance in the levelopment of apple growing in the States farther south. The speaker held that when stored as soon as picked many of the best varieties of the South equaled the arieties of the North in keeping quality. The local warehouse is considered the deal for quick storage and for the grower who is competent to handle his own crop. Cold storage is raising the standard of fruit growing by emphasizing the importance f physically perfect, well-developed fruit. It is directing attention especially to the act that diseased, wormy, poorly colored, immature, or bruised fruit has poor keep-ng quality. It emphasizes the necessity of careful picking, packing, and grading. Where the cold-storage warehouse is properly managed the better apples, like Grimes nd Mother, retain their finest qualities until March, and Jonathan, Northern Spy, nd Esopus Spitzenberg until April or May. There is always an undersupply of hese better varieties.

J. H. Hale, of Connecticut, discussed the subject of Grading and Packing Fruits or Long Shipment. Fruits for long-distance shipment must be grown for that pur-ose. Sorts that carry best are those grown on high, well-drained land on open-eaded trees. Color and quality in the fruit are secured by the liberal use of potash n the soil. The fruit when picked should be well matured, but not soft. It should e picked and shipped in rigid packages to prevent bruising. As soon as the fruit is aken from the tree it should be carried to the packing house and graded by hand nto different sizes, colors, etc. The best package for peaches and plums is the Georgia six-basket carrier, for apples and pears the 50-pound bushel box. All choice ruit should be wrapped in paper. It adds to the carrying and keeping qualities of he fruit, improves the color, and increases the returns from 10 to 25 per cent above he regular market price. When packed, the fruit should be placed in cold storage mmediately. Stripping off part of the leaves of very vigorous trees helps the color, exture, and shipping capacity of the fruit, but is slightly injurious to the quality.

In a paper entitled Should the Commercial Grower Plant Varieties of High Quality? G. T. Powell called attention to the great desirability and profit in growing fruit of high quality. Fruit of poor quality lessens the desire of the public for fruit, thus greatly affecting the demand.

The provisions and working of the Canadian fruit-inspection law passed in 1901 were explained by W. A. McKinnon, Chief of the Fruit Division of the Canadian Department of Agriculture. The law requires that the name and address of the grower be placed on every closed package of fruit, as well as a mark showing the grade. It is required that first-grade fruit shall consist of well-grown, nearly uniform specimens, well colored and uniformly packed. Ninety per cent of any package must be sound and free from worms or disease. If the fruit is packed so that more than 15 per cent is inferior to the facing, it is declared a misdemeanor. Under the terms of the law inspectors are empowered to enter all premises and inspect all packed fruit. They have the right to detain shipments until inspected, and to mark on the package the character of the fruit, but can not confiscate it. They are subject to fine if they exceed their authority by unnecessarily delaying shipment. The results of the policy of fruit inspection in Canada have been very gratifying. Confidence has been restored in British markets and the export trade developed wonderfully as a result of the act.

Dr. W. D. Bigelow, of the Bureau of Chemistry of this Department, discussed Pure Food Legislation and its Relation to the Fruit Grower, calling attention to the various methods used in adulterating jellies and other fruit products, and urging the desirability of a Federal law compelling the correct labeling of all fruit products. A resolution favoring such a law was adopted by unanimous vote.

Other papers read were as follows: Fruit Gardens, J. H. McFarland; Pomology at the St. Louis World's Fair, F. W. Taylor; The San José Scale in the Orient, C. L. Marlatt (E. S. R., 14, p. 535); Judging Fruits by Scales of Points, F. A. Waugh; Waste in Apples, W. R. Lazenby (E. S. R., 15, p. 43); Fruit Culture in the Pacific Northwest, S. W. Fletcher. One evening was given up to the discussion of ideals in pomology and another to the progress of pomology in America during the past fifty years.

The Ad Interim Committee on Examination of New Fruits, which has been established since the last biennial meeting, made its first report. The committee is composed of 50 members, headed by a general chairman and divided into 7 subcommittees of a chairman and 6 members each. Each subcommittee has jurisdiction over a certain class of fruits. It is their duty to examine and pass upon the merits of such seedling fruits as shall be entered and furnished by originators for examination when the fruit is in proper condition. The committee reported that 33 entries had been received during the year. A variety of peach from Georgia was named the Hiley, after the originator, and was awarded a Wilder medal.

A committee was appointed to prepare fruit score cards that may be used for judging fruits in the society's work and also at the coming World's Fair at St. Louis.

Additional by-laws were adopted by the society providing for a standing committee which shall report biennially on injurious insects and diseases of pomological importance.

One of the most important reports at the meeting was that of the special committee on revision of the rules of nomenclature, appointed at the Philadelphia meeting four years ago, which was adopted. The chief provisions of this report were as follows:

Rule 1. No two varieties of the same kind of fruit shall bear the same name. The name first published for the variety shall be the accepted and recognized name, except in cases where it has been applied in violation of this code. In explanation of this rule the paramount right of the originator, discoverer, or introducer of a new variety to name it within the limitation of this code is recognized and emphasized.

Rule 2. The name of a variety of fruit shall consist of a single word. One of the xplanations attached to this rule is to the effect that no variety should be named nless distinctly superior to existing varieties in some important characteristic, nor ntil it has been determined to perpetuate it by bud propagation, nor should the name f a person be applied to a variety during his life without his consent.

Rule 3. In the full and formal citation of a variety name, the name of the author vho first published it should also be given.

Rule 4. Publication consists (*a*) in the distribution of a printed description of the ariety named, giving the distinguishing characteristics of fruit, tree, etc.; or (*b*) in he publication of a new name for a variety that is properly described elsewhere, such ublication to be made in any book, bulletin, report, trade catalogue, or periodical, roviding the issue bears the date of its publication and is generally distributed mong nurserymen, fruit growers, horticulturists, etc.; or (*c*) in certain cases the general recognition of a name for a propagated variety in a community for a number of years shall constitute the publication of that name.

Rule 5. No properly published variety name shall be changed for any reason except conflict with this code, nor shall another variety be substituted for that originally described thereunder.

A large number of explanatory notes and interpretations accompany the code. Officers for the next two years were elected as follows: J. H. Hale, president; J. Craig, secretary; and L. R. Taft, treasurer. Seven silver Wilder medals and 8 bronze medals were awarded for exhibitions of fruit. One of the displays receiving a silver medal was that of a collection of 109 varieties of seedling apples from Minnesota.

Society of Horticultural Science.—Pursuant to a call issued by S. A. Beach, noted in a recent number of the Record, an organization of this new society was effected at Boston in September, in connection with the meeting of the American Pomological Society. About 30 prominent horticulturists, representing different sections of the United States and Canada, joined the society and others have signified their intention of doing so. The object and plans of the society are mentioned elsewhere in this number. The constitution provides for assigning subjects to referees and alternates for investigation. The subjects assigned for the next meeting were as follows: The Influence of Shade on Plant Culture, L. C. Corbett and B. M. Duggar; Orchard Tillage, A. R. Whitson and W. Paddock; Orchard Cover Crops, R. A. Emerson and J. Craig. A symposium on the progress of European and Canadian horticulture was assigned to 5 referees and as many alternates. The next meeting will probably be held at St. Louis during Convocation Week. The officers elected were as follows: President, L. H. Bailey; vice-presidents, T. V. Munson, G. B. Brackett, and E. J. Wickson; secretary-treasurer, S. A. Beach.

Necrology.—Veterinary science, comparative medicine, and hygiene suffered a severe loss in the death of Edmond Nocard, August 2, 1903, at the age of fifty-three years. Dr. Nocard was born in Provins, France, and after a classical college course entered the veterinary school at Alfort, where he graduated. His course in this institution was interrupted by service in the Franco-Prussian war. He subsequently became professor of pathology and clinical surgery at the Alfort school, and succeeded Goubaux as director of the school upon the retirement of the latter in 1887.

Dr. Nocard's contributions to veterinary science have been of unusual extent and value. He contributed greatly to the knowledge of rabies, tuberculosis, tuberculin, glanders, contagious pleuro-pneumonia, piroplasmoses, actinobacillosis, dourine, and other protozoan diseases, as well as to foot-and-mouth disease, contagious abortion, and white scour in calves. He was frequently called upon for important public service in the investigation and repression of animal diseases, not only in France but in various foreign countries, including the United States. His published works are exceedingly voluminous, including numerous articles in veterinary periodicals and more formal contributions, particularly the large volume entitled Maladies Micro-

biennes des Animaux, which was published in conjunction with Professor Leclainche and is perhaps the best work of its kind in existence.

Frederick Law Olmsted, celebrated American landscape architect, died at a sanitarium near his home in Brookline, Mass., August 28, aged 81 years. Mr. Olmsted established a new school of landscape architecture in America and did more to stimulate interest in it as an art and to influence its development than any other American. His name is associated with the development of more large park systems in this country than that of any other landscape architect. In cooperation with his partners he designed the public parks of New York City, Brooklyn, Boston, Montreal, Buffalo, and South Chicago; the Golden Gate Park at San Francisco, Niagara Falls Reservation, the World's Fair Grounds at Chicago, the U. S. Capitol Grounds and back terrace, the Biltmore Estate of G. W. Vanderbilt, and many other public and private parks. He was also the author of several books through which he first became known to the public. Among the more prominent of these are Walks and Talks of an American Farmer, A Journey through Texas, Our Seaboard Slave States, and A Journey to the Back Country. Mr. Olmsted retired from the active practice of his profession about 8 years ago, since which time the business has been carried on by John L. and F. L. Olmsted, Jr.

We note from *Science* that Ernest Menault, inspector-general of agriculture in France, and the author of numerous works on agriculture and economic entomology, has died at the age of 72 years.

Personal Mention.—Clarence T. Johnston, for several years past assistant in the Irrigation Investigations of this Office and in charge of the office at Cheyenne, Wyo., has resigned to accept the appointment of State Irrigation Engineer of Wyoming.

Clarence B. Lane, assistant in dairy husbandry at the New Jersey Station, has been appointed assistant chief of the Dairy Division of this Department. He succeeds Harry Hayward, who, as previously noted, resigned during the summer to assume charge of the newly organized agricultural department at the Mount Hermon School, near Northfield, Mass.

Charles V. Piper, of the Washington College and Station, has accepted an appointment as botanist in the Division of Agrostology in this Department, and will also have charge of the herbarium of grasses.

Alfred M. Sanchez, an assistant in the Bureau of Soils, has been appointed in the Bureau of Agriculture of the Philippines, where he will continue the soil investigations carried on last year by C. W. Dorsey.

Dr. David Morris, Imperial Commissioner of Agriculture for the West Indies, has been appointed by King Edward to be Knight Commander of the Most Distinguished Order of St. Michael and St. George.

Miscellaneous.—The Association of Official Agricultural Chemists will meet in Washington, November 20–23, immediately following the meeting of the Association of American Agricultural Colleges and Experiment Stations. The meetings of the chemists will be held in the lecture hall of Columbian University. The programme calls for reports of referees on food adulteration, dairy products, foods and feeding stuffs, sugar, nitrogen, potash, phosphoric acid, soils, ash, tannin, and insecticides, and of special committees on food standards and fertilizer legislation.

The Walnut Growers' Association of Southern California has offered an award of \$20,000 for a practical means of controlling the disease known as walnut blight or bacteriosis.

The report of the Irrigation Commission of India recommends the expenditure of \$150,000,000 in 20 years on protective works, and \$2,000,000 annually on loans for private irrigation work. The necessary funds are to be raised by loans and the interest charged to the famine grant.

The estate and garden of the late G. F. Wilson, near Woking, England, has been purchased by Sir Thomas Hanbury and presented to the Royal Horticultural Society.

EXPERIMENT STATION RECORD.

Vol. XV. November, 1903. No. 3.

The need of increased funds for the further development and extension of the experiment stations is brought out in the current report of the Director of this Office. The successful extension of their work in the case of a few stations, with the aid of special appropriations from the States, is cited as illustrating the possibilities for enlarging the scope of the stations' work and the widespread benefits to agriculture which may result.

The States have done much toward supplying the stations with suitable buildings and other facilities. This is in accordance with the intent of the Hatch Act. A number of States have gone further and have made appropriations for current expenses or for carrying on special lines of investigation. Notable instances of this during the past year are appropriations by the California legislature of \$5,000 for the establishment of a poultry station and \$3,000 for viticultural investigations; by the Illinois legislature of \$25,000 for live-stock investigations, \$25,000 for soil investigations, \$10,000 for corn investigations, \$10,000 for horticulture, and \$15,000 for dairying—a total of \$85,000 per annum; by the Wisconsin legislature of \$1,500 annually for two years for tobacco investigations and \$2,500 annually for cranberry investigations, \$10,000 for the purchase of live stock, and a like sum for additional farm lands; in Hawaii, \$16,800 in aid of the Federal station for two years; in Missouri, a special appropriation of \$10,000 for the station and large college appropriations in which the station will share; in Tennessee, \$10,000 for the purchase of additional farm lands and \$600 for cooperative experiments with field crops and fertilizers on the type soils of the State; and in Utah, \$11,650 for station equipment and maintenance.

A number of States have also made special appropriations for substations, several of which are new. For example, Kansas appropriated \$32,550 for the equipment and maintenance of the new Fort Hays Substation; Nebraska, \$15,000 for the establishment and maintenance for two years of a substation for the semiarid region in the western part of the State; North Dakota, \$5,000 for a substation to be located at Edgeley; and Utah, \$12,500 for the establishment and maintenance

for two years of five experiment farms in different sections of the State, to test the possibilities of nonirrigable lands.

This, in addition to the regular appropriations which several of the States are making, the provision for printing their bulletins and reports in a number of instances, and other assistance, makes a very creditable showing for a considerable number of the States and indicates the appreciation in which the stations are held. Less than half the stations, however, were affected by such legislation, or receive any financial aid from the States for maintenance.

During the past year fifty stations shared in the benefits of the Hatch fund. Twenty-three of these were given additional State aid and twenty-seven received none. Of the State appropriations for Federal stations, six did not exceed $1,000, and only eight equaled or exceeded the Hatch appropriation of $15,000. Several of the appropriations were for the support of substations and were not shared by the Federal stations. The total State appropriations for stations and substations were but little more than 51 per cent of the Hatch fund.

The meagerness of the funds available for investigation in the twenty-seven unaided Federal stations is shown by the following figures from the statistical reports on the expenditures of the Hatch fund in those stations: The total receipts from the Hatch fund were $405,000. The expenditures for administration and permanent improvements (salaries, labor, traveling expenses, postage, stationery, libraries, and fixtures) amounted to $313,086.38, or an average of $11,595 for each station. The average amount expended for publications was $760. This leaves an average for each station of only $2,645 for the general expenses of investigations (chemical supplies, fertilizers, feeding stuffs, tools, implements, and machinery, scientific apparatus, live stock, seeds, plants, sundry supplies, freight and express, heat, light, water, and contingent expenses). Dividing this sum by the average number of investigators, we have an average of $264.50 for each investigator. The whole amount ($2,645) would hardly pay the expenses of a good-sized feeding experiment or a field experiment involving tests in several different localities. How inadequate, then, does such a sum appear when divided among ten investigators. Under these conditions it is not strange that so many problems of the farm remain unsolved; it is wonderful that our smaller stations have accomplished so much.

These figures show conclusively that, if our stations are to be continued on the broad basis on which they are at present organized, they must be supplied with larger funds for the general expenses of investigation, in order to conduct their work in a thorough and satisfactory manner. The States can and undoubtedly will supplement the National funds more fully as time goes on; but since the results obtained by the stations are in many cases of general value to the agriculture of

the United States, it seems proper that they should receive additional financial aid from the National Government now that they have demonstrated their ability to stimulate and increase the agricultural production of the country. This supplemental aid should, of course, be granted under conditions which will insure its exclusive application to meet the expenses of agricultural investigations, and which will stimulate the States to increase their contributions to the support of the stations.

In this connection it is well to consider that, with the increase of agricultural operations in this country, the States generally will be called upon to establish a much larger number of stations or substations than at present exist. The areas over which many of the stations in this country are required to extend their jurisdiction are so large that they can not meet the demands for investigations adapted to the various conditions of soil, climate, and rational agricultural practice in their several States. In no section of the United States are there as many stations in proportion to land area as in France or Germany. In our smallest States along the Atlantic Coast we have one station for 24,000 square miles; France and Germany have eight times as many. The South Central States with their 10 stations are 40 per cent larger than all of France and Germany with their 151 stations, and Texas alone, with one Federal station, is 27 per cent larger than either of those countries. The ratio of stations to area in France and Germany is 96 to 1 as compared with Texas, 28 to 1 as compared with Minnesota and the Dakotas, and 39 to 1 as compared with the Pacific States.

Under present conditions the stations as a rule are not able to grapple with the larger problems of our agriculture in a sufficiently broad and thorough manner to give the surest expectation of success. Generally speaking, they are now in a position to utilize larger funds effectively, since questions relating to organization and methods and lines of work have been largely solved.

The kind of work most needed at present is expensive, requiring investigators of the highest ability, ample facilities in the way of equipment and assistance, and opportunity for concentration of effort without interruption from inspection or routine work or for instruction. The experiment station is a university department standing at the head of the institution, and the fundamental importance of its educational function is already apparent. Its chief business is to find out new applications of science to agriculture which shall result in improved practices and products. On its success depends not only the advancement of agricultural practice in particular regions, but also the effectiveness of the agricultural colleges and other institutions for agricultural education.

The amount of data published by the stations on many agricultural

subjects is now very large, and the attempts which have been made to reduce this material to organized form, in order that it may be utilized for purposes of agricultural education, have shown that the stations are doing a great work in supplying the materials out of which a definite science of agriculture is being constructed, and on which courses of instruction in agriculture of different grades can be successfully based. Hence the highest interests of agricultural education, as well as the practical interests of agriculture, call for increased thoroughness and efficiency on the part of the stations in their efforts to solve problems in agricultural science and practice.

It is encouraging to note the progress of experiment station work in Alaska, as evidenced by the reports of Prof. C. C. Georgeson from year to year. The work there differs from that in any other locality of this country owing to the conditions under which it is carried on and the fact that it usually precedes even primitive attempts at farming. There is as yet no basis of practical experience on which to fall back, but the work is laying the foundation for a future agriculture. It partakes of all the elements of pioneering in a new country, and from the inaccessibility of many parts of the country and uncertainties of transportation it is carried on under unusual difficulties.

This is illustrated by the experience in opening the new station at Copper Center the past season. This station embraces a tract of about 775 acres of land in the valley of the Copper River, which has been temporarily withdrawn from entry by the Secretary of the Interior and set aside for the use of the station. The nearest port is Valdez on Prince William Sound. A military trail has been constructed from Valdez to Eagle on the Yukon, a distance of about 500 miles, and Copper Center is located on this trail a little over 100 miles inland. A start was made from Valdez early in the spring to transport the equipment of the station which was absolutely necessary to begin the work. The team purchased for the station was used for this purpose but proved inadequate for the undertaking, as the trail was very difficult, and transportation was completed by contract at a price which would be prohibitive to the ordinary individual.

During the past season about 10 acres of land have been cleared, plowed, and seeded to spring crops. These consisted chiefly of varieties of oats, barley, spring wheat, emmer, buckwheat, and various grasses. The season was rather backward, and some of the cereals were not received in time for early sowing. Their growth was impeded by dry weather following the seeding, but in spite of this all were in quite a flourishing condition July 20, and it was believed that many of the cereals would mature by the end of August if frost did not intervene. As noted in previous reports, the newness of the ground had an important influence on the growth of the crops. Where brush had

een burned or the ground previously cleared the growth was much etter than elsewhere. The superintendent in charge of the station ucceeded in maintaining a fairly good garden, and peas, radishes, and ettuce were supplied from it by the middle of July. Other hardy egetables promised well.

A log house 14 by 28 feet was constructed during the past summer, nd additional buildings and equipment are urgently needed. In ddition to the ground seeded, 6 or 7 acres have been cleared and by ext spring it is expected to have at least 20 acres under cultivation, rains and forage plants being grown on a farm scale.

Professor Georgeson estimates that there are about 10,000 square niles of good agricultural land in this valley, with perhaps half as much nore in mountain valleys which lead out into the interior plain. The oil is rich and well adapted to cultivation, and it is believed feasible to grow good cereal crops at least three years out of four. Notwithstanding the rich mineral deposits of the Copper River country, it is believed that they will ultimately be exceeded by the value of the agricultural products, if this country is properly opened up.

We give in this issue the plans of the new building for farm mechanics at the Iowa Agricultural College. This department is not only new at that institution, but is one of the latest products of specialization in agricultural instruction in this country. It is an attempt to do for that part of rural engineering what has already been done for agronomy and for animal production at many of the colleges—to bring together in a logical way the scattered instruction which bears on this branch of agriculture, and to work out systematic and well-rounded courses in it.

A number of colleges are now considering the establishment of departments of rural engineering or farm mechanics, and there is much interest in the development of these subjects as independent lines of work. The Illinois College of Agriculture has had an instructor in farm mechanics for several years past; the Wisconsin College has received a State appropriation of $15,000 for a farm-engineering building, and the North Dakota College has of late been giving special attention to this subject. In Minnesota the College of Agriculture has obtained an appropriation of $5,000 for a building for its course on farm machinery, and the officers of the State fair have granted the college the use of a large pavilion in which machines loaned by manufacturers are to be housed for instructional purposes.

The opportunity for useful and effective work, both in instruction and in experimentation, is abundant; and the new courses will offer further opportunity for the agricultural student to specialize, and for the prospective farmer to receive systematic training in the theory

of farm-machinery construction, for example, as well as in its practical operation and management.

In no other country is such extensive use made of farm machinery and the scarcity of farm labor will tend to its increased use in th future rather than otherwise. The total value of implements an machinery on the farms of this country, according to the recent census was $761,261,550, an average of $133 per farm, taking the countr over, and of 90 cents per acre of farm land. Much of this machiner is elaborate and complicated in construction, and requires mechanica skill or genius for its most efficient operation and care, not to mentio the making of small repairs. It represents an important part of th farmer's invested capital upon which he must pay or earn interest That there is an enormous waste of money due to neglect and unskillful handling of this part of the farm equipment must be obvious t anyone who has traveled through the regions where it is most used.

The record of two tenants on neighboring farms in Nebraska is case in point as showing how much of this waste may be avoided These two men have been living on the same farms for the past nin years. One of them is still using the same harvester which he purchased the first year he took the farm; the other has bought and "wor out" three self-binders. In eight and a half years there has been difference of $1,900 in the outlay for farm machinery by these tw men. Both farms are about equally equipped. The difference is that as a result of better care and more skillful use, one man's tools hav lasted about three times as long as the other's. Such examples o extravagant mismanagement are by no means uncommon. It is ofte one of the great leaks on the farm.

The agricultural high school at Berlin has a well-developed an efficient department of farm machinery. In the opinion of the hea of that department, nothing has done more to improve agricultura methods in Germany than the study by the young men of the tools o their own and other countries; and out of it have resulted man improvements in construction. Other foreign institutions are givin attention to instruction and experimentation along these lines.

While farm machinery is only one of several subjects embraced i this new department, it will naturally be quite an important part a the outset. Along with it will go questions relating to farm buildings, silo construction, fence building, underdrainage, etc. Out o these can be constructed a department of instruction which wi strengthen and round out the work of the agricultural colleges, an will also suggest numerous lines of profitable investigation.

NEW BUILDING FOR FARM MECHANICS AT IOWA COLLEGE OF AGRICULTURE AND MECHANIC ARTS.

The building for the new department of farm mechanics is an addition to Agricultural Hall, and is connected with it by a corridor 27 feet long by 15 feet wide. The main part of the new building is 60 by 100 feet and contains two main floors. Each of these floors has a balcony about 12 feet wide, which is supported by steel columns. The second floor balcony extends over only a part of that floor, the remainder being inclosed and constituting an attic or third floor. The effect is, therefore, that of a four-story building, there being windows on each of the main and balcony floors.

The first or ground floor (fig. 5) contains a large machinery operating room 66½ feet long by the full width of the building, with an approach 14 feet wide and paved with brick. This room will be used for the study and operation of farm motors, such as gas engines, steam traction engines, etc. At one side is a row of double forges supplied with blast from a fan, and a double row of anvils, for students' use, and across the end is a row of benches. On this floor are also located wood-working and iron-working shops for experimental purposes, both well equipped with hand and power machines, and also tool rooms, toilet room, and a supply of lockers. These rooms and the corridor all have a brick floor. The balcony of this floor will be used as a carpenter shop for students of this department, and be provided with circular saws, lathes, grindstone, emery wheel, etc.

On the second floor (fig. 6) are located offices for the head of the department, a class room about 21 by 30 feet, a drafting room 22 by 27 feet, and a students' study and reading room 17 by 22 feet. About half of this floor will be occupied by a smaller machine room 51 feet 7 inches by the width of the building. This room will be used for setting up, operating, and testing various kinds of farm machinery, such as binders, mowers, corn planters, corn shredders, plows, wagons, etc. The connection with the main building is upon this floor.

The balcony and third floor (fig. 7) will be used for storing farm machinery not in use, and will contain an office for assistants in the department, a mailing room, and several storage rooms. Photographic and dark rooms for instructing the students of this department in photography will be located on this floor.

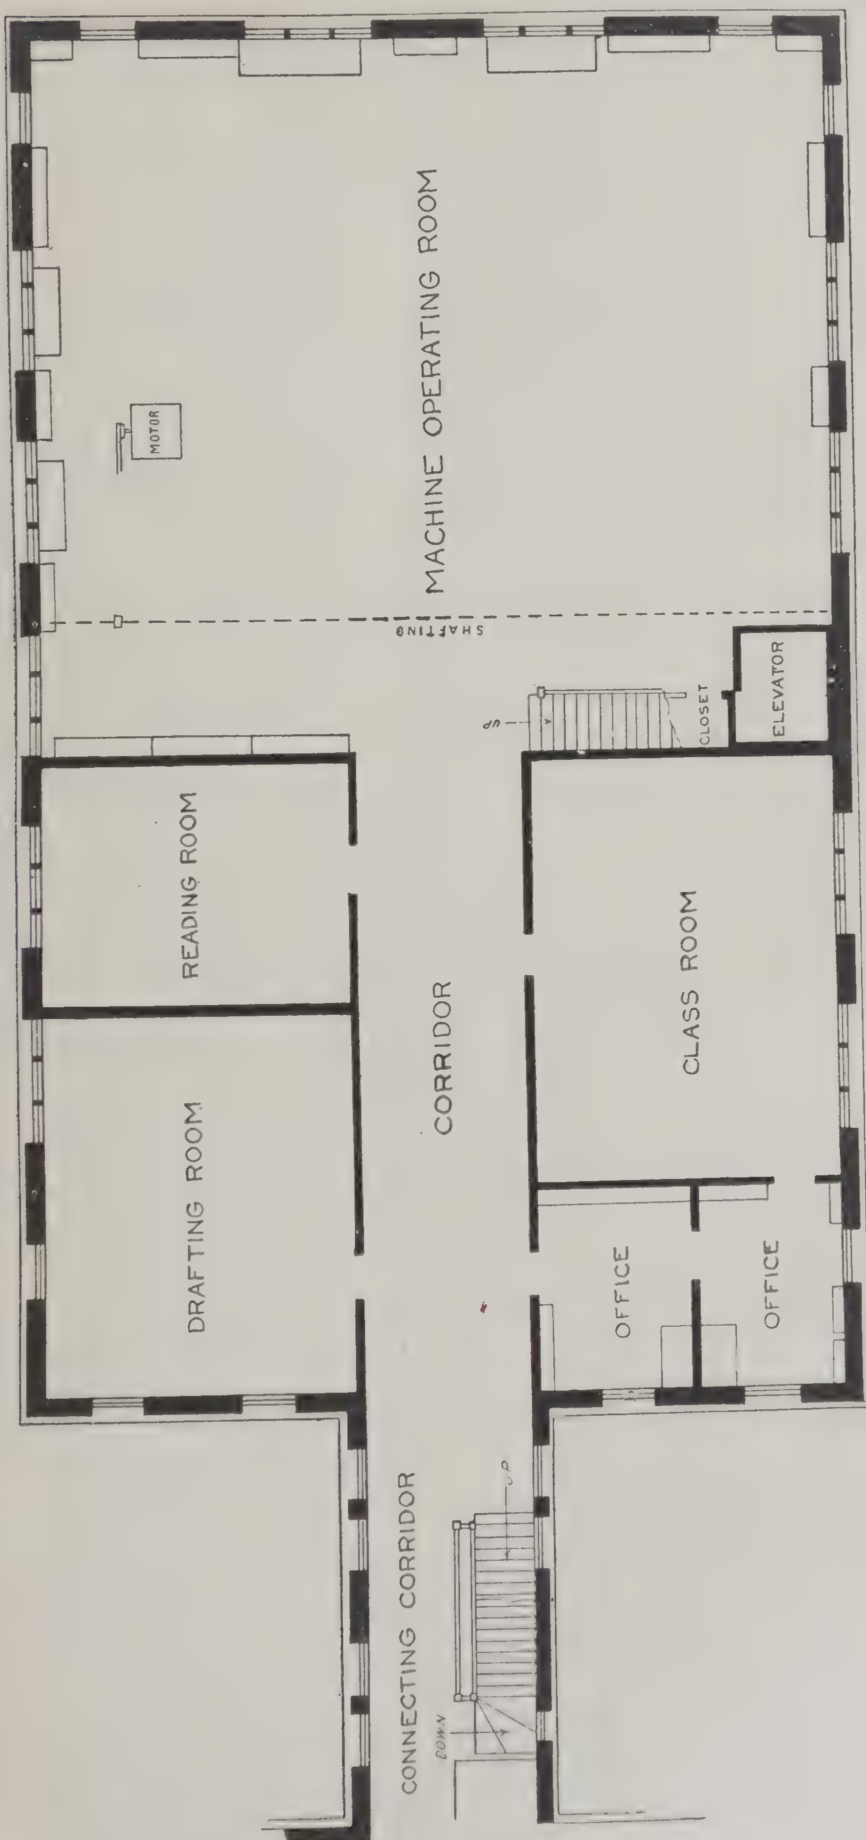

Fig. 6.—Second-floor plan of the Farm Mechanics' Building.

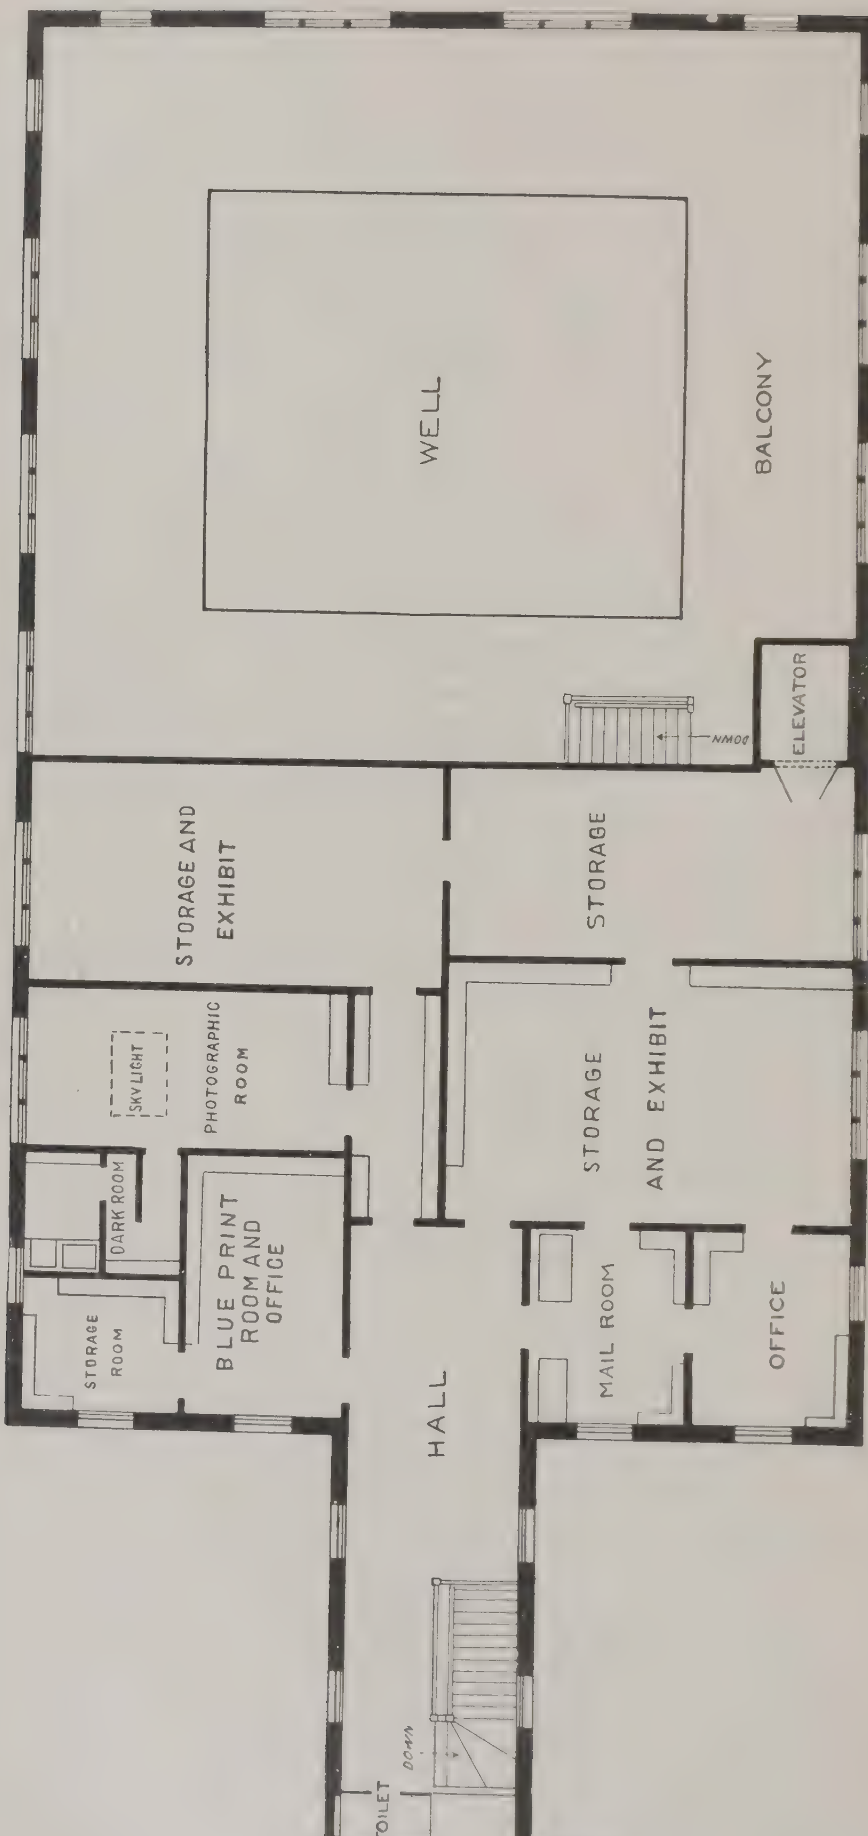

FIG. 7.—Balcony and third-floor plan of the Farm Mechanics' Building.

The building has a large elevator with openings on each floor and balcony. It is very substantially constructed of brick, stone, and steel, and is fireproof throughout. The cost, including heating, plumbing, furniture, and other equipment, will be between $65,000 and $70,000. Those familiar with such buildings state that when completed it will be the best and most thoroughly equipped building for instruction in farm mechanics in this or any other country.

Although this department is new at the college, it already has considerable material in the way of equipment. A 12-horsepower steam engine has been donated by a thrashing-machine company, to be used for instruction purposes, and a wagon company has furnished a farm wagon especially constructed for experimental work. The equipment of this wagon includes 10 sets of wheels of different heights and different widths of tire, to be used in tests to determine the best kinds of wheels for different roads, and sets of roller and ball-bearing axles, which will be tested and compared with the ordinary friction axles to determine the relative draught. The roller bearings were especially manufactured for this wagon and are thought to be the first roller bearings used on a farm wagon. A steel grain tank having a capacity of 150 bushels also goes with the wagon. The department is also provided with a newly-invented dynamometer which registers maximum and minimum draughts on a sheet of paper, and by an ingenious device shows the average draught during the test.

It will be the aim of the department to cooperate with the implement manufacturers in various ways. A friendly spirit has already been exhibited by these manufacturers. Quite a number of machines have already been received from them which will be used for practice work by the students, and many others have been promised as soon as the new building is ready to receive them. Representatives of these implement manufacturers will be invited to lecture before the students in farm mechanics from time to time, explaining in detail the construction of the machines which they are manufacturing, with the aid of specimens of these machines for illustration. In this way it is hoped to obtain for the students the best possible information on implement construction by men who are specialists in their lines.

The aim will be to make the collegiate course thoroughly practical. Students will be trained in the fundamental principles of construction of farm machinery, and in the setting up, operating, and adjusting of various kinds of implements. Besides farm machinery, the department embraces instruction in farm drainage, road construction, irrigation, planning farm buildings, mechanical drawing, carpentering, blacksmithing, and horseshoeing. Courses are provided in farm and field machinery, in farm power machinery, in drainage, and farm buildings, and opportunity is offered for postgraduate work. A number of postgraduate students are taking farm mechanics this year as

a major study, with the expectation of fitting themselves for teaching this subject; and many inquiries are being received from prospective students.

The new department is in charge of Prof. C. J. Zintheo, recently instructor in agricultural engineering at the North Dakota Agricultural College, who was formerly in the employ of a large implement concern, and has had experience in both the practical and theoretical aspects of the subject.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Nitrogen in protein bodies, T. B. Osborne and I. F. Harris (*Jour. Amer. Chem. Soc., 25 (1903), No. 4, pp. 323–353*).—In studying the decomposition products of various protein preparations the authors have obtained fairly uniform results with Hausmann's method, which consists in boiling the sample with strong hydrochloric acid and then determining the nitrogen expelled in the form of ammonia by distillation with magnesia, the nitrogen precipitated by phosphotungstic acid from the ammonia-free solution, and the nitrogen in the filtrate from the phosphotungstic acid precipitate. Tests were made of the method, and under the conditions in which it was used by the authors it is believed to yield valuable comparative results. It has been found that preparations obtained from different sources and previously believed to be the same substance have yielded by this method such different proportions of nitrogen in the several groups as to show beyond doubt that they are entirely distinct; and, on the other hand, confirmatory evidence has been obtained on the identity of other preparations of different origin. The following table indicates the source of the different proteins and summarizes some of the analytical data:

Nitrogen in various protein bodies.

Name and source of protein.	Nitrogen as ammonia.	Basic nitrogen.	Non-basic nitrogen.	Nitrogen in magnesium oxid precipitate.	Total nitrogen.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Globulin (wheat)	1.42	6.83	9.82	0.28	18.39
Globulin (cocoanut)	1.36	6.06	10.92	.14	18.48
Globulin (squash seed)	1.28	5.97	11.04	.22	18.51
Edestin (hemp seed)	1.88	5.91	10.78	.12	18.64
Excelsin (Brazil nut)	1.48	5.76	10.97	.17	18.30
Corylin (hazel nut)	2.20	5.75	10.70	.16	19.00
Globulin (cotton seed)	1.92	5.71	11.01	....	18.64
Globulin (castor bean)	1.96	5.64	11.00	.12	18.75
Corylin (walnut)	1.78	5.41	11.51	.15	18.84
Conglutin (lupin)	2.12	5.20	10.38	.18	17.90
	2.65	5.13	10.30	.14	18.21
Legumin (pea, lentil, horse bean, vetch)	1.69	5.18	10.92	.17	17.97
Globulin (flax seed)	2.00	4.77	11.47	.22	18.48
Vicilin (pea, lentil, horse bean)	1.78	4.75	10.37	.21	17.11
Nucleovitellin (egg yolk)	1.25	4.65	10.16	.22	16.28
Vignin (cowpea)	1.91	4.28	10.81	.25	17.25
Globulin (sunflower)	2.57	4.27	11.52	.24	18.58
Conalbumin (egg white)	1.21	4.16	10.49	.26	16.11
Amandin (almond)	3.05	4.15	11.55	.17	19.00
Phaseolin (kidney bean, adzuki bean)	1.74	3.97	10.18	.29	16.20
Glycinin (soy bean)	2.11	3.95	11.27	.12	17.45
Legumelin (pea, lentil, horse bean, adzuki bean)	1.04	3.71	10.96	.38	16.09
Leucosin (wheat)	1.16	3.50	11.83	.43	16.93
Casein (cow's milk)	1.61	3.49	10.31	.21	15.62
Ovalbumin (egg white)	1.34	3.30	10.58	.29	15.51
Glutenin (wheat gluten)	3.30	2.05	11.95	.19	17.49
Gliadin (wheat, rye)	4.20	.98	12.41	.14	17.66
Hordein (barley)	4.01	.77	12.04	.23	17.21
Zein (corn)	2.97	.49	12.51	.16	16.13

The wide range in the percentages of basic nitrogen in the different proteins is considered the most striking feature shown by these figures. The ammonia also showed marked variations.

Cotton-seed meal and gluten meal examined by the same method showed marked differences in the percentages of nitrogen in the different groups, but the authors suggest that these chemical differences are apparently of but little importance from the standpoint of animal nutrition.

The precipitation limits with ammonium sulphate of some vegetable proteins, T. B. OSBORNE and I. F. HARRIS (*Jour. Amer. Chem. Soc., 25 (1903), No. 8, pp. 837–842*).—In the determinations reported a quantity of protein was dissolved in one-tenth saturated ammonium sulphate solution, the solution filtered, and 2 cc. mixed with enough one-tenth saturated sulphate solution so that when precipitated with a saturated sulphate solution the final volume would be 10 cc. In the following table are given the cubic centimeters of saturated sulphate solution required to first render the solution permanently turbid, to precipitate the bulk of the protein, and to remove all traces of the substance:

Saturated ammonium sulphate solution required to precipitate vegetable proteins.

Name and source of protein.	Lower limit.	Most precipitated.	Upper limit.
	Cc.	*Cc.*	*Cc.*
Globulin (English walnut)	2.8	2.8–4.6	6.6
Globulin (black walnut)	2.8	2.8–4.6	6.6
Edestin (hemp seed)	3.0	3.0–4.0	4.2
Edestin monochlorid	3.0	3.0–3.9	3.9

Globulin (squash seed)	3.3	3.5–4.1	4.4
Amandin (almond)	3.5	3.5–5.0	5.3
Corylin (filbert)	3.7	3.7–5.3	6.6
Excelsin (Brazil nut)	3.8	4.0–5.0	5.5
Conglutin—less soluble portion (lupine)	4.2	4.3–6.0	7.3
Conglutin—more soluble portion (lupine)	4.6	6.4–8.2	8.7
Globulin (cotton seed)	4.6	5.0–6.0	6.4
Legumin (vetch, lentil, horse bean)	5.4	5.5–6.5	7.5
Phaseolin (kidney bean)	6.4	6.5–8.2	8.8

The specific rotation of some vegetable proteins, T. B. OSBORNE and I. F. HARRIS (*Jour. Amer. Chem. Soc., 25 (1903), No. 8, pp. 842–848*).—The averages of numerous determinations, calculated to degrees of circular polarization, are as follows: Edestin (hemp seed) —41.3, globulin (flaxseed) —43.53, globulin (squash seed) —38.73, excelsin (Brazil nut) —42.94, amandin (almonds) —56.44, corylin (filbert) —43.09, globulin (English walnut) —45.21, globulin (black walnut) —44.43, phaseolin (kidney bean) —41.46, legumin (horse bean) —44.09, zein (corn) —28.00, gliadin (wheat) —92.28.

The globulin of the English walnut, the American black walnut, and the butternut, T. B. OSBORNE and I. F. HARRIS (*Jour. Amer. Chem. Soc., 25 (1903), No. 8, pp. 848–853*).—A study of protein preparations from the nuts of *Juglans regia*, *J. nigra*, and *J. cinerea* showed a close agreement as regards the percentages of nitrogen in the different decomposition products and the specific rotation. The globulins from the different sources are therefore considered identical, and the name juglansin is given them. In comparison with the globulin (corylin) from the filbert the only positive difference was in the greater quantity of ammonia (about 0.4 per cent) yielded by corylin, which has led the authors to conclude that the globulins of Juglans and Corylus are chemically distinct.

The carbohydrate group in the protein molecule, T. B. OSBORNE and I. F. HARRIS (*Jour. Amer. Chem. Soc., 25 (1903), No. 5, pp. 474–478*).—The Molisch reaction was not obtained with avenalin, edestin, and globulin, and the reaction with a large number of other vegetable proteins was so slight as to be attributed to a con-

tamination of the preparation with some carbohydrate. "The evidence of a carbohydrate group in the protein molecule which Molisch's reaction affords can not, therefore, be accepted as conclusive, other evidence which shows that more than insignificant quantities of carbohydrate are present being also necessary."

The tryptophane reaction of various proteins, T. B. Osborne and I. F. Harris (*Jour. Amer. Chem. Soc., 25 (1903), No. 8, pp. 853–855*).—The Hopkins-Cole reagent was applied to a number of proteins, 50 mg. of each being mixed with 6 cc. of glyoxylic acid solution and 6 cc. of concentrated sulphuric acid added. The absence of the color reaction was not established in any instance, although in the case of zein it was very slight.

The albuminoid substances in corn, Donard and Labbé (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 4, pp. 264–266*).—The albuminoid material extracted from corn by treatment with potash alcohol was separated into 3 portions, one soluble in amyl alcohol, one insoluble in amyl alcohol but soluble in ethyl alcohol, and one insoluble in both alcohols. The 3 substances are thought to be separated by only slight differences of constitution, such as different degrees of hydration.

The analysis of oils and allied substances, A. C. Wright (*London: Crosby Lockwood & Son, 1903, pp. VI + 241, figs. 5*).—It is stated to be the definite aim of this work to present "the subject in a form suited to the needs of the student and beginner, while at the same time including all recent developments likely to be found of value in practical work. . . . An attempt has been made to indicate the extent to which reliance may be placed on methods for detecting adulteration. It is hoped that the subject has been treated throughout in such a manner that the book may serve as a laboratory guide for chemists who are not extensively engaged in oil analysis, or who have to deal with only a limited number of oils." Different chapters deal with the occurrence and composition of oils, fats, and waxes; the physical properties of oils, fats, and waxes, and their determination; the chemical properties of oils, fats, and waxes from the analytical standpoint; detection and determination of nonfatty constituents; methods for estimating the constituents of oils and fats; description and properties of the more important oils, fats, and waxes, with the methods for their investigation; and the examination of certain commercial products.

Olive oils and olive-oil substitutes, L. M. Tolman and L. S. Munson (*Jour. Amer. Chem. Soc., 25 (1903), No. 9, pp. 954–962*).—Analyses were made of 38 samples of pure California olive oils, the average composition being as follows: Specific gravity at 15.5° C. 0.9168, butyro-refractometer reading at 15.5° C. 69.2, index of refraction at 15.5° C. 1.4711, Maumené number 46.8, specific temperature reaction 101.6, Hübl number 85.1, iodin number of liquid fatty acids 92.8, melting point of fatty acids 22.5° C., free fatty acids as oleic 0.85 per cent. The average composition of 18 samples of pure Italian olive oils was as follows: Specific gravity 0.9163, butyro-refractometer reading 67.8, index of refraction 1.4709, Maumené number 44.9, specific temperature reaction 99.1, Hübl number 81.5, iodin number 94, melting point 25.4, free fatty acids 1.11. Analyses of the following oils are also reported: Cocoanut, palm, lard, peanut, mustard, rape, almond, sunflower, corn, cotton seed, poppy, and linseed.

Does cholesterol occur in olive oil? A. H. Gill and C. G. Tufts (*Jour. Amer. Chem. Soc., 25 (1903), No. 5, pp. 498–503*).—Determinations were made of the melting point of the alcohol obtained from olive oil, from which it is concluded that the substance is phytosterol and not cholesterol.

A modification of the Babcock-Blasdale viscosity test for olive oil, H. Abraham (*Jour. Amer. Chem. Soc., 25 (1903), No. 9, pp. 968–977, figs. 3*).

The viscosity of the soap solution as a factor in oil analysis, H. C. Sherman and H. Abraham (*Jour. Amer. Chem. Soc., 25 (1903), No. 9, pp. 977–982*).

A contribution to the chemistry of rice oil, C. A. Browne, Jr. (*Jour. Amer. Chem. Soc., 25 (1903), No. 9, pp. 948–954*). The constants of rice oil as determined in a sample obtained from rice bran were as follows: Specific gravity 0.8907, melting

free oxid by filtration, and the separate determination of the arsenious oxid in the filtrate and in the residue.

Titration with potassium iodate, L. W. ANDREWS (*Jour. Amer. Chem. Soc., 25 (1903), No. 7, pp. 756–761*).—The method proposed is based upon the titration of potassium iodid, for example, with potassium iodate in presence of a large excess of hydrochloric acid, using chloroform or carbon tetrachlorid as indicator. The author has adapted the method to the determination of iodids, free iodin, chromates, chlorates, antimony, arsenic, and iron. The method "is adapted to the determination of almost all the substances to which Bunsen's process of distillation with potassium iodid and hydrochloric acid is applicable, with at least equal precision, with less expenditure of time and far simpler apparatus. It is furthermore applicable in certain cases in which the Bunsen method is not, as, for example, the titration of arsenic or antimony in the presence of copper and ferric compounds."

Chemistry of dyestuffs, G. VON GEORGIEVICS, trans. by C. SALTER (*London: Scott, Greenwood & Co., 1903, pp. VI+402*).—A translation of the second German edition.

The chemical industry in Germany, E. L. HARRIS (*U. S. Consular Rpts., 72 (1903), No. 275, pp. 527–536*).—Statistical information on this subject.

Report of the senior analyst for the year 1902, C. F. JURITZ (*Cape Town, 1903, pp. 73*).—During the year analyses were made of 1,568 samples, including milk, butter, cheese, coffee, wine, water, soils, fertilizers, coal, etc., the results being reported in this publication and discussed.

BOTANY.

Studies in the Cyperaceæ, T. HOLM (*Amer. Jour. Sci., 4. ser., 16 (1903), No. 91, pp. 17–44, figs. 14*).—The author gives the results of his extended study of the genus Carex as represented in Colorado, giving a synopsis of species and a description, together with critical notes on all material known to exist within that State. In addition he discusses the geographic distribution of the species, comparing the distribution of the sedges from the Arctic region, Europe, and portions of the Rocky Mountains.

Influence of various stimulants on the respiration of plants, V. ZALYESSKI (*Zap. Novo-Alexandri Inst. Selsk. Khoz. i Lyesor, 15 (1903), No. 2, pp. 1–41; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 3, pp. 351, 352*).—After having determined the respiratory energy of gladiolus bulbs, the author made a study of the effect of various stimulants as shown by the modification of their respiration. In the first series the bulbs were subjected to the influence of ether. This was found to act as a marked stimulant, the influence of the ether being shown by a curve which expresses the influence of the ether on the respiration of the bulb, being one of excitation or depression when the respiration was above or below normal. Very large quantities of ether tend to diminish the respiration of the bulbs.

In the second experiment the influence of change of temperature was studied and it was found that transferring the bulbs for 2 hours from a temperature of 16.8° C. to one of from 38 to 38.8° increased the respiration. After a number of days the respiration returned to its normal state. If the bulbs be kept at 38 to 40° for a considerable time the respiration is considerably lowered. This depression, however, is attributed not to the injury caused the bulbs, but to their continued drying. Bulbs so treated, after being placed 4 hours in water, regained their energy of respiration. From this the author is led to conclude that water absorbed by bulbs acts as a stimulus in raising the respiration for a time. Other investigations were carried on to determine the effect of air pressure and the influence of mechanical injuries on plant respiration.—P. FIREMAN.

Stimulants of plant growth and their practical application, O. LOEW (*Landw.*

Jahrb., 32 (1903), No. 3, pp. 437–448, pls. 2).—The results of experiments with different substances, including rubidium chlorid, sulphate of manganese, uranium nitrate, sodium fluorid, calcium iodid and iron sulphate, as stimulants of plant growth, are reported. The experiments were made with barley, rice, peas, oats, *Brassica chinensis*, and radishes, grown in pots and in the field. The data show that these substances have a stimulating effect, and the author believes this to be of value in agricultural practice, but states that through an accumulation of the same in the soil their influence becomes injurious.

The toxic effect of H and OH ions on seedlings of Indian corn, F. A. Loew (*Science, n. ser., 18 (1903), No. 453, pp. 304–308*).—According to the author, attempts have been made within the past 5 years to determine the toxic effect of various chemical solutions upon plant life. This involved the theory of ionization and is based upon the electrical conductivity of the solutions. After discussing some of the theories and previous investigations, the author gives an account of experiments in which the effect of these various dilutions of potassium hydroxid, sodium hydroxid, hydrochloric and sulphuric acid on seedlings of Indian corn was tested.

The test solutions were made in 4 different dilutions, and, after germinating the corn, the sprouted grains were placed in test glasses in such a way that the radicle was held in contact with the solution. The seedlings were then kept in a dark chamber for 24 hours, after which the growth or elongation was noted. The results obtained by the different experiments are shown in tabular form, from which it appears that the corn seedling lived and grew in a 1/128 normal solution of the alkalis and 1/512 normal solution of the acids. This shows that corn seedlings live in an alkali solution more than 3 times as strong and an acid solution 12 times as strong as that in which the seedlings of white lupine live, as previously reported (E. S. R., 11, p. 1100).

The physiological rôle of mineral nutrients in plants, O. Loew (*U. S. Dept. Agr. Bureau of Plant Industry Bul. 45, pp. 70.*)—This is a revised edition of Bulletin No. 18 of the Division of Vegetable Physiology and Pathology (E. S. R., 11, p. 1008), with some additions. The following is added to the final remarks:

"A question of considerable importance for agriculture is the judicial regulation of the lime and magnesia content of the soil, especially when mineral fertilizers are employed. This regulation must be based on the knowledge of the readily assimilated amounts of these bases. Hence only the finer soil particles should serve for analysis. When a soil is much richer in magnesia than in lime extensive liming is necessary. The liming should be done chiefly with the carbonate and only in part with slaked lime and the sulphate. On the other hand, when the magnesia content is much less than that of lime the addition of a powdered magnesian limestone or magnesite is necessary. Burned magnesite and artificially precipitated magnesium carbonate must be avoided under all circumstances, since they are too finely divided and too easily absorbed."

Experiments by May (E. S. R., 13, p. 630) and by Aso and Furuta (E. S. R., 14, p. 14) are cited as having shown that "cereals thrive best when the lime content of the soil only slightly exceeds that of magnesia. Crops having more abundant foliage, however, require considerably more lime. For the most luxuriant development cabbage needs twice as much lime as magnesia, while buckwheat requires three times as much lime as magnesia."

Bacteria and the nitrogen problem, G. T. Moore (*U. S. Dept. Agr. Yearbook 1902, pp. 333–342, pls. 6*).—A review is given of the importance of nitrogen for plant growth and the different sources from which nitrogen is obtained. The assimilation of nitrogen through the root tubercle organisms which are found on the roots of many leguminous plants is discussed, and the results of investigations on the cultivation of this organism for artificial inoculations are briefly described.

The author found that the bacteria could be made to grow on media which did not contain any of the decoctions of the host plant, such as are used in the German

preparations; and a formula of a medium was discovered in which the bacteria grew readily and were capable of active growth when placed in the proper conditions of inoculation. The organisms were found not only to be capable of fixing a large amount of nitrogen, but did not lose this power by prolonged drying. On this account it is possible to distribute the inoculating material, and arrangements have been made for that purpose. A description is given of the methods by which the organism is to be applied to the soil.

ZOOLOGY.

Audubon societies in relation to the farmer, H. OLDYS (*U. S. Dept. Agr. Yearbook 1902, pp. 205–218, pls. 2, figs. 2*).—The author presents a discussion of the value of birds, the danger of their extinction, the objects of Audubon societies, their work in securing and enforcing legislation, and the interest of farmers in bird protection.

Birds in their relations to man, C. M. WEED and N. DEARBORN (*Philadelphia and London: J. B. Lippincott Co., 1903, pp. 380, pls. 20, figs. 95*).—The purpose of this volume is to present a general account of economic ornithology for the United States and Canada. The authors have summarized the work of this Department, the experiment stations, and other institutions in studying the feeding habits of birds. Special accounts are presented of the economic relations of a number of the more important species and families of birds. The authors discuss, also, the methods of protecting game birds and encouraging the presence of birds near orchards and human habitations. In an appendix to the volume, copies are given of the bird law of the American Ornithologists' Union and the Lacey bird law, together with a discussion of the principles of bird laws, and a partial bibliography of the economic relations of North American birds.

Birds and man, W. H. HUDSON (*London: Longmans, Green & Co., 1901, pp. 217*).—A popular and appreciative account of the relationship between birds and man, with particular reference to daws, wrens, ravens, owls, and geese, and with chapters on the birds of London and Selborne.

Birds and horticulturists, H. A. SURFACE (*Pennsylvania State Dept. Agr., Zool. Circ. 1, pp. 12, pls. 3*).—Notes on nesting boxes and other means of encouraging the establishment of bird colonies near houses and cultivated fields. Attention is also called to the economic value of birds and to the necessity for further study of their feeding habits.

Birds versus gardening, C. E. PEARSON (*Jour. Roy. Hort. Soc. [London], 27 (1902), No. 1, pp. 55–60*).—Attention is called to the depredations committed by the various birds on garden crops. The birds which are mentioned as most injurious are the English sparrow, blackbird, linnet, grosbeak, and other members of the sparrow family.

Two years with the birds on a farm, E. H. FORBUSH (*Massachusetts State Bd. Agr. Rpt. 1902, pp. 111–161, pls. 3, figs. 5*).—The studies reported in this paper were made on a farm near Wareham, Mass. Attempts were made to attract birds by distributing suitable food, especially during the winter season, and by the construction of attractive nesting places. Special attention was given to a determination of the effect of seed-eating birds upon the prevalence of weeds. It appeared that a number of common weeds were almost exterminated on the farm on account of the destruction of the seeds by birds. The majority of birds which were kept under observation by the author are believed to do considerably more good than harm upon farms maintained for diversified agriculture. Crows, jays, hawks, cats, and squirrels are considered to be the most important enemies of beneficial birds.

A popular handbook of the birds of the United States and Canada, T. NUTTALL (*Boston: Little, Brown & Co., 1903, pp. LIII [illegible] 90[illegible], pls. [illegible], figs. [illegible]*).—The

present edition of Nuttall's Handbook of Birds has been revised and annotated by M. Chamberlain. The volume is divided into two parts, viz, land birds, and game and water birds. The habits and economic relations of each bird are discussed, in addition to descriptive notes, and an account of variations in distribution.

Ornithology, M. W. DOHERTY (*Ontario Agr. Col. and Expt. Farm Rpt. 1902, pp. 30–32*).—The author presents a table of notes on the migration of a number of species of birds.

The best method of poisoning small birds, B. C. ASTON (*New Zealand Dept. Agr. Leaflets for Farmers, No. 66, pp. 3*).—For destroying the English sparrow and other birds which are injurious to grain, the author recommends the use of wheat dampened with milk and sprinkled with powdered strychnin.

Food habits of the common garden mole, L. L. DYCHE (*Trans. Kansas Acad. Sci., 18 (1901–2), pp. 183–186*).—The author examined the stomach contents of 67 moles taken at various seasons throughout the year. Earthworms were found to constitute 42 per cent of the entire food. The moles had eaten myriopods, grasshoppers, insect eggs and larvæ of various kinds, as well as ants and other adult insects. About 4 per cent of the food taken by the moles was of vegetable origin. This included the seeds of grass, hemp, and other plants, as well as small quantities of corn.

Annual report of the New York Zoological Society for 1902 (*New York: Zool. Soc., 1903, pp. 205, pls. 41, figs. 15*).—The executive committee, of which H. F. Osborn is chairman, presents a report of the general management, equipment, scientific work, and publications of the society (pp. 33–49). W. T. Hornaday, director of the zoological park, gives a report on the mammals, birds, reptiles, administration, and miscellaneous work connected with the zoological park (pp. 56–79).

H. Brooks, pathologist of the zoological park, gives an account of the diseases which prevailed among the animals of the park during 1902 (pp. 101–120). Deaths were most frequent among the primates, 67 out of 170 deaths having occurred in this group. Of the 67 deaths, 30 were from tuberculosis. Notes are also given on pneumonia, gastro-enteritis, parasitic diseases, actinomycosis, distemper, rabies, and on the pathological effects of captivity on wild animals. As chief among the effects of captivity, the author mentions fatty degeneration and certain changes in the blood vessels. The annual report of the veterinarian is presented by F. H. Miller (pp. 131, 132). Distemper occurred in 10 animals, while actinomycosis was observed in 4 antelopes. The affection was believed to have spread from a specimen captured in Montana. Notes are also given on the recurrence of Miescher's sacs, *Trichodectes cervus*, and blood filaria in sea lions.

W. R. Blair discusses the modes of tubercular infection in wild animals in captivity (pp. 133–136). It is believed that in a large percentage of cases infection takes place by inhalation rather than by ingestion. The alimentary tract apparently becomes affected secondarily. The same author presents a report on cysticerci in wild ruminants (pp. 137–144). The following articles in the report may also be mentioned: Observations on the Development of Reptiles, by R. L. Ditmars (pp. 145–153); Some Notes on the Psychology of Birds, by C. W. Beebe (pp. 154–159); The Home of the Giant Tortoise, by R. H. Beck (pp. 160–174); The Caribou, by M. Grant (pp. 175–196).

The monthly bulletin of the division of zoology, H. A. SURFACE (*Pennsylvania State Dept. Agr., Mo. Bul. Div. Zool., 1 (1903), No. 5, pp. 32, pls. 2*).—Brief notes are given on plant diseases, method of preparing ammoniacal solution of copper carbonate, insects injurious in September, peach diseases, preservation of robins, flies on live stock, Pennsylvania law against peach yellows, peach rosette, and other diseases, gapes in fowls, San José scale, relation of forestry and zoology, and the destruction of burrowing animals by fumes.

METEOROLOGY—CLIMATOLOGY.

Monthly Weather Review (*Mo. Weather Rev., 31 (1903), Nos. 4, pp. 165–216, figs. 7, charts 10; 5, pp. 217–258, figs. 3, charts 22; 6, pp. 259–307, figs. 10, charts 9*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts for the months of April, May, and June, 1903, recent papers bearing on meteorology, etc., these numbers contain the following articles and notes:

No. 4.—Special contributions on The Water Equivalent of Snow on Ground, by C. A. Mixer; River Floods and Melting Snow (illus.), by C. A. Mixer; Typical October Winds on Our Atlantic Coast, by T. H. Davis; The Franco-Scandinavian Station for Aerial Soundings, by L. Teisserenc de Bort; Note on the Radiation Formulas and on the Principles of Thermometry, by E. Buckingham; The Influence of Light and Darkness upon Growth and Development, by D. T. MacDougal; The Fulton Automatic River Gage at Chattanooga, Tenn. (illus.), by W. M. Fulton; and Antarctic Research; and notes on climatic factors in railroad engineering, meteorological expedition to the Bahamas, and Weather Bureau men as instructors.

No. 5.—Special contributions on March and Winter Winds (illus.), by W. B. Stockman; A Waterspout off Hatteras, by T. B. Harper; High Winds at Point Reyes Light, Cal., by W. W. Thomas and A. G. McAdie; Lantern Slides, by O. L. Fassig; Meteorological Observations Obtained by the Use of Kites off the West Coast of Scotland, 1902, by W. N. Shaw and W. H. Dines; A Curious Coincidence—Is it Accidental or Governed by Law [Periodicity in Rainfall and Pressure at Seattle, Wash.]? by G. N. Salisbury; Atmospheric Electricity Considered from the Standpoint of the Theory of Electrons, by H. Ebert; Abnormal Variations in Insolation, by H. H. Kimball; Hailstorms in Porto Rico (illus.), by W. H. Alexander; and Stages of the Mississippi River at Vicksburg, by W. S. Belden; and notes on cold weather in the Arctic and temperate zones, meteorology at the next meeting of the French association, exhibition of meteorological apparatus at Southport, England, international aerial research, and currents in Sandusky Bay.

No. 6.—Special contributions on "La lune mange les nuages"—A Note on the Thermal Relations of Floating Clouds (illus.), by W. N. Shaw; Tornado at Gainesville, Ga., June 1, 1903 (illus.), by J. B. Marbury; Weather Reports from Vessels at Sea, by A. G. McAdie; The Earthquake of June 2, 1903, at Washington, D. C., by C. F. Marvin; Autumnal Coloration of Foliage, by A. F. Wood; The Weather Bureau Seismograph (illus.), by C. F. Marvin; and Observations of Solar Radiation with the Angstrom Pyrheliometer, at Providence, R. I. (illus.), by H. N. Davis; and notes on Weather Bureau men as instructors, the climate and the sugar beet, and the moon's influence on the weather.

Storms of the Great Lakes, E. B. GARRIOTT (*U. S. Dept. Agr., Weather Bureau Bul. K, pp. 9, charts 968*).—This bulletin consists of "charts that describe graphically 238 of the more important storms that visited the Great Lakes during the 25-year period 1876 to 1900. The purpose of the compilation is to furnish observers of the Weather Bureau and shipmasters a handy reference which will aid them to recognize on the daily weather maps the general atmospheric conditions that attend the approach of lake storms."

The climate of Illinois, J. G. MOSIER (*Illinois Sta. Bul. 86, pp. 45–76, figs. 2*).—This is a summary of climatic conditions in different districts of the State compiled largely from the records of the United States Weather Bureau. The general summary given is in part as follows:

"The rainfall for the northern district is 33.48 in., the least being 21.46 in. in 1891, the greatest being 47.22 in. Seventeen and four-tenths per cent of the rain falls in winter, 28.1 per cent in spring, 31.9 per cent in summer, and 22.6 per cent in autumn.

May is the wettest month. The rainfall of the central district is 38.01 in. The least rainfall was 22.85 in. in 1879, the greatest, 48.67 in. in 1876. Eighteen and eight-tenths per cent of the total rainfall occurs in winter, 29.7 per cent in spring, 28.9 per cent in summer, and 22.6 per cent in autumn. May has heaviest rainfall. The rainfall of the southern district is 42.19 in. The least was 30.05 in. in 1872, the greatest, 55.68 in. in 1882. About 21.6 per cent falls in winter, 30.6 per cent in spring, 26 per cent in summer, and 21.8 per cent in autumn. March has most rain.

"The average rainfall for the State is 37.39 in. The least was 25 in. in 1901, the greatest, 47.39 in. in 1898. Six northern counties have 11.3 in. less than seven southern counties. The Ozark Ridge in the southern part of the State makes the rainfall of the counties in which it is situated 7.15 in. more than those immediately above the ridge. A rainy region is situated along the Wabash River up as far as Crawford County. The average temperature for the State is 52.3° F. Northern tier of counties 46.9°, southern counties 57.6°. Northern summers are 7° cooler than southern, while northern winters are 17.2° cooler.

"The average temperature for the northern district is 48.9°. January is the coldest month, 22.1°; July is the hottest, 74.6°. Lowest temperature recorded, 31° below zero. The extreme range of temperature is 143°; average annual range about 115°. Highest temperature in summer of 1901. The average temperature for the central district is 52.7°, the extreme range being 139°; the average annual range being about 109°. Lowest temperature recorded was 28° below zero in 1884; highest, 112° in 1901. The average temperature for the southern district, 55.9°. Lowest temperature observed was 23° below zero, in February, 1899, the highest being 115° in 1901. Extreme range is 138°, with average annual range about 103°.

"The average date for the last killing frost in spring is 15 days later in northern than in southern part, and the date for the first killing frost in fall is 12 days earlier than in the southern. The difference between dates of last killing and first killing frosts for extreme parts of State is 40 days.

"November, December, January, February, March, and April are the cloudy months of the year, being cloudy for 56 per cent of the daylight in the northern, 53½ in each of the other sections. The other months of the year are less cloudy, having 45½ per cent in the northern, 40½ in the central, and 42 per cent in the southern. December is the cloudiest month for the northern and southern parts, and March for the central part."

Wet and dry seasons in California, A. G. McAdie (*U. S. Dept. Agr. Yearbook 1902, pp. 187–204, pl. 1, figs. 7*).—The available data for rainfall during the rainy season are compiled and discussed with reference to permanent change or periodicity in rainfall. "There does not appear to be any evidence of a permanent change in climate. Wet and dry seasons come and go with little regularity. A deficiency in rainfall seldom extends over two seasons, and the same is true of excessive rainfall."

Rainfall and irrigation, E. A. Beals (*U. S. Dept. Agr. Yearbook 1902, pp. 627–642, figs. 6*).—A discussion of the amount and distribution of rainfall in different parts of the world with reference to the utilization of the water in irrigation.

Climate of the forest-denuded portion of the Upper Lake region, W. L. Moore (*U. S. Dept. Agr. Yearbook 1902, pp. 125–132, pl. 1*).—"The distinguishing features of the climate of the Upper Lake States may be summed up about as follows: The winter climate is cold and dry, but there is considerable snow in the northern and eastern districts. The transition seasons, spring and autumn, are characterized by frequent alternations of clear, fair skies and cloudy, rainy, or snowy weather. The fluctuations of temperature are at times sharp. The summer is warm, with long days and short, cool nights. The rainfall is generally fairly abundant and much more constant than is the case to the west and southwest. The hot, desiccating winds that so often wither and kill the growing crops of the Lower Missouri and

Central Mississippi valleys are entirely absent. The air is healthful and physically invigorating to a remarkable degree."

Psychrometric observations in the forest and in the steppe, N. Adamov (*Trudi. Opuitn. Lyesn., 1902, No. 1; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 2, pp. 249, 250*).—The author reports the results of preliminary observations made with the aid of a psychrometer on the distribution of heat and humidity in fields and woods, at the surface of the soil and at a height of ⅔ ft., and also in the tops and over the tops of trees. The results are not conclusive, but indicate that, on open fields and clearings in the woods, the air is somewhat warmer than in the forest, while the humidity is, on the contrary, somewhat greater in the forest than on the field.—P. FIREMAN.

Observations on the humidity of the air, T. O. Frizendorf (*Khozyain, 1902, No. 49; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 2, p. 251*).—The author, on the basis of observations extending over 4 years, recommends Treska's method of forecasting, which is as follows: If the temperature of the dew-point is higher than the mean temperature of the day a frost may be expected; if it is zero there will be a thunderstorm; if it is greater than zero and less than 3 there will be rain, a difference greater than 3 and less than 6 indicates more or less cloudiness; if the difference is equal to 6 fine weather may be expected; if it is 7 to 8 a strong windstorm is probable. A barometric rise and an east wind increase the chances of fine weather, while a barometric fall and a west wind lower the chances.—P. FIREMAN.

Spring frost in the Mediterranean climate, M. Chassant (*Ann. Ecole Nat. Agr. Montpellier, n. ser., 2 (1903), No. 4, pp. 291–323, pls. 6*).—This is a record of observations made at the meteorological station of the national school of agriculture at Montpellier during the period from 1893 to 1902. The general characteristics of the climate of the Department of Herault, in which Montpellier is situated, are discussed. These are droughts and prolonged high temperatures in summer, irregularity of rainfall, and extremes of temperature observed during some years, sometimes in winter, sometimes in summer. The observations which are summarized include temperature, pressure, direction and velocity of wind, and cloudiness. The larger proportion of the frost observed occurred during periods of low pressure. The frosts were, it is claimed, a result of a current of cold air which acted in conjunction with nocturnal radiation.

WATER—SOILS.

The contamination of public water supplies by algæ, G. T. Moore (*U. S. Dept. Agr. Yearbook 1902, pp. 175–186, pls. 2*).—The importance of a more careful microscopic study of water with reference to wholesomeness is pointed out, and plant and other organisms affecting the color, taste, or odor of water are discussed, particular attention being given to the structure, multiplication, and effects on water of Spirogyra of the Chlorophyceæ, blue-green algæ (Schizophyceæ), Diatomaceæ, and Syngeneticeæ. Methods of preventing pollution, including covering reservoirs, keeping water free from organic matter, aeration, etc., are briefly described.

Potable waters, L. Grandeau (*Jour. Agr. Prat., n. ser., 5 (1903), No. 24, pp. 753, 754*).—A brief general discussion of the qualities which potable water should possess.

On the rate of movement of underground waters, E. Fournier and A. Magnin (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 14, pp. 910–912*).—Experiments with fluorescein, salt, starch, etc., in the region of Jura are reported. Among the facts brought out is that fluorescein is diffused more slowly than are cultures of micro-organisms and other contaminating agents.

Analysis of waters and interpretation of the results, J. K. Haywood (*U. S. Dept. Agr. Yearbook 1902, pp. 283–294*).—The significance of the various determinations made in sanitary and mineral analysis of water, and analysis of water for irrigation and boiler purposes is explained.

The soil: An introduction to the scientific study of the growth of crops, A. D. HALL (*London: J. Murray, 1903, pp. XV + 286, pls. 13, figs. 4*).—The author states in his preface that this book "is primarily intended for the students of our agricultural colleges and schools, and for the farmer who wishes to know something about the materials he is handling day by day. While a certain knowledge of chemistry is assumed, it is hoped that the subject is so treated as to be intelligible to the non-technical reader who is without this preliminary grounding. Though the book is in no sense an exhaustive treatise, it has been my desire to give the reader an outline of all the recent investigations which have opened up so many soil problems and thrown new light on difficulties that are experienced in practice."

The subject of soils is treated in its chemical, physical, and biological relations, and different chapters discuss the origin of soils, the mechanical analysis of soils, the texture of the soil, tillage and the movements of soil water, the temperature of the soil, the chemical analysis of soils, the living organisms of the soil, the power of the soil to absorb salts, causes of fertility and sterility of soils, and soil types. Appendixes give chemical analyses of typical soils, and a classified bibliography of some of the more important works on soils.

The subject is discussed, of course, mainly from the standpoint of British conditions, but the results of European and American investigations are drawn on freely, but discriminatingly.

The book is notable not only for its general excellence, but because it has none of the staleness of a mere compilation; but possesses the originality and suggestiveness to be expected in the work of an author so actively interested, as teacher and investigator, in the subjects discussed.

Report on composition of muskeg soils, H. SNYDER (*Minnesota Sta. Bul. 81, pp. 234–238*).—Descriptions and chemical analyses of 10 samples of muskeg (peaty) soils are given. All the samples were decidedly acid, high in organic matter and nitrogen, and low in mineral matter. Suggestions are made regarding the treatment of the soils under cultivation.

Agricultural soils of the Province de la Union, C. W. DORSEY (*Philippine Bureau Agr. Bul 1, pp. 12, pls. 4*).—The physiography and soils of the province are described, together with the crops generally grown.

The amounts of readily water-soluble salts found in soils under field conditions, F. H. KING (*Science, n. ser., 18 (1903), No. 454, pp. 343–345*).—It is shown that by drying soils at a temperature of 110 to 120° C. a much larger amount of soluble salts is obtained than is yielded by the same soils fresh from the field, the amounts in some cases being more than trebled. The causes of this are discussed. The readily water-soluble constituents in the first, second, third, and fourth feet of a Wisconsin soil unfertilized and receiving different amounts of manure and guano are reported, showing the comparatively large amounts of soluble salts carried by ordinary soils.

The nitrogen compounds of arable soils, G. ANDRÉ (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 13, pp. 820–822*).—In continuation of previous investigations (E. S. R., 14, p. 1056) the author determined the total and ammoniacal nitrogen (by the methods used in previous investigations) in soil from the surface and at depths of 35 to 65 cm. on April 1 and 16, and October 27, 1902, and October 25, 1901. The largest amount of ammoniacal nitrogen was found in the lower layers of the soil in spring.

Nitrification as dependent upon organic and humified substances, SMIRNOV (*Mater. Izuchen. Russ. Pochv, No. 14, pp. 1–19; abs. in Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4 (1903), No. 1, p. 117*).—The author observed the progress of nitrification in 4 soils containing different amounts of humus (from 0.42 to 3.55 per cent). In all cases a certain regularity was noted in the accumulation of nitric acid, depending upon the time and upon the amounts of humus. Thus, in the soil with 0.42 per

cent of humus and containing 1.5 mg. of nitric nitrogen per 100 gm. of soil there was found after 19 days 14 mg., after 36 days 25.5 mg., and after 73 days 28 mg. In the soil with 3.55 per cent of humus containing 0.5 mg. of nitrate nitrogen there was found after the same lengths of time 21, 38.5, 50.5, and 53 mg. per 100 gm. of soil.—P. FIREMAN.

Influence of protecting forest strips on the moisture of the soil of the surrounding area (*Trudi. Opuitn. Lyesn., 1902, No. 1; abs. in Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4* (*1902*), *No. 2, pp. 248, 249*).—Observations on the area between 2 forest strips were carried out during 3 years, from 1899 to 1901. For the determination of the moisture, samples were taken at different depths from 10 to 600 cm. in the middle of the strips, and at distances of 14, 35, 70, 140, and 665 ft. from them. On the basis of a large number of determinations, the author arrives at these tentative conclusions:

(1) Protecting strips at the age of 6 to 8 years have a positive influence on the increase of the moisture of the soil and subsoil of the adjoining field at a distance not exceeding 70 ft. (2) This influence is the strongest in the spring after the thawing of the snow, is still perceptible in the dry period of the summer, and gradually weakens toward the fall. (3) The influence of the protecting strips on the increase of the humidity of the adjoining field is explained by the snow-accumulating capacity of the strips, in consequence of which a heavy snow cover is retained not only inside the strips, but also along their borders to a distance of about 70 ft.—P. FIREMAN.

Soil, cultivation, and irrigation, W. MAXWELL (*Queensland Agr. Jour., 12* (*1903*), *No. 6, pp. 384–397*).—A general discussion with special reference to Queensland conditions.

Crops used in the reclamation of alkali lands in Egypt, T. H. KEARNEY and T. H. MEANS (*U. S. Dept. Agr. Yearbook 1902, pp. 573–588, pls. 4, figs. 2*).—Notes are given on the climate, soils, irrigation work and methods, methods of reclaiming alkali, and crops used in the process of reclamation in Egypt. The latter include barnyard grass (*Panicum crus-galli*), sorghum, rice, samar (*Cyperus laevigatus*), berseem or Egyptian clover, and cotton. "Of the crops used for the specific purpose of aiding in reclaiming alkali lands in Egypt, probably only two, sorghum and berseem, will be found practically useful in the United States."

FERTILIZERS.

Influence of applications of straw on the yield, D. N. PRYANISHNIKOV (*Vyestnik Selsk. Khoz., 1902, No. 52, pp. 3, 4; abs. in Zhur. Opuitn. Agron.* [*Jour. Expt Landw.*], *4* (*1903*), *No 1, p 89*).—Finely cut straw was mixed with soil in pots at rates of $\frac{1}{4}$, $\frac{1}{2}$, and 1 per cent of the weight of the soil taken (4.5 kg.). The yields of barley and oats obtained decreased uniformly with the increase of straw applied.—P. FIREMAN.

Gypsum as a means of fixing ammonia in the decomposition of manure, S. A. SEVERIN (*Syesd. Dyeat. Selsk. Khoz. Opuitn. Dyelu., St. Petersburg, 1902, Dec., pt. 1, pp. 124–132; abs. in Zhur. Opuitn. Agron.* [*Jour. Expt. Landw.*], *4* (*1903*), *No. 1, pp. 88, 89*).—In laboratory experiments by the author with unsterilized and sterilized manure (inoculating in the latter case with pure cultures of organisms capable of inducing ammoniacal fermentation as well as with a water extract of manure) the addition of 4 per cent gypsum to the manure intensified the decomposition of the manure 10 to 20 per cent, and at the same time preserved the manure from the loss of ammoniacal nitrogen.—P. FIREMAN.

Fertilizing with sulphate of ammonia and organic nitrogen in comparison with nitrate of soda, P. WAGNER ET AL. (*Arb. Deut. Landw. Gesell., 1903, No. 80, pp. 340*).—This is a detailed account of pot and field experiments made at the Darmstadt station and on a uniform plan by a number of cooperating experiment stations in different parts of Germany. The nitrogenous fertilizers employed included nitrate

of soda, sulphate of ammonia, guano, ground bone, dried blood, cattle manurend, a a number of other organic forms of nitrogen.

It was found in the pot experiments that 100 parts of ammoniacal nitrogen yielded 93 parts of nitric nitrogen in the soil. The average results of the pot experiments showed that the different nitrogenous fertilizers were utilized by crops in the following relative proportions: Nitrate of soda 100, ammonium salts 94, Damarara guano 91, Peruvian guano 87, green manures 77, horn meal 74, dried blood 73, castor pomace 73, poudrette (Bremen) 60, Krottnauer manure 51, Blankenburger manure 49, wool dust 26, concentrated cattle manure 22, ground leather 16, sea ooze 12, sediment from settling reservoirs 10. In experiments with oats, ammonium salts were 98 per cent as effective as nitrate of soda in producing grain and 97 per cent as effective in producing straw. It appears also from the results of experiments with oats, beets, and carrots that soda had a decided effect in increasing the yield.

In the field experiments with barley, oats, wheat, rye, potatoes, and beets the relative effectiveness of nitrate of soda and ammonium sulphate was as 100 : 70. The lower effectiveness of the latter is attributed to loss of nitrogen in form of ammonia. In the field experiments, as in the pot experiments, it was found that soda produced a decided effect in increasing yields and that nitrate of soda and sulphate of ammonia produced the same relative proportions of straw and grain or leaves and roots. The possible injurious effect on the physical properties of soils of the continued use of sodium salts, like nitrate of soda, is cautioned against.

The method of making the field experiments is fully described.

The effects on plants of a deficiency of nitrogen, phosphoric acid, or potash, H. WILFARTH and G. WIMMER (*Jour. Landw., 51 (1903), No. 2, pp. 129–138, pls. 3*).—A summary is given of the results of pot and field experiments extending over several years with potatoes, sugar beets, tobacco, buckwheat, and a number of other plants, including fruit trees. The pot experiments were made by the method followed at the Bernburg experiment station,[a] using pure sand mixed with 6 per cent of purified peat.

It was observed that a marked deficiency of any of the essential fertilizing constituents resulted not only in a decrease in yield, but often in some change in the percentage composition of the plant substance. The latter effect was most marked in the carbohydrates in case of a deficiency of phosphoric acid. With a marked deficiency of nitrogen, the percentage of carbohydrates was oftener higher than lower. With a deficiency of phosphoric acid there was a small decrease. Thus sugar beets insufficiently supplied with nitrogen contained a larger percentage of sugar than those abundantly supplied, while a deficiency of phosphoric acid resulted in a reduced percentage of sugar.

The effect of a deficiency of one or the other of the essential fertilizing constituents was also shown in the relative proportion of roots and leaves, as in sugar beets, but especially in the appearance of the leaves. Observations on the latter point are recorded in detail and it is claimed that in case of sand and water cultures the leaf appearance furnishes a reliable means of determining whether the plant needs nitrogen, phosphoric acid, or potash. The indications are not so reliable in case of field experiments.

The leaves of plants suffering from nitrogen hunger were light-green to yellowish, finally drying to a light brownish-yellow color. With a deficiency of phosphoric acid the leaves were deep green, but showed black spots beginning on the edges but spreading over the whole leaf, which finally dries up to a dark brown or dark green color. In cases of very severe phosphoric acid hunger the leaves of sugar beets curl under from the tips, but as a rule the leaves of plants suffering from nitrogen and phosphoric acid hunger are of normal shape and general appearance, although reduced in size.

[a] Arb. Deut. Landw. Gesell., Nos. 34 and 68.

The effects of potash hunger which are especially characteristic have been described elsewhere in the Record (E. S. R., 13, p. 1030).

The effects produced by plant food deficiencies are very similar in many cases to those produced by insects or fungus diseases or by injurious gases.

A process for making available phosphates, C. H. DEMPWOLF, Jr. (*Jour. Amer. Chem. Soc., 25 (1903), No. 8, pp. 818–825*).—An account is given of experiments undertaken with a view to utilizing niter cake, a by-product of the manufacture of sulphuric acid, in the production of available phosphate from bone ash and rock phosphate. By heating the phosphate with niter cake and charcoal, as high as 73 per cent of the phosphoric acid was rendered available. By treating ground rock phosphate with niter cake in solution and allowing to stand for 4 weeks, about 55 per cent of the phosphoric acid was rendered soluble in water. The latter method is considered the more practical from a business standpoint.

Frost and potash fertilizers, A. COUTURIER (*Jour. Agr. Prat., n. ser., 6 (1903), No. 30, pp. 118, 119*).—Various observations are reported to show that crops fertilized with potash fertilizers are more resistant to frost than those not so treated.

Analyses of fertilizing substances sent on for free examination, C. A. GOESSMANN (*Massachusetts Sta. Bul. 89, pp. 3–8, 12–15*).—Analyses are reported of miscellaneous materials, including wood ashes, ground fish bone, tankage, dissolved boneblack, acid phosphate, complete fertilizers, high grade sulphate of potash, nitrate of soda, cotton-seed meal, acetylene gas tank refuse, cocoanut fiber pith, sewage, and soils. Notes are also given on the valuation of fertilizers, and on taking samples for analysis.

Tabulated analyses of commercial fertilizers, J. HAMILTON and W. FREAR (*Pennsylvania State Dept. Agr. Bul. 109, pp. 208*).—Analyses and valuations of 450 samples of fertilizers examined during the year ended December 31, 1902, are reported and discussed.

Fertilizers, R. E. ROSE and E. E. MCLIN (*Florida Dept. Agr. Mo. Bul., 13 (1903), No. 83, pp. 17–35*).—Notes on valuation and tabulated analyses.

FIELD CROPS.

Review of the work of the Northeast Experiment Farm since its organization in May, 1896, H. H. CHAPMAN (*Minnesota Sta. Bul. 81, pp. 181–234, pl. 1, figs. 7*).—A brief description is given of the equipment and improvements of this experiment farm, located at Grand Rapids, which is a branch of the Minnesota Station; and the results obtained since its establishment are reported and discussed in detail. Directions for the culture of the different crops here dealt with are also given.

In a 6-year test of 7 varieties of oats, Improved Ligowo led in productiveness with a yield of 49.8 bu. per acre, followed, in the order given, by Lincoln, Early Gothland, Early Swedish, White Russian, Archangel, and White Wonder. The average yield of all varieties was over 44 bu. per acre. The yields for 1901 and 1902 of 20 new varieties are also shown in comparison with the yields of 9 of the best old kinds. Many of the new varieties were introduced by this Department, and are showing superior quality and productiveness. The results with different methods of soil preparation for oats were in favor of fall plowing. In one experiment the seed of the same variety grown continuously at the farm was compared every year with seed of the same variety grown at the State experiment station. During the 4 years this test has been in progress the seed from the experiment station has outyielded the home-grown seed by an average of 7.9 bu. per acre.

Eleven varieties of wheat grown for 5 years have given an average yield of 17.4 bu. per acre. In 1902, 4 varieties of macaroni wheat gave an average yield of 15.4 bu. per acre, as compared with 22.3 bu. for the ordinary wheats. The blue stem wheats

have so far given the largest yields at the farm. The author recommends not to sow wheat on spring-plowed land. A yield of 22.9 bu. per acre of winter wheat is reported.

The 6-rowed varieties of barley have given the best results. Manshury, one of the best varieties of this type, averaged 24.9 bu. per acre for 7 years, and Champion of Vermont, the best 2-rowed sort, gave an average yield of 21.6 bu. per acre.

The average length of the growing period for different grains as observed at the farm for 7 years was as follows: Barley 93 days, oats 109 days, and wheat 113 days.

The results with spelt, winter rye, flax, buckwheat, and beans are briefly noted. The experience with spelt was not encouraging. Winter rye gave good results and during 6 years was never injured by winterkilling.

The results for grasses, clover, and alfalfa, grown alone and in mixtures, are tabulated and comments on the value of the different crops for the region are given. Red clover grown separately or in combination with grasses has given good results, but alfalfa in 3 trials never survived the winter. Among the mixtures the high yields, in each case over 4 tons of hay per acre, are recorded for red clover with brome grass and timothy, red clover with redtop and timothy, and red clover with wheat grass.

Forage crops dealt with in this connection are corn, millet, and peas. In 1901 a yield of 5.05 tons of corn fodder was obtained per acre. Dent corn varieties maturing in southern Minnesota and northern Iowa are recommended for fodder in the region in which the farm is located. The results with a number of flint and dent corn varieties are given. Of the flint varieties Squaw, North Dakota White, and North Dakota Yellow ripened in the locality. The dent corn varieties usually did not mature. Japanese was the most productive of the different varieties of millet grown, but its coarseness is regarded as detrimental to its feeding value. The difference in yield between German, Common, Siberian, and Hungarian millets was not very large. On light sandy soil in 1896 peas yielded from 8 to 13.5 bu. per acre, and in 1898 on bottom land underlaid with clay the yield was from 15 to 28.8 bu.

Potatoes at the farm grew best on light sandy or sandy loam soils. In a test of 48 varieties for 2 years Early Michigan led with a yield of 346.3 bu., and Salzer Million Dollar, which ranked last, produced only 132.3 bu., or 214 bu. per acre less than the best yielding sort.

Of the root crops grown ruta-bagas have uniformly given the largest yields and have shown themselves adapted to the largest range of soil conditions. The average yield of 4 varieties in 1900 was 24 tons per acre, while 6 varieties of mangels, 2 of sugar beets, and 4 of carrots averaged 17.6, 13.3, and 7.2 tons per acre, respectively. Root crops, owing to weather conditions, have not been uniformly successful at the farm.

Outlines of rotation experiments in progress and notes on the clearing of lands are given, and the swamp lands of the region are described.

Other parts of this bulletin are noted elsewhere.

Practices in crop rotation, G. K. Holmes (*U. S. Dept. Agr. Yearbook 1902, pp. 519–532*).—A general review of past and present practices in crop rotation is given and the more common rotations in which specified crops are grown in different States are outlined. Various factors affecting crop rotation are discussed.

Crop rotation for South Dakota, E. C. Chilcott (*South Dakota Sta. Bul. 79, pp. 69, figs. 9*).—In connection with an outline of the experiments conducted and a report on the results obtained, chemical and mechanical analyses of soil from the station plats and the meteorological records for the growing season for each year from 1897 to 1902, inclusive, are presented. The experiments comprise 24 rotation tests, and the results of each test are briefly discussed. The moisture and fertilizer requirements of the different crops grown are compared. The average yield of all wheat plats for 5 years was 14.47 bu. of grain and 2,292 lbs. of straw per acre, and

this is taken as the standard of comparison for the different rotations. The average yield of oats was 43.64 bu. of grain and 2,231 lbs. of straw, and of barley 37.25 bu. of grain and 1,963 lbs. of straw. In these average results the ratio of grain to straw for wheat, oats, and barley was 1:2.65, 1:1.58, and 1:1.15, respectively.

The best average yields were obtained from wheat following summer fallow, but the difference in yield as compared with wheat following corn amounted to only ⅓ of a bushel per acre, and for this reason the rotations containing corn crops are regarded as much more profitable than those with summer fallow. The lowest yields of grain and straw were obtained where wheat followed oats. The yields of wheat after millet were below the general average, and on account of this fact millet is regarded as having but little value as a restorative crop. Wheat after peas also yielded less than the general average, and where the peas were plowed under for green manure the yields were not as good as where corn had been grown the previous year. Continuous cropping with wheat resulted in an average yield of about 1.5 bu. per acre below the standard. Wheat after roots gave about the same results as after corn, and when grown after vetch the yields were slightly better than when following peas.

The value of brome grass in the rotation is pointed out, and directions for its use and treatment in this connection are given.

The effects of growing corn on succeeding crops are summarized as follows:

"The soil is kept in the best condition for the growth of nitrifying and other beneficial bacteria.

"Chemical changes, in part dependent upon, and in part independent of, the growth of bacteria are induced; thus reducing the unavailable plant food to forms in which it can be readily assimilated by the growing plants.

"The soil moisture is conserved and kept stored in the soil for the use of the succeeding crop instead of being evaporated from the surface.

"A less amount of moisture is used by the corn crop than by any of the other crops under consideration; and, therefore, a larger store of soil water is available for the succeeding crop."

The seasons of 1900 and 1901 represented unfavorable and favorable conditions, respectively, and a comparison is made of the effects upon the yields of wheat and oats produced by the immediately preceding crop during these seasons. In 1900 the average yield of wheat from 30 plats was only 9.15 bu. per acre, while in 1901 from the same plats and in the same rotations it was 16.38 bu. The average yield of oats from 8 plats was 20.69 bu. per acre in 1900 and 47.87 bu. in 1901. An increase in yield of 8.04 bu. per acre was obtained where wheat followed summer fallow, corn, potatoes, or peas plowed under, and an increase of 16.12 bu. of oats where this crop was grown after corn instead of after wheat. The yields of both crops in 1901 were quite uniform, and there was no apparent advantage in growing wheat on summer fallow or corn land during this favorable season.

In observing the effects of the frequency of cropping with wheat the author found that where wheat was grown only once in 5 years the average yield was 15.27 bu.; and where grown every 2 years, 15.33 bu. per acre. The yields in the other groups differed from each other by less than 1 bu. per acre, and were considerably less than for the 2 and 5 year periods. The failure to detect any relation between the length of the interval between wheat crops and the yields strengthens the author's former conclusion that the yields depend almost entirely upon the crop immediately preceding the wheat crop.

In addition to the report on the rotation tests the results of experiments in the application of manure to wheat are given. The quantities of manure applied ranged from 4,000 to 9,600 lbs. per acre. In 1897 the average increase on the manured plats was 1.9 bu. and in 1898 2.99 bu. These results proved profitable.

Industrial progress in plant work, B. T. GALLOWAY (*U. S. Dept. Agr. Yearbook 1902, pp. 219–230*).—This paper briefly reviews the progress made in the improve-

ment of corn, wheat, oats, rye, barley, rice, cotton, hay, and forage crops in the United States, and points out the influence which the work of this Department and the experiment stations has had upon the results thus far obtained.

Experience and results in plant breeding, O. Pitsch (*Deut. Landw. Presse, 30 (1903), Nos. 47, p. 415; 48, pp. 429, 430; 49, p. 40*).—Breeding experiments with mangels, sugar beets, and wheat are described. Golden Tankard and Petite Anglaise mangels were planted together with Kleinwanzlebener sugar beets, and natural crosses were obtained. The work of selection carried on for several generations is discussed and brief notes of the results are given.

A comparative study of the anatomical structure of mangels and sugar beets is reported, and the conclusion is drawn that in a measure the sugar content of mangels is higher in proportion as the anatomical structure of the mangel approaches the finer structure of the sugar beet. It was found, however, that the anatomical structure did not serve as a guide in the selection of mother beets. Further investigation, in which the dry matter was taken into consideration, showed that a high percentage of dry matter, a fine anatomical structure, and a high specific gravity are closely related, and that these qualities are usually not found in specimens high in weight. Specimens showing these 3 qualities, together with a relatively high weight, are considered good mother beets.

A new variety of wheat was originated by the author several years ago by crossing Essex and Rouge Inversable, a Bordeaux wheat. This new variety, known as Bordeaux Bastard, has given better yields than Essex and other standard sorts. Later, crosses between Squarehead and Challenge wheats were obtained, and these are here described. The crosses showing the characters of the Squarehead wheat in the spike were more productive and produced a heavier grain than the new varieties in which these characters were absent. It was also observed that individuals of Bordeaux Bastard wheat having the Squarehead type of ear were much more winter resistant than plants with the common type.

Congressional seed and plant distribution circulars, 1902–1903 (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 25, pp. 23–82, pls. 3, figs. 3*).—These circulars prepared by different members of the scientific force of the Bureau of Plant Industry and one by the chief of the Bureau of Soils, originally printed to accompany seeds sent out through the Congressional distribution, consist of descriptions of varieties and directions for their culture and have been collected and published here for the purpose of permanently recording them.

Among the different subjects considered are the plan of distribution and allotments of Congressional seeds and plants in 1902–3, directions for planting bulbs, methods of cultivating and ginning short and long staple upland and Sea Island varieties of cotton, growing pure cotton seed of good quality, and the culture of different types of tobacco. Historical and descriptive notes are given on the Rivers Sea Island cotton and Sea Island cotton No. 224, varieties tested with reference to their resistance to the wilt disease. A description with a history of the variety is also given of the Iron cowpea, a variety "most noteworthy for its resistance to the cowpea wilt disease and root knot."

Variety tests with Swedish barley (*Deut. Landw. Presse, 30 (1903), No. 32, p. 272*).—The results of variety tests with Swedish barley are briefly noted. Hanna barley ripened early and seemed well adapted to light soils in dry locations. Svanhalskorn barley matured as early as Hanna, but appeared to be better adapted to heavy than to light and dry soils. Swedish Chevalier, a late variety, ranked second in yield and last in quality and gave equally good results on light and heavy soils. Princess barley ripened latest and as a rule gave the best yields on the heavier soils. During the wet season of 1902 it also yielded well on light land. This variety ranked third in quality.

Nitrate of soda as a fertilizer for brewing barley (*Deut. Landw. Presse,*

30 (1903), No. 38, p. 332).—Samples of barley grown in cooperative fertilizer experiments were examined with reference to the purity of the grain, the size, shape, uniformity, color, and mealiness of the kernel and the texture of the hulls, resulting in an average number of points of 21.39 for the samples grown without fertilizers, and of 21.67 for samples from plats fertilized with nitrate of soda, Thomas slag, and kainit. These results are considered as indicating that the use of nitrate of soda does not injure the quality of the barley for brewing purposes. Applications of nitrate of soda in connection with phosphoric acid and potash for the purpose of increasing the yield are recommended.

Variety tests with red clover, O. PITSCH (*Deut. Landw. Presse, 30 (1903), Nos. 38, pp. 331, 332; 41, p. 362*).—The results of tests with 3 continental varieties and American red clover conducted for 4 years are given. Maas, a continental variety, ranked first in the yield of dry matter.

The corn crop, C. G. WILLIAMS (*Ohio Sta. Bul. 140, pp. 67–88, figs. 5*).—This bulletin discusses at some length the selection of seed corn and points out the desirable and essential characters of corn used for seed. Directions for selecting the seed corn with a view to increasing the protein content are given, together with descriptions of the ears of 28 varieties grown at the station. The mean temperature and rainfall at the station for the 5 months of the corn-growing season for 15 years are given in a table. The results of field experiments conducted by the late J. F. Hickman are reported.

A comparison of drill and hill planting covering a period of 4 years shows that planting 1 grain every 12 in. in the row gave the best yield. A distance of 18 in. between single grains gave a marked reduction in the yield. Planting 2 grains every 24 in. gave practically the same results as 1 grain every 12 in.

Experiments in deep and shallow cultivation were carried on for 9 years. Deep cultivation consisted in working the soil with a shovel cultivator to a depth of 4 in., and shallow cultivation in stirring the soil with a spring-tooth cultivator to a depth of an inch a d a half. The average results for the 9 seasons show that the shallow-cultivated plats yielded 4 bu. of grain and 213 lbs. of stover more per acre than the plats receiving deep cultivation.

Of 47 varieties under test for a varying number of years, 22 never completely matured. The best maturing varieties were Hess White, Leaming, Leaming Cuppy, Minnesota King, and Murdock 90 Day. The best yielding varieties stood in the following order: Missouri Leaming, Reid Yellow Dent, Henderson Eureka, Farmer Favorite, Darke County Early Mammoth, and Leaming. Pride of the North, King of the Earliest, Early Butler, and Extra Early Huron Dent are pointed out as good early varieties. Leaming and Reid Yellow Dent are suggested as suitable for the section of the State south of the 40th parallel; Leaming and Clarage for the section between the 40th and 41st parallels, and Clarage and White Cap Yellow Dent for the northern part of the State.

Improvement of corn by seed selection, C. P. HARTLEY (*U. S. Dept. Agr. Yearbook, 1902, pp. 539–552, pls. 7*).—This article discusses the possibilities of increase in yield and improvement in quality of corn; points out the importance of stalk, ear, and kernel in selecting seed, and calls attention to other points to be considered in this connection. Directions are given for the selection of seed, the planting and cultivation of a seed patch, and the storing of seed corn.

The results of 6 breeding experiments, showing the necessity of giving attention to the characters of stalk, ear, and kernel in selecting seed are briefly reported. A stalk of Pedrick Golden Beauty corn, producing exceptionally broad leaves was fertilized with pollen from the same plant, and the seed from the resulting ear produced plants exhibiting the same character. The seed from these plants also produced broad-leaved plants. In one experiment 3 short and very leafy stalks of tall-growing white dent corn were cross pollinated one with another. The resulting

seed produced plants resembling the parent stalks. A test of seed ears varying in the percentage of shelled corn showed that each seed ear transmitted its character in this respect to its offspring. Another test of seed ears showed that the longer the seed ear the greater was the average length of the ears produced.

Experiments have also been made to test the extent to which the size of the germ can be transmitted. The results almost without exception showed the germs of the progeny of the large-germed ears to be plainly larger than those of the progeny from the small-germed ears. The individuality of kernels was studied by planting red and white kernels from a spotted ear of white dent. About one-half of the ears produced had kernels like those planted and the rest of the ears were white. In a second test of this kind various kernels of a hybrid ear followed the same rule of transmitting their individual characters.

The commercial grading of corn, C. S. Scofield (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 41, pp. 24, pls. 4*).—This bulletin discusses the methods and purposes of grading corn; points out the value of definite grade standards and grade uniformity, and describes the methods of determining the percentage of moisture, color, damaged grains, and broken grains and dirt in a cargo of corn. The rules recently recommended by the Chief Grain Inspectors' National Association for the grading of corn are given, and the classes and grades of corn are defined.

"In grading commercial corn there are two classes of elements to be considered: First, those which indicate condition—moisture, percentage of moldy, rotten, or otherwise damaged kernels, and percentage of broken grains, dirt, and other foreign material; and second, those which indicate quality—color, plumpness, relative proportion of starchy to hard material, and relative size of germ." Moisture, percentage of colors in mixtures, percentage of damaged grains, and percentage of broken grains and dirt are regarded as the essential elements in determining the grade.

Improvement of cotton by seed selection, H. J. Webber (*U. S. Dept. Agr. Yearbook 1902, pp. 365–386, pls. 3, dgm. 1*).—This article describes the methods of selection which may be used by cotton planters and breeders, and points out some of the important improvements and results that can be produced by such means. Improvements in the yield of fiber and seed, length of staple, strength of fiber, season of maturing, resistance to disease and storms, and adaptation to soil and climate are considered.

Flaxseed production, commerce, and manufacture in the United States, C. M. Daugherty (*U. S. Dept. Agr. Yearbook 1902, pp. 421–438*).—After considering the growth and development of flaxseed production and manufacture in the United States, the author discusses the products from flaxseed and their uses and describes the manufacture of linseed oil. Statistics on the cultivation and production of flaxseed, the internal commerce in the product, and the production of linseed oil are presented.

Preliminary report on the commercial fibers of the Philippines, J. W. Gilmore (*Philippine Bureau Agr., Farmers' Bul. 4, pp. 58, pls. 4*).—Brief general information is given on the fibers exported from the Philippines and those largely used by the natives. The fiber plants discussed include Manila hemp, maguey, pineapple, cotton, ramie, pangdan, burri or talipot palm, nipa, and rattan. A partial list of the fibrous plants of the Philippine Islands is given. The text of the bulletin is in English and Spanish.

Forage conditions and problems in eastern Washington, eastern Oregon, northeastern California, and northwestern Nevada, D. Griffiths (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 38, pp. 52, pls. 9*).—The field work of 1902, which is here reported, was largely supplementary to that of 1901 (E. S. R., 14, p. 136). The investigations of the season were confined to the drainage area of the Columbia River and to the Great Basin. A general account of these regions is given, and the range is described with reference mainly to its condition and its flora. The occur-

rence and value of a large number of range plants is noted, together with the cultivated plants grown as meadow and hay crops. Notes are also given on the reclamation of swamp lands in this section, the needs of the region, poisonous plants, weeds of meadows and pastures, and a number of diseases injurious to forage crops. The cultivation in this region of alfalfa, timothy, redtop, awnless brome grass, wheat, barley, rye, cheat, and roots as forage crops is considered.

The needs of the region, as summarized by the author, are summer pasture for sheep, hay and pasture crops suited to the highland regions of the Blue and Warner mountains, an early maturing perennial grass for the desert basins where water for irrigation can be obtained for only a very short time, a variety of alfalfa requiring less water than the common form, and another one resisting the effect of soluble salts in the soil. The following native grasses are recommended as worthy of cultivation: Wild wheat (*Elymus triticoides*), bunch blue grass (*Poa lævigata*), short-awned brome (*Bromus marginatus*), mountain rye grass (*Elymus glaucus*), bunch wheat grass (*Agropyron spicatum inerme*), and giant rye grass (*Elymus condensatus*). Brief notes on their value are given.

Field experiment with nitrate of soda on forage crops, E. B. VOORHEES (*New Jersey Stas. Bul. 164, pp. 1–13, 28, pls. 3*).—This work is in continuation of experiments with various forms of nitrogen begun in 1898 (E. S. R., 13, p. 742). In 1902 the crops were grown on acre plats. The following table is explanatory of the experiments and the results obtained.

Results of field experiments with nitrate of soda in 1902.

Kind.	Date of application.	Amount of nitrate applied.	Date of cutting.	Yield. Untreated acre.	Yield. Treated acre.	Gain. Total.	Gain. Percentage.	Value at $3 per ton.	Cost of nitrate per acre.	Net gain over cost.
		Lbs.		*Tons.*	*Tons.*	*Tons.*	*Perct.*			
Rye	Apr. 1	150	May 4–16	4.76	6.55	1.79	37.6	$5.37	$3.38	$1.99
Wheat	...do....	150	May 16–26	4.64	7.50	2.86	61.6	8.58	3.38	5.20
Barnyard millet	July 10	160	Aug. 13–22	7.63	13.38	5.75	75.4	17.25	3.60	13.65
Barley	Sept. 12	160	Oct. 13–16	1.20	2.36	1.16	96.6	3.48	3.60	—.12

It is concluded that the use of nitrate of soda as a top dressing for wheat, rye, and millet increases the yield and improves the quality of the crop. An application of 150 lbs. per acre applied broadcast about April 1, is recommended for wheat and rye, and 150 to 200 lbs. per acre for millet and other summer cereals as soon as the crops are well started.

Leguminous forage plants, J. WITHYCOMBE (*Oregon Sta. Bul. 76, pp. 47–68, figs. 4*).—This bulletin gives popular information relative to the growing of leguminous forage plants in Oregon. The different plants considered are red clover, vetch, alfalfa, crimson clover, field pea, sainfoin, soy bean, and cowpea.

It was observed at the station that the roots of some alfalfa plants withstood the presence of water in the soil, while the roots of other plants either stopped growth or rotted off when reaching a certain degree of moisture. This effect is considered as indicating the possibility of developing by selection a type of alfalfa better adapted to the soil and climatic conditions of western Oregon than the type suited to arid soils and grown under irrigation.

Crimson clover sown in the fall of 1901 germinated about September 1 and yielded the next spring 23.67 tons of green forage per acre, while in 1902 the seed germinated about November 1 and the yield of green forage in the spring of 1903 was only 6.67 tons per acre. The field pea and the cowpea are not considered valuable for western Oregon.

Fertilizer experiments with hops (*Deut. Landw. Presse, 30 (1903), No. 29, p. 224*).—The results of 3 years experiments with nitrate of soda are reported. All plats received 720 kg. of Thomas slag and 360 kg. of 40 per cent potash salt per hectare. Nitrate of soda was applied at the rate of 400 and 650 kg. per hectare, either the entire quantity applied in the spring or $\frac{1}{3}$ of it applied in the fall. One plat received barnyard manure instead of nitrate of soda. As compared with the check plat, the increase in yield per hectare on the various plats receiving different fertilizers was as follows: Barnyard manure, 91 kg.; 400 kg. of nitrate of soda applied in the spring, 109 kg.; the same application $\frac{1}{3}$ applied in the fall, 120 kg.; 650 kg. of nitrate of soda applied in the spring, 204 kg.; and the same amount, applying $\frac{1}{3}$ in the fall, 215 kg.

On the check plat where no nitrate of soda was applied, and on the plat receiving barnyard manure, many strobiles ripened early and the lower leaves of the plant turned yellow, which is considered due to the insufficient supply of nitrogen in the soil. Where the largest quantity of nitrate of soda was applied the hops matured latest and were in general of a better quality than where only 400 kg. per hectare were used. The hops from the plats receiving the heaviest application of nitrate were stronger in aroma and the strobiles were of a deeper green in color, as compared with the crop obtained on the other plats. As a rule plants best supplied with nitrogen were most resistant to drought, plant disease, and insect enemies.

In a separate experiment with the same fertilizer applications, but confined in each instance to a single hill, the yields were as follows: Without nitrate of soda, 195 gm. of dried hops; with 400 kg. of the nitrate per hectare, $\frac{1}{3}$ applied in the fall, 256 gm.; and with 650 kg., $\frac{1}{3}$ applied in the fall, 317 gm.

Time of harvesting horse beans, A. GRÉGOIRE (*Bul. Agr.* [*Brussels*], *19 (1903), No. 4, pp. 525–531*).—A study was made of the composition of the horse bean at different stages of growth and the results of the analyses made on different dates are shown. It was found that the formation of organic substance in the horse bean continues very actively up to the close of the vegetative period. During the last 2 months of growth the plant accumulates only nitrogenous substance and carbohydrate material, with the exception of fat and cellulose. The composition of these substances at the close of the vegetative period was found to be the same as during the early growth. The percentage of nutritive matter and its digestibility increased continually during the growing season. With these results in view the author recommends late harvesting.

Ten years' experiments with oats, C. G. WILLIAMS (*Ohio Sta. Bul. 138, pp. 39–52*).—Previous results in this series of experiments have been noted (E. S. R., 11, p. 234). The results for the different seasons are here shown in tables and discussed. American Banner, Improved American, Colonel, and Clydesdale, all varieties of the Welcome type, gave the largest average yield per acre and heaviest weight per measured bushel. Plowing sandy clay soil as compared with merely disking it proved profitable. The use of 9 to 10 pecks of seed per acre gave better results than the use of a smaller quantity. Using only the heaviest seed was found very advantageous, and sowing not over 1 inch deep gave better returns than deeper seeding. Broadcasting gave heavier yields than drilling 2 or 3 inches deep. The author does not conclude that broadcasting is better than drilling, but believes that oats are commonly drilled too deep.

Tests of yellow and green grained strains of different varieties of rye, A. GEERKENS (*Fühlings Landw. Ztg., 52 (1903) Nos. 8, pp. 269–274; 9, pp. 311–315*).—The experiments here reported were at once variety tests and breeding experiments. Petkuser rye proved to be the hardiest variety under test, and its superiority in this respect was especially shown on light soils. On heavy soils Russian Staudenroggen was fully equal to Petkuser in resisting winter weather. Göttingen rye showed the lowest degree of hardiness. The best yields were obtained from strains origi-

nated by the selection of greenish grains as compared with strains derived from yellowish kernels. The greater productiveness of the progeny of the green kernels, was most apparent where the plant food supply of the soil was smallest.

Observations were also made to determine the relation between the color of the grain and the form of the head. Former experiments have indicated that apparently there is a relation between green grains and short and compact heads, and yellow grains and long loose heads. The author does not consider this relation a very close one, because it is observed only in classifications based on the compactness and length of the spike and never becomes apparent where the classification is made according to the color of the grain. This feature is not regarded as hereditary. The strains with the least compact heads were the most productive. The author concludes that breeding for green grain and, within certain limits, for loose heads may be done simultaneously without connecting these two characters.

The cultivation of sisal in Hawaii, F. E. CONTER (*Hawaii Sta. Bul. 4, pp. 31, figs. 9*).—This bulletin after briefly noting the history of the sisal industry and describing the 2 varieties, *Agave rigida elongata* and *Agave rigida sisalana*, contains an account of the culture of sisal and its preparation for market, with notes on the diseases and insect enemies of the plant and the prospect of the sisal industry in Hawaii.

Culture and composition of the soy bean, G. LECHARTIER (*Ann. Sci. Agron., 2 ser., 1 (1903), No. 3, pp. 380–396*).—The results of culture and fertilizer experiments in progress for several years are reported, and analytical data for the green crop and the ripe seed are given in tables. It is estimated that the soy bean is capable of producing under the climatic conditions of Brittany a yield of 20,000 to 30,000 kg. of green forage per hectare. When sown in April the crop can be utilized in September. The pods were found to constitute about one-third of the entire crop by weight. The analyses presented show that the pods contain more nitrogenous matter and more fat than the stalks and leaves. The seed is especially rich in these substances and is considered superior in this respect to that of other leguminous crops.

The yields of seed in the experiments varied from 1,500 to 1,800 kg. per hectare. The seed did not mature completely in Brittany in cool and moist seasons, and for this reason the culture of this crop for the seed is considered better adapted to the warmer and drier provinces of France. It is concluded from the result that the yield of 2,000 to 3,000 kg. of green crop withdraws from the soil 32 to 48 kg. of phosphoric acid, 125 to 188 kg. of lime, 41 to 62 kg. of magnesia, and 71 to 106 kg. of potash per hectare. These figures for phosphoric acid and potash correspond to 200 to 300 kg. of superphosphate and a maximum quantity of 200 kg. of chlorid of potash. The crop contains from 100 to 150 kg. of nitrogen per hectare. From 100 to 200 kg. of nitrate of soda per hectare is thought to be the proper quantity of nitrogenous fertilizer for the crop.

Sugarhouse refuse as a fertilizer for sugar beets, F. STROHMER (*Mitt. Chem. Tech. Vers. Stat. Centralver. Rübenz. Ind. Oesterr.-Ungar., 1903, No. 149, pp. 1–31*).—Results obtained in 1902 are reported, but in summarizing the work the results of the previous year are also taken into consideration. In no case did the use of sugarhouse refuse prove injurious to the quality of the beets. The substance did not show any special advantage, but is regarded of value simply for the nitrogen and potash it contains. The nitrogen of the refuse acts like the nitrogen given in the form of nitrate of soda, and the potash similar to the potash given in the form of the sulphate.

Beets for distillery and forage purposes, L. MALPEAUX (*La betterave de distillerie et la betterave fourragère. Paris: Masson & Co., pp. 194, figs. 15*).—A popular treatise on the history and culture of beets for distillery and forage purposes. Chapters are also given on the feeding of beets and the manufacture of alcohol.

The California sugar industry, G. W. SHAW (*California Sta. Bul.* [illegible], *pp.* [illegible],

figs. 15).—This bulletin contains a historical review of the beet-sugar industry in California. The present magnitude of the industry is shown by a comparison of the value of the sugar produced with the values of other products of the State, and by a list of factories in operation, the location, capacity, and invested capital of which is given. The history of the industry is considered in 3 periods—the early period from 1857 to 1880, the dormant period from 1880 to 1887, and the modern period from 1888 to 1902. The different factories are described and statistics for each one are presented.

Sugar-cane culture in the Southeast for the manufacture of table sirup, H. W. Wiley (*U. S. Dept. Agr., Bureau of Chemistry Bul. 75, pp. 40*).—This bulletin presents the results of experiments with fertilizers for sugar cane conducted in Georgia, together with the reports of special agents on the culture of the crop in Georgia, Alabama, Mississippi, and Florida. The work is carried on under the supervision of the Bureau of Chemistry of this Department.

Fertilizer experiments on sugar cane, W. B. Roddenbery (pp. 5–24).—The experiments were conducted on 2 fields, designated as A and B. Field A, in cultivation about 20 years, is in a low state of fertility. Field B, in cultivation only 5 or 6 years, and in a much higher state of fertility, produced a very rank crop of velvet beans, which was plowed under the fall before the experiments were begun. On several series of plats different methods of applying a normal fertilizer formula were tested. Experiments with varying proportions of plant foods were carried on, and cotton-seed meal and nitrate of soda, cotton seed and cotton-seed meal, and kainit and muriate of potash, as fertilizers for sugar cane, were compared. The normal formula was as follows: 16 per cent acid phosphate, 1,200 lbs.; 8 per cent cotton-seed meal, 400 lbs.; 19 per cent nitrate of soda, 200 lbs., and 50 per cent muriate of potash, 200 lbs. An application of 1,200 lbs. per acre of this formula was used. The composition and cost of the fertilizer is reported.

The results show that velvet beans have a high fertilizing value, but that the maximum is reached only when phosphoric acid and potash are applied in the fertilizer. Applying a part of the fertilizer at the time of planting and the rest at intervals during the growing season gave the best returns. The use of different applications of the normal formula on the 2 fields indicated that on land in a good state of fertility, such as field B, an application of 800 or 1,000 lbs. per acre is the most profitable, while on poorer soil, as in field A, from 1.200 to 1.500 lbs. may be used to advantage.

Fertilizers furnishing large quantities of phosphoric acid and potash were more effective than those furnishing small quantities of these ingredients. Muriate of potash gave somewhat better results than kainit. Doubling the quantity of phosphoric acid given in the normal formula on field A gave a decrease of 1.5 tons of cane per acre and a gain of only 3.5 tons over the plat which received no phosphoric acid. For this soil 100 lbs. per acre of phosphoric acid is considered sufficient. Doubling the normal ration of this same element on field B gave a gain of 3 tons per acre and a gain of over 13 tons over the plat receiving no phosphoric acid. An application of about 200 lbs. of phosphoric acid per acre is believed to be the most profitable proportion for this soil. Applying double the quantity of potash was of no advantage on either field, and it is concluded that 50 lbs. per acre of actual potash is sufficient for both fields.

Nitrate of soda proved a better source of nitrogen than either cotton-seed meal or cotton seed on the poorer soil, while on the more fertile field nitrate of soda and cotton-seed meal gave the same tonnage. Cotton seed was found to be the most expensive fertilizer of the 3 substances. Cotton-seed meal gave $14 per acre more profit than the same value in cotton seed, and nitrate of soda $12 more than the same value in cotton-seed meal. A high percentage of nitrogen in the fertilizer was found to assist germination and favor suckering, while applying quantities of complete fer-

tilizers in the furrow with the seed cane prevented germination. Doubling the nitrogen of the normal formula on field A gave a gain of 3 to 3.5 tons and an increase in profit of about $9 per acre, while on field B doubling the nitrogen reduced the yield. For field A 65 lbs. of nitrogen per acre given in the form of nitrate of soda, and for field B 20 lbs. are recommended.

The following application per acre is recommended for field A: 12.5 per cent acid phosphate, 800 lbs.; cotton-seed meal, 100 lbs.; nitrate of soda, 300 lbs.; and muriate of potash, 100 lbs. The application recommended for field B is as follows: 12.5 per cent acid phosphate, 1,600 lbs.; nitrate of soda, 100 lbs.; and muriate of potash, 100 lbs.

Reports of special agents on the sugar industry, G. L. Spencer et al. (pp. 25–40).—A review of the sirup industry of the United States is given, and the methods of cane growing for sirup making in the different States and localities are described. The composition of the cane juices sampled at factories in the various sections is reported. The averages of the analyses at the different places are given in the following table:

Summary of analytical data on cane juices.

Town and State.	Composition of juice.			Number of samples.
	Sucrose.	Reducing sugar.	Purity.	
	Per cent.	*Per cent.*		
Cairo, Ga	11.42	1.68	77.49	27
Guyton, Ga	10.50	2.24	70.69	32
Waycross, Ga	12.83	1.64	75.82	16
Quitman, Ga	11.95	1.60	77.97	32
Geneva, Ala	12.26	1.73	77.43	16
Magnolia, Miss	12.75	1.46	76.41	28
Huntington, Fla	12.52	1.40	76.11	2
Average	12.03	1.82	75.99	

From the data presented it is concluded that for the manufacture of sugar the canes would not be profitable, but that for sirup making they are of excellent quality. "The high quantity of reducing sugar, which interferes with sugar manufacture, is no bar to sirup manufacture; on the contrary it is an advantage, as the reducing sugar is quite as sweet and palatable as sucrose and has a much lower coefficient of crystallization. Hence, its presence in the product, while impairing neither its appearance nor its taste, improves the selling qualities of the sirup by diminishing the tendency to crystallization."

A primer on the cultivation of sugar cane, W. S. Lyon (*Philippine Bureau Agr., Farmers' Bul. 1, pp. 40*).—This bulletin is an English and Spanish edition of a popular paper on sugar-cane culture in the Philippine Islands.

Cultivation of tobacco, C. W. Dorsey (*Philippine Bureau Agr., Farmers' Bul. 5, pp. 20, figs. 4*).—The methods employed in modern cultivation of tobacco are briefly outlined; the growing of tobacco under shade in the United States is described, and the conditions of tobacco culture in Sumatra, with special reference to the industry in the Philippines, are discussed.

Universal nomenclature of wheat, N. A. Cobb (*Agr. Gaz. New South Wales, 12 (1901), No. 12, pp. 1614–1629, pl. 1; 13 (1902), Nos. 1, pp. 74–90, pls. 3, figs. 10; 2, pp. 214–243, pl. 1; 4, pp. 415–418; 8, p. 850, pls. 3; 14 (1903), No. 6, pp. 546–549, pls. 4*).—This series of articles discusses the value of a universal nomenclature of wheat and a uniform system of describing varieties. A sample description is given of Blount-Lambrigg wheat. In addition to this discussion the results of examining a list of wheats as to the structure of the aleurone layer are given. The biological analysis of the kernel, the flour cells, and other cell layers of the wheat grain, and methods of staining and of preparing sections for the microscope are described. The series

of varieties studied in this connection are classified as to the color of the straw, their late or early maturity, and their high or low nitrogen content.

Saragolla wheat, D. G. Fairchild (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 25, pp. 9–12*).—This article calls attention to the value of Saragolla wheat for the manufacture of macaroni. The variety is grown in southern Italy, and is regarded as the best for the production of a fine-flavored product. A description is given of the process of making macaroni employed by the steam factories in one of the most important macaroni-manufacturing districts in southern Italy.

A study of the wheats of the Province of Santa Fé, C. D. Girola (*Estudio sobre los trigos de la Provincia de Santa Fé. Buenos Aires: Min. Agr., 1902, pp. 47, maps 2*).—A general discussion of wheat culture in the province, with cultural directions and statistical data. A number of varieties are described in detail, as are also the impurities which occur in wheat seed.

Experiments with wheats of the Province of Cordova, C. D. Girola (*Estudio sobre trigos de la Provincia de Córdoba. Buenos Aires: Min. Agr.* [*1902*], *pp. 14*).—The results of physical analyses of 40 samples of wheat comprising 6 varieties are reported and discussed.

Seed wheat, N. A. Cobb (*Sydney: Govt. Printer, 1903, pp. 60, figs. 36; reprint from Agr. Gaz. New South Wales, 14* (*1903*), *Nos. 1, pp. 33–50; 2, pp 145–169; 3, pp. 193–205, figs. 36*).—The method of grading seed wheat to show the proportion of 7 different sizes of kernels in a sample is described, and the results of grading a large number of varieties of wheat according to this method are presented in a table.

Trials with large plump and small shrivelled grains for seed are reported. Large, plump seed proved to be best in germination, plant-producing power, yielding capacity, and the production of grain of a high quality. The author discusses the advantages of grading seed wheat and describes a number of machines used for this purpose.

Influence of the awns on the transpiration of the spike and the quality of the grain, L. Perlitius (*Mitt. Landw. Inst. Univ. Breslau, 2* (*1903*), *No. 2, pp. 305–381, pls. 3; abs. in Deut. Landw. Presse, 30* (*1903*), *No. 50, pp. 450, 451*).—Observations made to determine the activity of the awns of wheat and barley showed that a considerable portion of the water transpired by the spike passes through these organs and that the quantity increases with their length. Awned wheat spikes in some cases transpired double the quantity of water transpired by awnless heads or heads from which the awns had been removed. In the case of barley it was fourfold instead of being double the quantity. Transpiration was most active during the development of the spike and the grains. The period of maximum activity varied with the different types of spikes, and it always occurred during the development of the grains before these had reached the milk stage. The length of the awns and the vegetative period of the spikes were inversely proportional to each other.

It is further concluded that the awns have a decided influence upon the volume and weight of the kernels, and that their action in this direction takes place shortly before the kernels are in the milk. The results of chemical analyses indicate that the grain of awn varieties is lower in nitrogen and higher in starch than that of awnless sorts. The absolute amount of ash in the grain is believed to be increased by the activity of the awns, and for this reason awn varieties are capable of using mineral fertilizers to best advantage. The final conclusion from these experiments is that awn cereal varieties under normal weather conditions ripen earlier than the other varieties.

The anatomical structure of the glumes and awns of wheat and barley was studied and is here compared in a series of illustrations. A list of 55 references bearing on the different phases of the work reported is given.

Investigations on the stooling of grains, W. Rimpau (*Landw. Jahrb., 32* (*1903*), *No. 2, pp. 317–336; abs. in Deut. Landw. Presse, 30* (*1903*), *Nos. 44, pp. 392,*

393; 45, p. 398).—The results of investigations on the influence of the stooling capacity on the productiveness of different varieties of wheat, oats, barley, and rye are reported and compared with the results obtained by Schribaux in similar work. The plants under observation were grown in rows 6 m. long and 25 cm. apart. Single kernels were planted 5 cm. apart in the row. The different varieties entering into the experiments are described. The data for each plant, comprising the length of stem and head, the total weight, the number and total weight of the kernels produced, and the average weight per single grain are shown in tables. The author states that the results do not indicate, as Schribaux asserted, that the most productive varieties of grain have the lowest stooling capacity. This was found to be the case in a number of instances, but is not regarded as occurring with sufficient regularity to be considered the rule.

The different stems of the plant were studied in order to determine whether any relation existed between the order of their appearance and their productivity. The data show that the stems thrown up in the stooling process were frequently as productive, and sometimes more so, than the initial stems, and this is regarded by the author as showing that the initial stem can not be considered as being regularly the best.

A comparison of the first 3 stems with the 3 following ones, with reference to the same point, did not show a regular advantage in favor of the earlier appearing stems. It is shown that under normal conditions more than 3 stems per plant are seldom produced. For breeding purposes the selection of well-stooled plants, but only those with uniform stems and heads, is recommended.

Stack ensilage, A. CONLON (*Council Agr., Tasmania, Bul. 7, pp. 8, figs. 5*).—Directions are given for the preparation of stack ensilage, and the temperatures recorded in the stack are shown on a chart.

HORTICULTURE.

Cassell's dictionary of practical gardening, W. P. WRIGHT (*London, Paris, New York, and Melbourne: Cassell & Co., Ltd., 1902, vols. 1, pp. VII + 480, pls. 10, figs. 335; 2, pp. 480, pls. 10, figs. 219*).—This is a well-illustrated encyclopedia of practical horticulture, dealing with the propagation and culture of fruits, vegetables, foliage, and flowering plants and shrubs, out of doors and under glass. The articles on each subject are concisely written. Such matters as the derivation of plant names, habitats of different plants, history of introduction, and botanical details are omitted. Attention is centered on propagation, soil, and general culture, with a list of the best species or varieties. Notes are usually given also on the height, flowering period, degree of hardiness, and color of the flowers of different plants. Various horticultural practices are described and explanatory entries made under the different terms used in horticulture. The materials used in gardening operations are also described.

New experiments in electro-culture, P. VAN BIERVLIET (*Rev. Gén. Agron. [Louvain], 12 (1903), No. 5, pp. 193–200*).—The author conducted some electro-culture experiments with barley, oats, potatoes, strawberries, and carrots, using the electrical machine devised by S. Lemström (E. S. R., 14, p. 352). The season for the experiment was very unfavorable. Nevertheless, the results on the whole show considerable increase on the plats subject to electro-culture. This increase was about 50 per cent for strawberries, 13.8 per cent for potatoes, 13 per cent for carrots, 10.5 per cent for barley grain, and 21.65 per cent for barley straw. Notwithstanding the unfavorableness of the season, and the necessity for interpreting the results obtained with caution, the author still believes that the application of electricity as proposed by Lemström has a decided influence on crop growth.

Is it more advantageous to use seeds the year they are harvested, or after several years preservation? GROSDEMANGE (*Rev. Hort. [Paris], 75 (1903), No. 13,*

pp. 304, 305).—This is an abstract of a paper read by the author at the Paris Horticultural Congress, May 22, 1903. It presents results of a preliminary study on the germination of seeds. The author states that in the majority of cases fresh seeds give the best results, but with the following exceptions: With carrots, 2-year-old seed gives less leafy plants and more highly colored roots. The use of 3 or 4 year old chicory seed tends to prevent premature greening. With cabbage, the use of 2 or 3 year old seed tends to produce better heads than fresh seed. With gherkins, pumpkins, and melons, seed 2 or 3 years old is preferred; fresh seed produces too leafy vegetation. Likewise corn salad seed 2 or 3 years old is preferred to fresh seed. With radishes, fresh seed is preferred for outdoor soil, since it produces more robust plants, but seed 2 or 3 years old is preferred under glass because it produces a less leafy product.

Commenting on these results, M. Bazin stated that fresh seeds should always be preferred when it is wished to produce plants with a strong leaf growth, while for plants which it is desired should head well, like cabbage, salads, melons, cucumbers, etc., it is preferable to use seeds 2 to 3 years old. With ornamental plants, particularly with balsams, seed more than a year old tends to produce double flowers to a much greater extent than fresh seed.

Three new plant introductions from Japan, D. G. FAIRCHILD (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 42, pp. 24, pls. 6*).—The 3 new plant introductions discussed in this bulletin are Mitsumata, a Japanese paper plant; Udo, a new winter salad; and Wasabi, a kind of horse-radish. These various plants are described and their culture, as observed in Japan and the places in the United States where each is likely to succeed, are noted. From Mitsumata (*Edgeworthia papyrifera*) a superior kind of paper is made. The plant grows about 5 ft. high, and the paper is made from the bark. Udo (*Aralia cordata*) is grown in a manner somewhat similar to asparagus. The edible portions of the plant are the young shoots which are blanched by being covered with earth, and are available for use the second year from seed and for a series of years thereafter. It is not expected that this salad plant will compete with lettuce, but it is believed that it will make a very desirable winter change. Wasabi (*Eutrema wasabi*) is propagated from suckers and grown 2 years in the field before being marketed. It is considered a very appetizing relish.

Plant introduction notes from South Africa, D. G. FAIRCHILD (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 25, pp. 13–22*).—These notes consist of brief accounts of 3 Cape seedling grape varieties—the Red Hanepoot grape, *Vitis rupestris metallica*, and the Le Roux grape; two fruit-bearing hedge plants—*Carissa grandiflora* and *C. arduina*, commonly called amatungulas; Rhodes grass (*Chloris virgata*), the Kafir plum, and the Natal pineapple. Attention is called in connection with these notes to the rooi-bloem, a new corn parasite which is causing damage in the South African corn fields.

Experiments in mulching, R. A. EMERSON (*Nebraska Sta. Bul. 80, pp. 26*).—Comparative records are given of the yield and behavior of lettuce, cabbage, tomatoes, peas, beans, cucumbers, watermelons, muskmelons, sweet corn, beets, salsify, carrots, parsnips, onions, potatoes, and sweet potatoes when grown on plats kept cultivated throughout the season and on plats mulched with straw. The work has been under way for the 3 seasons 1900–1902. Irrigation was practiced on a portion of each plat in the dry year of 1901. In 1902 the comparison was made on both bottom land and upland. The mulch used for the most part was old straw applied about 4 in. deep after settling. Generally it was put on about a month after the seed was sown and after the plants had received 2 or 3 cultivations. A special test is reported of different kinds and depths of mulches for potatoes.

Mulching proved of doubtful value with lettuce. It was difficult to apply the mulch without injury to the tender plants, thus decreasing the stand, and in only 1 year out of the 3 was the size of the head larger on the mulched than on the cultivated area.

Cabbage appeared to be benefited by mulching. Two years out of 3 the size of the heads was noticeably larger and rotted less on the mulched plats. The mulched cabbage, however, suffered more from the attacks of grasshoppers. It is stated that the plants are more easily mulched 2 to 4 weeks after planting than when smaller.

With tomatoes the mulched plants were smaller but the fruit yield larger than with cultivated plants. Less rot and more perfect specimens also characterized the fruit of the mulched plats. In general mulching proved advantageous with tomatoes, but care should be taken not to apply the mulch before the young plants are well established. Mulched tomatoes are also injured more by early fall frosts than when cultivated.

Mulched peas were somewhat later than cultivated peas, but further work is required with this crop before any definite conclusions can be drawn.

Navy and Golden Wax beans were decidedly benefited by mulching. The Lima beans showed but little difference as regards the 2 methods of culture. It is believed that in normal seasons mulching increases the yield of beans over cultivation except in cases of late planting or naturally late varieties, when, by delaying maturity, the beans are more likely to be injured by early fall frosts.

A larger yield of better developed cucumbers was secured on the mulched than on the cultivated plats. The mulched plants were somewhat later than the others and were less affected by plant lice. The results with muskmelons and watermelons were not conclusive. The tests showed, however, that if mulching is to be practiced with these crops, the mulch must not be applied until the plants are thoroughly well established. Mulching proved very undesirable with sweet corn during the wet season, and it is thought doubtful if it will ever prove of practical use for this easily cultivated crop. The yields obtained with beets were not decidedly in favor of either method of culture. It is thought probable, however, that less labor is required to mulch beets than to cultivate them. Salsify, like beets, showed no marked differences in favor of either method of culture. On low ground, during a wet season, arrots proved to be benefited by mulching, while the reverse was true with parsnips. The quality of the parsnips was also poorer on the mulched ground.

Early mulching of onions proved decidedly injurious. Transplanted onions on mulched plats gave slightly increased yields in some instances and decreased yields in others. The labor involved in mulching is probably less than in cultivation. Mulching proved undesirable with drilled onions owing to the difficulty of spreading the straw without injuring the stand of plants.

With potatoes, mulching on the whole has proved very satisfactory. The yield has been increased by mulching and the quality injured only in very wet seasons. In a special test of a 4-in. and 8-in. straw mulch and early and late mulching, a 4-in. mulch applied late in the summer, after several cultivations, has given the best results.

The best results with sweet potatoes were secured on mulched plats ridged and irrigated, the increased yield being about 19 per cent greater than on cultivated plats. The vines, however, were injured to a greater extent by early fall frosts than those on cultivated plats. The vines did not take root through the straw mulch as they do on cultivated ground, which is considered a decided advantage for mulching.

The moisture content of the mulched and cultivated plats of cabbage, peas, beans, cucumbers, watermelons, sweet corn, and beets was determined during the season of 1900 and found to average 18.2 per cent in the mulched plats and 17.1 per cent in the cultivated plats.

Briefly summarized, the results of these experiments show that with lettuce, drilled onions, and sweet corn, mulching is undesirable. With beets, salsify, carrots, parsnips, transplanted onions, peas, and melons, the labor requirements and yields are about the same by either method. Very favorable results have been secured by mulching cabbage, tomatoes, beans, cucumbers, potatoes, and sweet potatoes.

"Whether mulching shall be used in a particular case depends upon the vegetables to be grown. Early spring vegetables requiring only a few cultivations can usually be grown more cheaply by cultivation than by mulching. Furthermore, very early mulching, before the ground has become thoroughly warm, is apt to retard the development of the vegetables. On the other hand, summer or fall vegetables that require frequent cultivation throughout the season are grown as a rule with less labor by mulching than by cultivation."

If vegetables can be mulched in the summer after they have been given a few cultivations, it is believed much better results will be secured than by the now common method of entire neglect when the rush of summer work comes on.

Field experiments with nitrate of soda on market garden crops, E. B. VOORHEES (*New Jersey Stas. Bul. 164, pp. 14–28, pl. 1*).—An account of further work in the use of extra amounts of nitrate of soda for carrots, cabbage, celery, and cucumbers grown on ground already heavily fertilized (E. S. R., 14, 247). The experiments were also planned to study the value of different amounts and fractional methods of application.

Further work with carrots seems to confirm the results reported in 1901 to the effect that extra applications of nitrate of soda have a depressing effect on this crop, the yields being considerably less where additional amounts of nitrate of soda were used than where it was omitted.

Cabbage has again been greatly benefited by the use of extra amounts of nitrate of soda. The quantity has been greatly increased and the quality improved. The average increased yield on all the plats receiving additional quantities of nitrate of soda has been about 150 per cent more than where no additional amount was used. Whether the nitrate should be given in 2 or 3 applications was not brought out very clearly. When 300 lbs. of nitrate of soda per acre was used the best results were secured when it was distributed in 3 applications. But when 400 lbs. was applied, 2 applications resulted most advantageously. Larger profits resulted from the application of 400 lbs. per acre than from 300 lbs. In this experiment it is shown that the use of each 100 lbs. of nitrate of soda resulted in an increased yield of from $17 to $21.76. Since the price of nitrate of soda seldom exceeds $2.25 per 100 lbs., the profitableness of its use is plainly seen.

The most striking example of the value of additional amounts of nitrate of soda has been obtained with celery. The increased yields with its use have varied from 6,600 to 18,900 lbs. per acre, and the quality and selling price of the celery have been improved. Each dollar invested in nitrate of soda for this crop has given a return of from $25.47 to $39.05. There was a lack of uniformity in regard to the amounts of nitrate of soda used and the methods of application. When 300 lbs. was used per acre the best results were secured when it was applied in 3 equal applications, but when 400 lbs. was used the best results were secured from 2 applications. The experiment is believed to show that where the land is reasonably fertile and has received the ordinary dressing of manure and fertilizer, the use of nitrate of soda at the rate of 300 lbs. per acre in 3 equal applications is sufficient.

Cucumbers were grown in 1902 for making mustard pickles, and the crop was allowed to ripen before any were picked. The field was first fertilized with complete fertilizers, and then a test made of the value of additional amounts of nitrate of soda. The increased yield of all the plats, due to the use of nitrate of soda, was 86.5 per cent. The best results were secured when 300 lbs. of nitrate of soda was used per acre in 3 applications, the increased yield in this instance over the control plat being 126 per cent.

The final conclusions for the year's work are the same as those of 1901 (E. S. R., 14, p. 248), to the effect that after a crop has been fertilized with a complete fertilizer according to the usual custom, an additional amount of nitrate of soda may

still be used at a profit with nearly all vegetable crops: the yield is increased and the quality improved by the use of 300 to 400 lbs. per acre.

Fertilizers for special crops, A. F. WOODS and R. E. B. McKENNEY (*U. S. Dept. Agr. Yearbook, 1902, pp. 553–572*).—A popular article dealing with the use of fertilizers for roses, violets, carnations, chrysanthemums, tomatoes, and lettuce.

Suitable fertilizers in the cultivation of lettuce, BEAUCAIRE (*Sci. Amer. Sup., 55 (1903), No. 1428, p. 22883; trans. from Le Phosphate*).—An account of the culture of lettuce in washed sterilized sands with (1) no fertilizers, (2) farm manure, (3) complete fertilizer, (4) special complete fertilizer, (5) nitrogen and phosphate, (6) nitrogen and potash, and (7) potassium phosphate. The lettuce in the pot without fertilizer had sickly yellow leaves and produced no branches, notwithstanding the fact that it was sprinkled with a solution of ferric sulphate. The pots with farm manure and the complete fertilizers produced perfect crops of lettuce. Plants in pot 5, without potash, made a poor development of stalk, while in pot 6, without phosphoric acid, even a less development was made.

In commenting upon these results it is stated that lettuce, in order to produce seeds in quantity, requires a soil rich in nitrogen, and that phosphoric acid is more useful than potash. Ferric sulphate is also believed to prevent the plants from yellowing and to facilitate fructification. A 5 per cent solution is recommended when the flowers begin to appear.

Garden vegetables, H. H. CHAPMAN (*Minnesota Sta. Bul. 81, pp. 244–247*).—In a review of the work of the Northeast Experiment Farm since its organization in May, 1896, an account is given of the growth of certain vegetables, fruits, and shrubs. The 2 varieties of watermelons that have ripened at the station are Hungarian Honey and Fordhook. It has been found necessary to start tomatoes in the greenhouse in order to ripen them before frost. Sweet corn has always matured sufficiently for table use, even the later varieties. Strawberries ripen from July 4 to 20. It is recommended that new beds be set out in the spring in 4-ft. rows and 18 in. apart in the row. Matted rows give the best results. In the fall after the ground is frozen they should be covered 2 to 3 in. deep with straw. The most satisfactory varieties are Brandywine, Clyde, Splendid, Lovett, and Bederwood.

Raspberries and blackberries can be successfully grown when trained to hills and bent over and covered with dirt or straw in the fall for winter protection. Only the hardiest varieties of apples like Hibernal, Patten Greening, and Duchess can be successfully grown in the extreme northern counties of the State. Poor success has followed the setting out of trees on sandy soil. A clay subsoil at not too great a depth is advocated with a northeast slope, but a level or southern slope with suitable soil is better than a northern slope with sandy soil. Nearly all varieties of American native plums are hardy. Cheney is the best variety tested. Aitkin is recommended for planting at the same time for pollinating Cheney.

Vegetable and bush fruits, L. R. TAFT and M. L. DEAN (*Michigan Sta. Bul. 209, pp. 103–122*).—Notes are given on the better varieties of pole beans, bush beans, cabbages, lettuce, garden peas, sweet corn, potatoes, tomatoes, raspberries, blackberries, currants, and gooseberries grown at the station during 1902. This work is a continuation of that carried on for a number of years at the station (E. S. R. vol. 14, pp. 143).

New onion culture, T. GREINER (*New York: Orange Judd Co., 1903, rev. and enl. ed., pp. 112, figs. 52*).—This work has been rewritten and considerably enlarged. The bibliography given contains a very full list of references to experimental work in onion culture done by the agricultural experiment stations.

A new preserving melon, the "Triamble" (*Agr. Gaz. New South Wales, 14 (1903), No. 7, p. 587*).—A description is given of a new preserving melon supposed to be a hybrid between the Rio pumpkin and the common preserving melon. It is stated to be a very heavy cropper, exceedingly hardy, and able to stand dry weather

well. Specimens weighing 56¼ lbs. are recorded, though the average size appears to be less than 20 lbs.

Germination of truffle spores; culture and character of truffle mycelium, L. Matruchot (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 18, pp. 1099–1101*).—The author succeeded in growing pure cultures of the spores of the Perigord truffle (*Tuber melanosporum*) and of the Burgundy truffle (*T. uncinatum*) on cut potato tubers to which a nutritive liquid was added and the whole rendered as aseptic as possible. The spawn developed within a few weeks in practically unlimited quantities and was clearly proven to be identical with wild spawn.

Artificial culture of the truffle, R. Dubois (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 21, pp. 1291, 1292*).—The author succeeded in growing truffle spores by placing them in contact with living vegetable tissue. A thin piece of truffle, the upper part of which contained the asci, was introduced into a tuber or root able to resist dessication for a long period. A notch or gash was first made in the tuber as aseptically as possible, and the piece of truffle fitted tightly into this. The whole was then kept in a moist dark place. Within a few weeks spawn developed at the point of contact. The spawn was gathered and sown in vessels containing a gelatinous mass, composed of cooked starch, glucose, glycerin, asparagin, and a little tannin. The spawn developed rapidly, appearing in large white spots, but at the end of the year had not produced fruiting organs. The spawn was then seeded at the foot of truffle oaks. The results have not yet been ascertained.

Fungus cultures (*Gard. Chron., 3. ser., 33 (1903), No. 861, pp. 414, 415*).—This is a brief review of the work of L. Matruchot and R. Dubois, noted above, who were successful in cultivating truffle spores. In addition the work of E. Boulanger, who succeeded in growing truffle spores as early as 1898, is noted. It is claimed that Boulanger succeeded in germinating the ascospores of the truffle in a sterilized watery liquid. "The spawn developed well on slices of carrot, on the same material buried in calcareous earth, in calcareous earth only, on mold, and under the ordinary conditions in which cultures are made, but carbonate or bisulphate of lime facilitated development.

"The ascospores of *Tuber uncinatum* yielded a well-developed spawn, and this gave rise to a 'perithecium,' that is, to the truffle itself; tasteless, scentless, and deformed doubtless, but nevertheless an adult perithecium, inasmuch as it contained normal asci. The spawn also developed a conidial form, wherein the spores were united together in numerous clusters and connected by mucilage."

American horticultural manual. II, Systematic pomology, J. L. Budd and N. E. Hansen (*New York: John Wiley & Sons, 1903, pp. 491, pls. 9, figs. 386*).—This volume supplements Part 1 (E. S. R., 13, p. 1044), and contains an outline of the numerous systems of classification which at one time or another have been used for classifying apples. Descriptions are given of all those varieties of fruits so far as known which are recommended at the present time by horticultural societies and growers. Nearly one-half of the book is devoted to the apple and the remainder to the usual orchard and small fruits grown in the United States, including grapes, cranberries, and nuts, and such subtropical fruits as the banana, date, fig, guava, custard apple, loquat, olive, citrus fruits, pineapple, etc.

Topworking orchard trees, G. H. Powell (*U. S. Dept. Agr. Yearbook 1902, pp. 245–258, pls. 4, figs. 8*).—A discussion of the purposes, methods, and advantages of topworking fruit trees with detailed directions for doing the work. Topworking is resorted to for the purpose of changing the variety, lessening the injury from sun scald and insects, modifying the vigor of the tree, hastening fruitfulness, and perpetuating desirable characteristics. Trees may be topworked either by budding or grafting. Budding is believed to be usually more satisfactory than grafting. "The operation is more simple, the wound heals more quickly, and the form of the tree can be regulated to better advantage by inserting the buds on the body, but the most

satisfactory results follow the adoption of both branch and body budding on the same tree when one is needed to supplement the other."

It is not believed profitable to topwork trees over 25 or 30 years old. Only a part of the tops of trees this old should be removed in any one year. The article, while applicable to all orchard fruits, deals more particularly with apples and peaches.

Suggestions concerning apple culture, W. J. Green (*Ohio Sta. Bul. 137, pp. 25–38*).—Popular directions are given for planting, manuring, cultivating, and spraying apple orchards. Considerable space is given to a discussion of the grass-mulch method of cultivating orchards advocated by Grant Hitchings, of New York, and F. P. Vergon, of Ohio. In 1900 an orchard was planted at the station to test the grass-mulch method in comparison with the usual method of cultivation. So far the results have been very favorable to the grass-mulch theory.

Apple growing in Missouri, J. C. Whitten (*Missouri Sta. Bul. 61, pp. 105–130, figs. 6*).—Concise popular directions are given for the planting and care of orchards in Missouri, and marketing fruit, with notes on the varieties most suitable for commercial planting. It is stated that Ben Davis and Gano are grown to a greater extent in Missouri than all other varieties put together.

Manuring the banana, M. A. Couturier (*Jour. Agr. Trop., 2 (1902), No. 13, pp. 195–197; trans. in Jour. Jamaica Agr. Soc., 7 (1903), No. 5, pp. 175–178*).—A summary of the practices of manuring bananas in different countries. It is stated that the ash of the stems of the banana contains about 55 per cent of potash, while the ash of the fingers contains about 73 per cent of potash. While tropical soils usually show high percentages of potash, the soils of Central America, Madeira, and Guinea are quite deficient in this element. Soils on which bananas are grown continuously for a series of years are exhausted in the same manner as when other crops are grown and should therefore be given a complete fertilizer containing relatively large amounts of potash.

In Madeira, on volcanic soil, poor in potash and phosphoric acid and rich in nitrogen, a complete fertilizer analyzing 13 per cent of nitrogen, 20 per cent potash, and 16 per cent phosphoric acid has been used with good results. The manure was applied at the rate of about $1\frac{3}{4}$ oz. per plant in a trench made about 18 in. around the stem of the plant. This application is made twice a year. Instead of this fertilizer the author recommends the trial of a manure testing 20 per cent potash and 10 per cent phosphoric acid, using sulphate of potash and mineral superphosphate for the mixture. To reduce the expense of transportation, superphosphate containing 45 per cent phosphoric acid instead of a mineral superphosphate might be used. These should be mixed in the proportion of 344 lbs. of sulphate of potash and 530 lbs. of mineral superphosphate, or 211.2 lbs. of double phosphate per acre. With about 600 plants per acre each plant should receive from 14 oz. to 1 lb. 5 oz., care being taken to place the manure in a trench made around the stem.

In commenting upon this paper Mr. James Neish, translator, states that in growing a few specimens of the Chinese banana (*Musa cavendishii*), he sets out 2 closely-planted circles of the cowbean (*Vigna sinensis*) around each banana, for the purpose of furnishing nitrates to the bananas. The beans are dug into the soil at the period of flowering.

Cultivation and fertilization of peach orchards, M. B. Waite (*U. S. Dept. Agr. Yearbook 1902, pp. 607–626, pls. 6*).—Popular directions for the cultivation and manuring of peach orchards in different sections of the country.

The nursery, C. Baltet (*La pépinière. Paris: Masson & Co., 1903, pp. X + 841, figs. 285*).—This book deals comprehensively with the culture and practices observed in the nursery growing of fruits, forest trees, shrubs, vines, and many tropical plants.

Cold storage, with special reference to the pear and peach, G. H. Powell and S. H. Fulton (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 40, pp. 28, pls. 7*).—Besides a general discussion of the subject of cold storage, particularly as applied to

fruit, an account is given of some experiments to determine the influence of degree of maturity, delayed storage, storing at different temperatures, types of packages, wrapping, etc., on the keeping quality of pears and peaches; also the influence of cold storage on the flavor and aroma of fruit, and the behavior of fruit when removed from storage. Considering the whole country, it is estimated that about 300,000 bu. of pears are stored annually, mostly in the larger Eastern cities.

In the experimental work reported Bartlett and Keiffer pears were the varieties principally used. The Bartlett is a tender variety of good quality, ripening in hot weather. It is withdrawn from storage before cool weather. The Keiffer is a coarse, long keeping, hard pear, ripening in the fall and withdrawn from storage in cool weather. Work with Bartlett pears was carried out in western New York. Full grown but still green fruit was picked early in September and packed in tight and ventilated barrels, in 40-lb. closed boxes, and in slat bushel crates. Part of the fruit in each lot was wrapped in unprinted newspaper and part left unwrapped. Some of the fruit was put in storage within 10 hours after packing and an equal amount held 4 days before placing in storage. In the storage room part of the fruit was kept at a temperature of 32° F. and part at 36° F.

It was found that Bartlett pears packed in a closed 40-lb. box or a slatted crate could be kept in cold storage for 6 weeks in prime condition when stored within 48 hours after picking and placed in a temperature of 32° F. When the fruit was not placed in storage until 4 days after picking there was a loss of 20 to 30 per cent from softening and decay. Bartletts stored at a temperature of 32° F. were in prime commercial condition 4 to 5 weeks longer than when stored at 36° F. When packed in barrels and stored in a temperature of 32° F. soon after picking, the fruit at the center became yellow within 3 weeks, although the outside layers were firm and green. After 5 weeks the fruit at the center of the barrels was soft and of no commercial value, while the outside layers were still in good condition. There was practically no difference in the keeping capacity of the fruit in the tight and the ventilated barrels. The fruit in both the closed 40-lb. box and slatted crate kept uniformly firm and green through the package. The chief advantage derived from wrapping Bartlett pears seemed to lie in the mechanical protection to the fruit rather than in its efficiency in prolonging its season. Wrapping is advised for superior fruit designed for first-class trade.

The Keiffer pears used were selected from orchards in Maryland and Delaware. They were picked at 3 degrees of maturity, beginning when the fruit was two-thirds grown and continuing until it was fully grown and showing a yellowish tinge around the calyx. Part of it was placed in cold storage within 48 hours after picking and part left 10 days in common storage before being placed in cold storage. Duplicate lots were stored at 32 and 36° F., respectively. Some of the fruit at both temperatures was wrapped in parchment paper and unprinted newspaper and some left unwrapped. The packages used were barrels, 40-lb. closed boxes, and $\frac{5}{8}$-bu. baskets.

The results of the experiment show that Keiffer pears may be picked during a period of 3 weeks beginning when they are two-thirds grown and successfully stored until the holidays or much longer if necessary, providing the fruit is handled with the greatest care and placed in cold storage at 32° F. immediately after picking. Pears stored 10 days after picking soon began to discolor and soften at the core, though the outside of the pears appeared perfectly normal. Within 40 to 50 days the flesh was nearly all discolored. The fruit kept 3 months longer at a temperature of 32° than at 36° F. It kept much better in small packages than in barrels. The chief advantage of ventilated packages seemed to be in the greater rapidity with which the fruit cools. Pears stored in open packages for a long time wilt considerably. Closed packages are therefore recommended.

Wrapped fruit kept longer than unwrapped, and wrapping proved especially valuable as the season advanced. Nearly 50 per cent of unwrapped Keiffer pears

had decayed by January 1, while those wrapped in unprinted newspaper and parchment wrappers were still in good condition. Little practical difference was noted in the relative efficiency of tissue, parchment, unprinted newspaper, and wax paper for wrapping fruits. In storing fruits for a long time a double wrapper was more efficient than a single wrapper, a satisfactory combination being unprinted newspaper next to the fruit with the more impervious paraffin wrapper outside. No evidence was deduced from these experiments to show that cold storage injured the aroma or flavor of pears. On the contrary, the quality of the fruit was maintained longer at a temperature approaching the freezing point than at one any higher.

The results secured in these experiments indicate that pears should be picked before they mature and stored as quickly after picking as possible, and that the fruit should be stored at a temperature of about 32° F. unless it is desired to ripen it up slowly at a higher temperature. Small packages which cool very quickly are best. Wrapping prolongs the life of the fruit, protects it from bruising, lessens wilting and decay, and keeps it bright in color. The rapidity with which cold-storage fruit breaks down when placed on the market depends upon the degree of ripeness of the fruit and the condition of the weather.

The peaches used in the experiment were grown in Georgia and Connecticut. They were stored at temperatures of 32, 36, and 40° F., respectively. Various kinds of packages were used and the fruit was picked at 2 different degrees of ripeness. Equal quantities were wrapped and left unwrapped. The results show that when highly-colored firm fruit was placed in the storage house at 32° it could be kept in prime commercial condition for 2 or 3 weeks. After that time the quality deteriorated, though the peaches continued firm and bright in appearance for a month. Mellow fruit when stored deteriorated much more rapidly and unripe fruit shriveled. At the higher temperatures of 36 and 40° the fruit ripened much more rapidly and reached its profitable commercial limit within 1 to 2 weeks. At the lower temperature the fruit kept equally well in all packages for about 2 weeks, after which that in open baskets and Georgia carriers began to show wilting. In 20-lb. boxes the fruit remained firm throughout the storage season. Wrapping the fruit proved a great protection against bruising in transit. Fruit stored at 32° F. for 2 to 3 weeks stood up 2 or 3 days after removal, depending on the weather. It is pointed out in this connection that in shipping peaches those at the top of the car are likely to ripen much more rapidly than those in the bottom layers and hence should be marketed separately. The chief value of cold storage in the peach industry is likely to be found in the temporary storage of the fruit during an overstocked market.

Cold-storage systems (*Amer. Florist, 21 (1903), No. 796, pp. 217, 218*).—A discussion of cold storage in retarding growth of roots and bulbs so that they may be brought into bloom whenever desirable, with a description of 2 systems of cold storage (ammonia and brine) now in use by 2 different floral concerns. For lily of the valley pips the rooms are kept at 25 to 30° F. The temperature for bulbs, it is stated, is maintained at 17° for the first 14 days after the bulbs are stored, after which the temperature is permitted to rise to 24°, where it remains until all the bulbs are used.

Cold storage of fruits and the preservation of exhibition specimens (*Amer. Gard., 24 (1903), No. 443, pp. 384-386*).—The experiences of several experimenters who have been working with fruits in cold storage are summarized and formulas given for preserving fruits for exhibition purposes in liquid. The paper is an extract from Circular No. 2 recently issued by the department of horticulture of the St. Louis Exposition.

Canning, preserving, and evaporating fruits and vegetables, G. McCarthy (*Bul. North Carolina State Bd. Agr., 24 (1903), No. 4, pp. 3-45, figs. 11*).—Estimates are given on the cost of erecting canning factories of different capacities and directions given for the canning, preserving, and evaporating of a large number of varieties of fruits and vegetables. Some suggestions on the making of jellies, marmalade, apple butter, fruit wines, and brandies are included.

The preservation of fruits for exhibition purposes, H. L. Hutt (*Canadian Hort., 26 (1903), No. 8, pp. 321, 322*).—Formulæ are given for preserving fluids in which to preserve different kinds of orchard and small fruits for exhibition at fairs, etc.

Promising new fruits, W. A. Taylor (*U. S. Dept. Agr. Yearbook 1902, pp. 469–480, col. pls. 7*).—Notes on the origin and desirable characteristics of Stayman Winesap and Randolph varieties of apples, Philopena pears, Belle and Willett peaches, Brittlewood and Stoddard plums, and the Jordan almond.

Small fruits: origin, culture, and marketing, G. C. Butz (*Pennsylvania State Dept. Agr. Bul. 111, pp. 65*).—Directions are given for the culture of strawberries, raspberries, blackberries, dewberries, Loganberry, wineberry, Goumi, Buffalo berry, June berry, currants, gooseberries, cranberries, high-bush cranberries, and huckleberries. Notes are given in each instance on the botany of the particular fruit, methods of propagation, insects, and diseases affecting it.

Recent experiences with strawberries, J. T. Roberts (*Amer. Agr., 72 (1903), No. 11, p. 208*).—The author reports that in his experience during the dry strawberry season of 1902 mulched portions of the strawberry field did not withstand drought as well as unmulched. The very finest fruits ripened in beds exposed to the full glare of the sun, the incline being to the east. High sloping land appeared to be most retentive of moisture. The experience gained in renovating an old plat led to the conclusion that it is less expensive to plant out a new bed than to clean out an old one.

The marmalade industry, E. Hotter (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 7, pp. 597–619*).—This contains a discussion of the economic aspect of the marmalade industry, with an account of some experimental work in determining the effect of organic acids on copper and aluminum vessels, and of the effect on sugar cooked with fruits in a vacuum and open kettles.

In order to determine the effect of organic acids when boiled in copper and in aluminum dishes in the same manner as occurs when kettles are used for the manufacture of marmalades and jellies, 2 per cent and 5 per cent water solution of acetic, tartaric, citric, and malic acids, respectively, were evaporated at a boiling temperature (1) directly over a flame, and (2) in a water bath, and the amounts of copper and aluminum dissolved by the acids determined. The results obtained are tabulated. The acetic, citric, and malic acids dissolved a considerably larger amount of copper than of aluminum under like conditions. With the tartaric acid the amount dissolved was about the same in both copper and aluminum dishes. These results are believed to show that it is desirable in the manufacture of marmalade to substitute some metal like aluminum for copper, since salts of the latter are poisonous and injurious to health.

An investigation of the jams and jellies manufactured by 8 English firms showed that only 3 of these firms used cane sugar entirely in their products, the remaining 5 using from 25 to 30 per cent of glucose with cane sugar. Other data are given to show that in the cooking of fruit juice with cane sugar, long continued heat and the fruit acids gradually invert cane sugar and destroy levulose. It was found also that if the finished product obtained from fruit juice, boiled down in a vacuum, contained much over 2 per cent of acid, the product could not be preserved more than a year without showing the formation of caramel and consequent discoloration. An examination of a number of English marmalades showed only 1.5 per cent acid content. Some data are also contained on the amount of juice and its composition obtained by adding water to apple marc and subjecting it to great pressure.

Grape, raisin, and wine production in the United States, G. C. Husmann (*U. S. Dept. Agr. Yearbook 1902, pp. 407–420, pls. 8*).—This includes an account of the early history of grape growing in this country, its gradual development as a commercial industry, and present methods of grape culture for table use, wine, and

raisins. California produces practically all the raisins grown in this country, devoting about 65,000 acres to this industry. The same State leads in the production of wine, though nearly 70 per cent of the sparkling wines are made in the State of New York.

Wine making at home, G. McCarthy (*Bul. North Carolina State Bd. Agr., 24 (1903), No. 4, pp. 16–19*).—Brief directions are given for manufacturing red wines, and a recipe for cordials.

Fertilizing the vineyard, E. H. Twight (*Pacific Rural Press, 66 (1903), No. 7, p. 100*).—Fertilizer formulas and methods of working them out for vineyard application are given.

The agaves, a remarkable group of useful plants, E. W. Nelson (*U. S. Dept. Agr. Yearbook 1902, pp. 313–320, pls. 4*).—The range of culture of these plants, methods of growth, and uses for food, drink, soap, fiber, etc., are discussed.

The flower garden, Ida D. Bennett (*New York: McClure, Phillips & Co., 1903, pls. 34, pp. 257*).—This book contains considerable information on the culture of hardy outdoor ornamentals, and suggestions on tools, equipment, and methods of work. Chapters are given on annuals from seed, on vines, bulbs, and tuberous-rooted plants, aquatics, hardy lilies, window boxes, foliage plants, roses, and shrubs. There are also chapters on the location and arrangement of the garden, soils, fertilizers, etc.

Home floriculture, E. E. Rexford (*New York: Orange Judd Co., 1903, pp. 300, figs. 72*).—This book is intended as a practical guide to the care and management of flowering and other ornamental plants of the house and garden. The subject is discussed from the standpoint of the amateur.

Plants as a factor in home adornment, L. C. Corbett (*U. S. Dept. Agr. Yearbook 1902, pp. 501–518, pls. 3, figs. 3*).—This article discusses the aesthetic value of plants, their arrangement for adornment about the home, and gives the characteristics of a large number of shrubs and deciduous trees and plants used in landscape gardening.

Lilac forcing in France (*Gardening, 11 (1903), No. 263, pp. 354, 355, figs. 3; 12 (1903), No. 265, pp. 385, 386, figs. 5*).—An account of French methods of forcing lilacs.

Blind versus flowering wood for rose cuttings, L. C. Corbett (*Amer. Florist, 20 (1903), No. 773, pp. 298–300, fig. 1*).—The author studied the effect on flower production of growing roses from cuttings made from blind wood and from flowering wood, respectively. By blind wood is meant a branch of the rosebush which is terminated by a leaf instead of a flower bud. The experiment was carried on for 5 years. Each year the flowering wood for propagation was selected from plants grown from flowering wood, while the blind wood was taken from plants propagated from blind wood. It was intended in this way to study the cumulative effects of propagation through a series of years.

As between the blind-wood and the flowering-wood cuttings, little difference was found in their respective tendencies to form roots. The plants also grew with equal vigor. During the first year of the experiment plants propagated from flowering wood produced 156 per cent more flowers than plants propagated from blind wood. During the second and succeeding seasons the percentage of flowers produced from the flowering wood decreased instead of increasing. The percentage of flowers produced on the blind-wood plants also decreased but not in so great a proportion. The average number of flowers per plant obtained with 2 varieties for the season December 1 to May 31 for 5 years is as follows: *Bride*—from blind wood 8.26, from flowering wood 16.59; *Bridesmaid*—from blind wood 12.29, from flowering wood 16.98.

In order to test the relative merits of new plants produced from cuttings and plants 2 years old, a number of plants produced from blind and from flowering wood were left in the greenhouse over summer. These were severely pruned back and part of the earth in the benches replaced with fresh soil. The pruned plants were afterwards slowly started into growth. They produced most of their crop in the fall and

early winter while the cutting plants produced the heaviest bloom later in the season. The question as to which method is best will therefore depend upon the time the flowers are in greatest demand.

As a result of these experiments it is believed that, where bloom rather than stock plants is desired, the test is emphatic in showing the desirability of plants propagated from flowering wood. The cumulative effects of propagating roses from blind wood or from flowering wood year after year is not marked.

The propagation of the Easter lily from seed, G. W. OLIVER (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 39, pp. 24, pls. 7*).—The author advocates the growing of Easter lilies from seed rather than from bulbs as one method of avoiding the troublesome lily diseases. Reproduction from seed is shown to be entirely practicable and as rapid as from bulbs. Illustrations are given of seedling lilies in bloom 6 months and 13 days after germinating. Detailed directions are given for pollinating flowers, sowing the seeds, and the future care of plants.

Fertilizer experiments in 1899 with Chrysanthemum indicum, variety Viviand Morel, M. HOFFMANN (*Gartenflora, 52 (1903), Nos. 11, pp. 297–305; 12, pp. 315–319; 13, pp. 347–352, figs. 6*).—Pot fertilizer experiments with chrysanthemums were made at 4 different stations in Germany and the results obtained are here detailed. A soil of fair quality was used in each experiment. One pot was left unfertilized as a control. Fertilizers were added to 4 other pots in the liquid used for watering as follows: (1) Sulphate of ammonia in the proportion of 1 to 200; (2) sulphate of ammonia in the proportion of 1 to 50; (3) liquid manure in the proportion of 1 to 10; and (4) liquid manure in the proportion of 1 to 10, bone meal 1 to 200, and sulphate of ammonia 1 to 2,000. The experiments covered a period of 234 days. The plants were transplanted 4 times. Careful data were taken of the height of the plant, number of branches, color, width and length of the leaves, total weight of all the different parts at maturity, and the nitrogen content of the best of the largest and of the smallest roots, branches, leaves, and flowers. These data are all tabulated.

In general the nitrogen content of the leaves and flowers was about 3 times as great as the nitrogen content of the roots and branches. The best plants in these experiments were obtained by the use of sulphate of ammonia in the proportion of 1 to 50; following this came the plants fertilized with sulphate of ammonia in the proportion of 1 to 200, and then those fertilized with liquid manure to which bone meal and sulphate of ammonia had been added.

The book of the daffodil, S. E. BOURNE (*London and New York: John Lane, 1903, pp. XII+112, pls. 18, figs. 4*).—Cultural directions are given for the daffodil or narcissus, with descriptions of a large number of different varieties and notes on how to form a collection, exhibit specimens, and judge them at shows. This is the sixteenth of the series of Handbooks of Practical Gardening edited by H. Roberts.

Spraying to kill pond scum, H. P. HEDRICK (*Gardening, 11 (1903), No. 259, p. 295; Amer. Florist, 20 (1903), No. 785, p. 750*).—The green matted growth of low water plants which is frequently found in fish ponds, lily ponds, and water gardens, and which is usually got rid of by raking off and carting away, was destroyed by the author by spraying with Bordeaux mixture. The mixture was first applied full strength about August 1; 24 hours afterwards the green scum had turned brown and in another day had sunk to the bottom of the pond and the water was perfectly clear. Water lilies were slightly injured by the spray, showing that the Bordeaux mixture was a little too strong.

When the Bordeaux mixture was applied about $\frac{3}{4}$ full strength the same result was obtained with the green scum, with no bad effects to the lilies. After the first spraying it was about a month before a second was required. Fish and frogs in the pond did not appear to be injured by the spraying, while it is believed that the breeding of mosquitoes was materially checked. The author recommends a spray composed of 4 lbs. of copper sulphate, 4 lbs. of unslaked lime, and 60 gal. of water.

FORESTRY.

Reforestation, H. H. CHAPMAN (*Minnesota Sta. Bul. 81, pp. 247, 248*).—In order to investigate the cost and practicability of restocking with pine land which is too hilly, rocky, or sandy for agricultural purposes, a number of acres were laid off at the Grand Rapids Substation and planted in 1900 to white and Norway pine. The trees had been grown 2 years in nursery rows and were a size too large for successful planting. The cost of planting depended upon the distance between the trees. When set at intervals of 4 ft. the cost was $11.20 per acre. At 6-ft. intervals the cost was $5.60, at 8-ft. intervals $3.14, and at 10-ft. intervals $2.50 per acre. Notwithstanding the prolonged drought of 1900 nearly 95 per cent of the trees have lived and are now reported to be making rapid growth. In all 12.5 acres were planted, each acre representing a different type of planting. Four acres were pure white-pine plantation, 4 of Norway pine, and other areas of mixed plantings of white, Norway, and jack pine. An acre was also planted to test the relative merits of Norway and Scotch pine for Minnesota conditions.

Practicability of forest planting in the United States, W. L. HALL (*U. S. Dept. Agr. Yearbook 1902, pp. 133–144, pls. 4*).—According to the author forest planting can not be considered practicable throughout the entire United States, but there are a number of regions in which it is feasible. The considerations which determine the practicability of planting are the present supply of useful timber, the necessity of forests to provide shelter, protect the soil or conserve moisture, the capacity of a forest to produce another crop, the value of the ground for purposes other than forest growth, protection against fire or other serious injuries, and the probabilities of a fair return upon the investment.

When these factors are considered the author believes that planting is at present impracticable throughout the greater portion of the hardwood region of the eastern United States and the spruce forests of the Northeast, as well as the heavily timbered portions along the Pacific coast. In the eastern States under present conditions planting is considered desirable as farm wood lots, upon impoverished farm lands, and on cut-over nonagricultural lands. An estimate of costs and returns per acre from land planted to white pine, based upon 60,000 measurements of white pine, shows an average annual return of $2.25 per acre during a 40-year rotation. This estimate for white pine is believed to be applicable to red pine and Norway spruce over the greater portion of New England. In the middle West planting is recommended for cut-over portions of the white-pine belt, and wood lots throughout the agricultural regions. In the western States it would be confined largely to mountain areas, for the protection of watersheds and other irrigation works.

Forest planting on the plains, E. P. SANDSTEN (*Forestry Quart., 1 (1903), No. 4, pp. 140–144*).—An account is given of some of the earlier experiments in forest planting in the Sand Hill region of Nebraska, begun under the supervision of the Division of Forestry of this Department in 1891. They were carried out in Holt County, Nebr., where a considerable area was planted with bull pine, Scotch pine, and Banks' pine, and a variety of deciduous species, such as black locust, birch, box elder, cherry, and red oak were also planted. The condition of the trees as shown after 12 years is stated. The larger trees of the Banks' pine are from 15 to 20 ft. high, the Scotch pine from 4 to 12 ft., and the bull pine from 3 to 8 ft. The grove at present is dense in growth and fully covers the otherwise almost worthless sand hills. It is said that on the success of this early planting was largely based the recent establishment of the forest reserve in western Nebraska, which is to be planted under the supervision of the Bureau of Forestry.

Foresting in Nebraska sand hills, C. A. SCOTT (*F[illegible] (1903), No. 9, pp. 454–457, figs. 5*).—Notes are given on the progress of the work of the

Bureau of Forestry in its attempt to forest the sand hills in the western part of Nebraska. The Bureau having decided to grow its own nursery stock, a description is given of the preliminary efforts made to provide the necessary grounds. These have been covered with slat shades, and a large quantity of red cedar, jack pine, etc., has been seeded in these beds.

The pine lands of the South, H. C. PUTNAM (*Forestry and Irrig., 9 (1903), No. 9, pp. 446–452*).—A description is given of some of the pine lands of the South, attention being called to the possibilities of scientific forestry in promoting forest production in the Southern Atlantic Coast States. The necessity for the protection of the present forests from fire, destructive lumbering, etc., is pointed out, and the possibilities of handling the forest so as to produce a continuous crop is shown.

Forest problems in New Hampshire, P. W. AYRES (*Forestry Quart., 1 (1903), No. 4, pp. 221–225*).—The leading problems in New Hampshire forests are said to be the reforesting of white-pine areas, and the maintenance of the spruce output. Recent statistics show that nearly 2,000,000 acres of land have reverted from improved farm land to an unimproved state, and much of this is adapted to the growth of white pine. The author suggests the planting of areas upon which no reforestation has taken place, thinning when necessary, reforesting the cut-over areas, and extending the forest area over all lands which are not adapted to agricultural crops.

The question of the management of the spruce forests is a complicated one, and the author believes that the establishment of permanent reserves, which are to be economically managed, would aid in showing the possibilities of scientific forestry.

The New York forest-fire law, C. R. PETTIS (*Forestry Quart., 1 (1903), No. 4, pp. 134–139*).—The text of the New York forest-fire law is given, and the author discusses the duties of the different officers who are made responsible for its enforcement.

The forests of Canada, H. S. CULVER (*Forestry and Irrig., 9 (1903), No. 6, pp. 288–292*).—A description is given of the present condition of the timber areas of Canada, the author dividing the region into 3 great timber belts—the northern or spruce belt, the southern or commercial belt, and the British Columbia belt, which is west of the Rocky Mountains. The principal species of trees in these different regions are described and notes given on their proportionate abundance and their forest relations.

Investigations on the introduction of exotic forest trees in Prussia and Austria, R. HICKEL (*Ann. Sci. Agron., 2. ser., 1 (1903), No. 1, pp. 142–160*).—An historical review is given of attempts which have been made to introduce exotic species of forest trees in the forests of Prussia and Austria. Lists are given of the different trees introduced, most of the species being American, the author dividing them into 3 groups based upon their adaptability. Among the species found adapted to European forest cultivation are *Pseudotsuga douglasi*, *Picea sitchensis*, *Chamæcyparis lawsoniana*, *Thuya gigantea*, *Juglans nigra*, *Carya alba*, *C. amara*, and *Quercus rubra*. A second group of species which are not adapted to as wide range of conditions but which are suited to cultivation in restricted regions includes *Pinus rigida*, *Juniperus virginiana*, *Abies nordmanniana*, *Pinus laricio*, *Acer saccharinum*, *Betula lenta*, *Carya tomentosa*, and *C. porcina*. The following species are not considered worth further investigation: *Pinus jeffreyi*, *P. ponderosa*, *Acer dasycarpum*, *A. californicum*, *Fraxinus pubescens*, and *Carya sulcata*. A table is given showing the extent to which these different species have been introduced in the state forests of Germany between 1890 and 1900, and a review is also given for the introduction of similar species in Austria. After reviewing the conditions in general the author takes up a number of species describing them and giving the results of the attempts made to cultivate them. The present publication is confined to species of fir and spruce.

The forest flora of New South Wales, J. H. MAIDEN (*Sydney: Govt., 1903,*

pt. 3, pp. 55-74, pls. 4).—Botanical descriptions and notes are given of a number of Australian timber trees, together with their distribution and their timber characteristics and uses. The species here described are the red cedar (*Cedrela australis*), red mahogany (*Eucalyptus resinifera*), and the she-beech (*Cryptocarya oborata*).

Forestry at Hongkong, M. WINCHESTER (*Forestry and Irrig., 9 (1903), No. 6, pp. 280-284, figs. 4*).—The author states that in 1842, when Hongkong was ceded to Great Britain, the surrounding country was practically barren of vegetation. In 1878 planting was begun, the most extensive work being the setting out of 5,000 cocoa palms. By 1880 it had become demonstrated that trees could be made to grow on the exposed slopes; and in 1881, instead of planting nursery plants as heretofore, an attempt was made to produce the Chinese white pine by planting the seeds in place. This proved successful and was accomplished at about one-fifth of the cost of the nursery plan. Since that time a number of varieties of trees have been planted, and, although the Chinese white pine is the most prominent species, a large number of others are well represented. The region about Hongkong has become reforested, and but little is now done by the forest department aside from broadcasting seed and occasional planting to fill up areas where trees have for some reason been destroyed. This experiment is believed to be a practical demonstration of the feasibility of tree planting about large cities on hilly and rocky soils.

Administration report of the forest department of the Bombay Presidency, W. A. TALBOT, T. B. FRY, and R. S. F. FAGAN (*Forest Dept., Bombay Presidency, India, Rpt. 1901-2, pp. 98 + LXXVIII*).—This is a combined report of the Northern, Central, and Southern Forest Circles of the Bombay Presidency, covering the forest year 1901-2. The reserve forest area described embraces 11,959 square miles, divided as follows: Northern Circle, 1,434 square miles; Central Circle, 6,251 square miles, and Southern Circle, 4,274 square miles. In addition to the above areas, 1,250 square miles are designated as protected forest area. The changes in the various tracts during the year are noted, slight additions being indicated. Detailed accounts are given of the surveys made during the period covered by the report, and statements regarding the working plans and systems of forest management. The amount and value of the different kinds of forest products are tabulated, with comparisons of the previous years. A brief report on the forests of Sind is added.

Progress report on the forest administration in Coorg, C. D. MCCARTHY (*Forest Dept., Coorg, India, Rpt. 1901-2, pp. 27*).—The classified forest area under reservation on the 30th of June, 1902, is said to be 404,590 acres. A detailed report is given of the management of the forest lands, the means adopted for the prevention of forest fires, and the regulations concerning grazing and the use of the forest products. The gross returns are given, showing a considerable increase over previous years.

The locust, W. L. HALL (*Forestry and Irrig., 9 (1903), No. 6, pp. 307-309, fig. 1*).—The range, habits, and methods for planting the yellow or black locust (*Robinia pseudacacia*) are described. This tree, originally indigenous to the mountains from Pennsylvania to Georgia, has become widely naturalized throughout the United States east of the Rocky Mountains, and has proved itself adapted to some of the valleys of the farther Western States. The rate of growth is rapid, particularly in rich soils where the annual increase is from 2 to 4 ft. in height and $\frac{1}{4}$ to $\frac{1}{2}$ in. in diameter. This rate of growth diminishes after about 30 years, and the trees become mature in about 50 years. At this time they average from 40 to 80 ft. in height, with a diameter of 2 to 3 ft.

The timber of the locust has been found adapted to use as fence posts, in construction, for telegraphic insulators, and in the manufacture of vehicles. Its most common use is for fence posts, for which purpose it has been extensively planted. A post 4 to 5 in. in diameter may be produced on good soil in from 7 to 8 years, and will last from 8 to 15 years.

The locust is easily propagated, either from root cuttings or seed, and the seed retains its vitality for a number of years if buried deep in the ground. The seed should be drilled in well pulverized rich soil early in the spring, and the subsequent method of management will be determined by the purpose for which the plantation is made. In most cases the trees should stand 4 by 4 or 6 by 6 ft. apart. While the locust grows well in pure plantations, the best success usually follows where it is mixed with some heavy foliage tree such as osage orange, hardy catalpa, white elm, etc. It is a good tree to plant in mixtures with black walnut, the 2 species standing in alternate rows. At the expiration of about 15 years the locust in this case should be cut out for fence posts, leaving the black walnut for the final stand.

The poplars, C. Durieux (*L'Ing. Agr. Gembloux, 13 (1903), No. 11, pp. 500–511*).—The author describes poplars as forest trees, giving extended notes on *Populus alba*, *P. tremula*, *P. nigra*, and *P. canadensis* or *P. monilifera*. The reproduction of these different species is described and suggestions given for their propagation in the nursery and in permanent plantations.

Some Eucalyptus hybrids in the Mediterranean region, J. Trabut (*Rev. Hort. [Paris], 75 (1903), No. 14, pp. 325–328, figs. 3*).—The author gives a description of several well characterized hybrids of Eucalyptus which have originated in the region about the Mediterranean Sea. Most of these are said to be more vigorous and much better adapted to their surroundings than the species from which they were descended.

Japanese bamboos and their introduction into America, D. G. Fairchild (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 43, pp. 36, pls. 8*).—This bulletin discusses the importance of the bamboo industry in Japan, Japanese methods of propagating bamboos and managing bamboo groves, profits in the business, localities in the United States where the industry is likely to succeed, and gives popular descriptions of a large number of different varities and species of bamboos.

The subject is discussed primarily from the standpoint of bamboo as a forest tree. Methods of growing the edible bamboo are also described and some recipes given for its preparation for the table. It is stated that some species of bamboo will stand a temperature of 6° F. It is believed that there are in California, Oregon, Texas, and throughout the Gulf and Southern States many locations suitable for the culture of bamboo.

Studies of trees in winter, C. K. Schneider (*Dendrologische Winterstudien. Jena: Gustav Fischer, 1903, pp. VI+290, figs. 224*).—An account is given of the winter aspect of more than 400 species of trees and shrubs which are native and introduced in Germany. Keys are given based upon the bud, leaf scar, and structural characters, by which the different species in their winter condition may be determined.

Chemical studies of some forest products of economic importance, W. H. Krug (*U. S. Dept. Agr. Yearbook 1901, pp. 321–332*).—Studies have been begun on various forest products, such as tanning materials, resins, gums, etc., and a report is given of some of the investigations thus far carried on regarding the composition of American woods and barks. The analyses given show the moisture, total cellulose, xylan, soluble contents, tannin, ash, etc., for a number of specimens of the western hemlock (*Tsuga heterophylla*), red oak (*Quercus rubra*), chestnut oak (*Q. prinus*), white oak (*Q. alba*), and black oak (*Q. velutina*). Notes are also given on studies of the anatomy and histo-chemistry of oaks and an account of investigations of turpentine adulteration.

Numerous complaints have been made of the unsatisfactory behavior of turpentine oils, and a number of samples of oils from different sources were subjected to examination. Several specimens were found to contain adulterants, the principal adulterating material being petroleum in some of its fractions. When the lower boiling fractions, such as gasoline, were used, the specific gravity of turpentine was lighter, and, to counteract this, resin was added.

Notes on the occurrence of mannan in the wood of certain trees and in various roots and fruits, F. H. STORER (*Bul. Bussey Inst., 3 (1903), III, pp. 47–68*).—In continuation of a previous article (E. S. R., 14, p. 21), the author gives the results of his investigations on the occurrence of mannan in the wood of various trees, roots, and fruits. In the earlier publication the conclusion was reached that mannan was probably more abundant in pine trees at certain seasons of the year than others. In investigating this subject specimens were collected monthly during a year from a young, thrifty white-pine tree and subjected to examination by methods which are fully described.

It was found that pines, and presumably other coniferous trees, contain late in summer and early in autumn a large reserve supply of mannan. The physiological relation of this substance is somewhat obscure, but it is thought that it probably serves as a reserve food for the formation of new leaves to take the place of those which fall at the end of the season, or it may serve for the nourishment and growth during the winter of those leaves which, with the advent of spring, cause the falling off of the older foliage. The presence or absence of mannan in the wood of 17 other species as well as in the leaves, fruit, and other portions of a number of plants is indicated.

Tests on the physical properties of timber, F. E. OLMSTED (*U. S. Dept. Agr. Yearbook 1902, pp. 533–538, pls. 2*).—An outline is given of the timber testing work carried on in Europe, and a brief review of the timber tests that have been conducted in the United States, particularly those made some years ago by this Department as well as the ones conducted by other institutions. It is the intention to continue timber testing observations, and they will be made on a large scale representing different conditions of the timber market and of timber cutting. The experiments will be conducted on such a scale that the results obtained will be comparable and valuable to the lumber industry.

Factors influencing the volume of solid wood in the cord, R. G. ZON (*Forestry Quart., 1 (1903), No. 4, pp. 126–133*).—With the rapid development of the pulp industry, the importance of the accurate determination of the contents of stacks of wood has been largely increased. A number of factors which influence the volume of solid wood in the measured cord are mentioned, and their varying effect is shown. The principal factors described are length and diameter of the sticks, their form, the species, method of piling, measuring, etc. Tables are given showing the volume of wood in stacks, the computations being made for different lengths, diameters, and classes of wood.

The influence of forestry upon the lumber industry, O. W. PRICE (*U. S. Dept. Agr. Yearbook 1902, pp. 309–312, pls. 3*).—The author states that the lumber industry ranks fourth among the manufacturing industries of the United States, representing an invested capital of \$611,000,000, an annual outlay of more than \$100,000,000 in wages, and an annual value of products of \$566,000,000. Under the present system of cutting this production can not be long sustained, and the author seeks to show how, under conservative methods of lumbering, the industry may be prolonged and placed upon a stable basis. One of the results under a scientific system of management would be the elimination of the large sawmills and the erection of small mills in various localities. It would also tend to develop a class of trained forest workers such as are found in Europe, and by providing a steady supply of lumber it would cause less fluctuation in the market prices.

The forest and irrigation, HEFELE (*Bul. Col. Agr. Imp. Univ. Tokyo, 5 (1903), No. 3, pp. 345–371*).—The importance of forest growth as a conserver of water is discussed.

A bibliography of forestry, O. WILLIAMS (*Forestry Quart., 1 (1903), No. 4, pp. 163–172*).—A list of titles of articles relating to forestry which were published in United States Congressional documents and printed in what is commonly designated as the "sheep set."

SEEDS—WEEDS.

Report on the introduction and distribution of seeds and plants by the bureau of agriculture, W. S. Lyon (*Philippine Bureau Agr., Farmers' Bul. 7, pp. 18, pls. 3*).—A report is given of the introduction and distribution of seeds and plants, most of which were field and forage crops and vegetable seeds. The origin of the different varieties of plants is given, many of them being introduced for testing their adaptability to Philippine conditions.

The seeds of rescue grass and chess, F. H. Hillman (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 25, pp. 5–8, figs. 3*).—This has been noted from advance sheets (E. S. R., 14, p. 875).

Report of the section of seed control for the year ended June 30, 1902, A. Voigt (*Bot. Staatsinst. Hamburg, Ber. Abt. Samenkontrolle, 1902, XI, pp. 10*).—In this report the author gives an account of the investigations carried on by the section of seed control which is attached to the botanical institute of Hamburg. During the year covered, 2,760 separate investigations were made, the most of which were of clovers and other forage plants. The results of the different tests are shown in tabular form, and in general a decided improvement is noted in the purity and germinative vitality of the different samples of seeds over the results obtained the previous year. Investigations on the presence of dodder in different forage plants showed about 34 per cent to contain dodder seed in greater or less abundance. Notes are given on the various samples of seed investigated, the author commenting upon their quality.

Report of the Agricultural-Botanical Experiment and Seed-Control Station at Breslau, 1903, W. Remer (*Ber. Tät. Agrbot. Vers. Samenkontrollstat., Breslau, 1903, pp. 16*).—A report is given of the seed investigations carried on under the auspices of the seed-control station of the Agricultural Society of Breslau for the year ended March 31, 1903, 3,957 samples of seed having been examined. The maximum, minimum, and average percentage of purity, germination, and intrinsic worth of the different varieties of seeds are shown in tabular form. There were examined during the year 2,390 samples of red clover, 388 white clover, 473 alsike, 187 timothy, 67 alfalfa, 68 serradella, and a lesser number of a great many other varieties of seed.

The report also shows the presence of dodder seed in different samples of forage plants, the seeds of this parasite being found in 36.4 per cent of the samples of red clover, 26.2 per cent of white clover, 31.1 per cent of alsike, 15 per cent of yellow clover, 26.4 per cent of serradella, and 25.6 per cent of timothy seed. Brief notes are also given on plant diseases and other botanical subjects. The occurrence of many diseases of cereals, beets, potatoes, and other plants is noted, and suggestions are given of possible means for their prevention.

Troublesome weeds, J. B. Davy (*Transvaal Agr. Jour., 1 (1903), No. 4, pp. 110–112*).—Notes on the burrweed (*Xanthium spinosum*) and sida (*Sida rhombifolia*), and suggestions for their eradication.

Wild mustard, J. R. Anderson (*Dept. Agr. British Columbia, Bul. 11, pp. 12, figs. 2*).—A description is given of the wild mustard (*Brassica sinapistrum*) which is widely spread through Canada and which is probably one of the worst weeds occurring in the grain fields of that region. The methods of distribution of this weed are noted and suggestions made for its eradication by spraying with copper sulphate or iron sulphate solutions.

Eradication of wild mustard, H. Hitier (*Jour. Agr. Prat., n. ser., 5 (1903), No. 21, pp. 658, 659*).—A review is given of 3 years' experience in spraying fields of cereals for the eradication of the wild mustard. The various methods described include spraying with a solution of 3½ to 4 per cent copper sulphate, 2 to 3 per cent copper nitrate, 20 per cent iron sulphate, and 20 per cent sodium nitrate added to a 2 per

cent solution of copper sulphate. All of these treatments are said to be efficient for the destruction of wild mustard, wild radish, and other troublesome weeds and but slightly injurious to the cereals. When sprayed over the fields the extremities of the leaves of the cereals are slightly affected, but so far no injury has been observed to young leguminous plants such as clover, alfalfa, sainfoin, etc., which are seeded with the cereals.

Destruction of wild mustard, J. VANDERVAEREN (*Jour. Agr. Prat., n. ser., 5 (1903), No. 23, pp. 731, 732*).—The author describes a method of combating wild mustard which has been quite generally practiced in Belgium and which has thus far given excellent results. It consists in the distribution of 200 kg. of dry powdered sulphate of iron per hectare. This gives results equal to those where the herbicide is dissolved and sprayed over the fields, and is said to be not only cheaper but not to necessitate the use of as high-priced machinery for its application. The cost of spraying varies from 20 to 30 francs per hectare, depending on the material used, while the powdered sulphate of iron can be applied at a price not to exceed 12 francs per hectare. The copperas should be fresh and finely powdered, the hygroscopic sulphate of iron not being as efficient.

Destruction of wild mustard, D. DONON (*Jour. Agr. Prat., n. ser., 6 (1903), No. 30, pp. 110, 111*).—The result of experiments with a $2\frac{1}{2}$ per cent solution of copper sulphate and a 10 per cent solution of nitrate of soda is given, comparisons being made with untreated plats and those which had been sprayed with a 5 per cent solution of copper sulphate. The reduction of the amount of copper sulphate and addition of the nitrate of soda was equally as efficient in the eradication of mustard and was without injurious effect upon the crop. Indeed, the addition of the nitrate of soda is believed to have had a beneficial effect when applied to oats. The nitrate of soda alone is not as efficient as copper sulphate, but when the two were combined the results obtained were highly satisfactory. The application of this herbicide twice during the season, at the rate of 400 liters per hectare, practically destroyed all the wild mustard.

DISEASES OF PLANTS.

Twelfth annual report of the special committee for plant protection, 1902, P. SORAUER and M. HOLLRUNG (*Arb. Deut. Landw. Gesell., 1903, No. 82, pp. XXVIII + 214*).—This report gives the results of observations of a large number of vegetable pathologists and others upon the plant diseases occurring in Germany during 1902. After giving a review of the weather conditions for the year, the fungus and insect enemies of the different plants are noted, their distribution and amount of injury indicated, and where means have been adopted for combating them the results are given. The diseases are grouped under the principal headings of plant and animal enemies of cereals, beets, potatoes, leguminous plants, oil, vegetable and forage plants, fruit-producing plants, and grapes. A supplement is added in which is given a summary of the results of various preventive treatments, and the report concludes with a discussion on the predisposition of some plants to parasitic diseases.

Some diseases of cultivated plants, F. CORBOZ (*Bul. Soc. Vaud. Agr. et Vit., Lausanne, 1903, Nos. 162, pp. 323–329; 163, pp. 351–355*).—An account is given of various diseases of plants, grouping them under their respective causes. The author discusses those which are due to impoverishments in the physiological functions of the plant, those which are caused by meteorological conditions, temperature, electricity, etc., and those due to plant parasites. Among the plant parasites he describes not only the diseases caused by parasitic fungi, but parasites belonging to the higher orders of plants.

Disease-resisting varieties of plants, L. LEWTON-BRAIN (*West Indian Bul., 4 (1903), No. 1, pp. 48–5[illegible]*).—The author discusses the topic of disease-resistant varie-

ties of plants, describing what has been done in different parts of the world to obtain resistant varieties of grapes, wheat, cotton, coffee, potatoes, cowpeas, sugar cane, and violets.

Frost injuries to cereals in relation to fungus diseases, P. SORAUER (*Landw. Jahrb., 32 (1903), No. 1, pp. 1–68, pls. 4, fig. 1*).—On account of the unusual occurrence of fungus diseases of cereals during a season following a number of severe late frosts, a series of experiments was undertaken to ascertain the effect of frost and its relation to fungus diseases of cereals. The mechanical effect and physiological changes caused by freezing are described at considerable length.

Inoculation experiments with quite a number of parasitic fungi upon frost-injured plants and the effect of different times and conditions of seeding are reported upon. The author found certain injuries that could be attributed only to frost injury, but which resembled in their characteristics certain fungus diseases. Such, for instance, is the state of cereals known as blast, white heads, etc. Serious injury due to frost may be observed that in its earliest stages does not present any fungus mycelium, but later parasites may attack the plants. There are some fungi now believed to be obligate parasites which occur on sound healthy plants as well as upon those whose organs have become weakened from any cause whatever. The presence of some of the less active parasitic forms may be due to frost or other injuries in offering opportunity of entering the tissues of the host.

Care in sowing sound seed, although desirable and tending to reduce the amount of disease, will not wholly eliminate diseases in every case. Some wild grasses are hosts for some of the more destructive fungi of cereals, and their presence on these grasses may serve as a center to spread the infection. Plants weakened from any cause whatever are more subject to serious injury than healthy ones.

Preliminary observations on disease of cereals in Tunis, F. BŒUF (*Bul. Dir. Agr. et Com. [Tunis], 8 (1903), No. 27, pp. 185–193, figs. 5*).—The author describes a number of diseases which have appeared on wheat, barley, and oats in Tunis, and gives the results of determinations of the fungi which have been made at the Colonial School of Agriculture. The fungi present were *Erysiphe graminis, Puccinia rubigovera, P. graminis, Septoria tritici, Sphæroderma damnosum,* and *Cladosporium herbarum.* The principal injury seems to be caused by the Sphæroderma, and its appearance on the different plants is fully described. The development of the diseases, the influence of soil humidity and temperature, etc., are pointed out.

On the specialization of Erysiphe graminis, E. MARCHAL (*L'Ing. Agr. Gembloux, 13 (1903), No. 10, pp. 457, 458*).—In continuation of the previous paper on this subject (E. S. R., 14, p. 667), the author reports that as a result of further inoculation experiments he is convinced that there are definite forms of this mildew which are specialized upon certain cereal host plants.

Experiments for smut prevention, D. N. PRYANISHNIKOV (*Khozyain, 1902, No. 20, pp. 647–652; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 1, p. 112*).—The results are summarized as follows: Soaking during 12 hours in 0.5 per cent solution, or 6 hours in 1 per cent solution of copper sulphate, completely destroyed the smut. Soaking for 5 or 10 minutes in 0.125 per cent solution of formalin is insufficient; greater concentration should be tried (according to David an hour's soaking is required in 0.125 per cent solution). Formalin vapors applied in sufficient quantity destroy the smut, but when applied to large quantities of grain it is difficult to cause the vapors to thoroughly permeate the interior of the mass.

As to the influence of the different kinds of soaking on the germination of wheat, the experiments showed that 0.5 per cent solutions of copper sulphate is endured without great harm (after 12 hours soaking 91 per cent of the seeds germinate), while solutions exceeding 0.5 per cent are not suitable for protracted soaking. (1 per cent solution lowered the germination to 66 per cent.)—P. FIREMAN.

Combating oat smut, H. ROMMETIN (*Jour. Agr. Prat., n. ser., 6 (1903), No. 31,*

p. 145).—The results of the author's investigations on the prevention of oat smut by treatment of the seed with hot water are given. He has followed this method for a number of years, and is convinced that with ordinary care it is possible by treating the seed with water heated to 54° C. and sowing on clean soil to produce a crop which may be used for seed the subsequent year without treating. This may be continued for a third year if attention be paid to the thrashing machines and other implements so that the fungus spores may not be carried to the new crop.

Investigations in cereal rusts, E. MARCHAL (*L'Ing. Agr. Gembloux, 13* (*1903*), *No. 11, pp. 473–500*).—This is a résumé of an article by the same author, previously noted (E. S. R., 14, p. 1083).

Concerning the seed treatment of cereals with copper sulphate, F. PORCHET (*Chron. Agr. Canton Vaud, 16* (*1903*), *No. 12, pp. 352–357, fig. 1*).—On account of the rather common use of copper sulphate in solution for the prevention of cereal smuts, the author has made a study of the protective effect of the glumes of certain cereals, such as oats and barley. He conducted his experiments with equal numbers of seeds with and without the protective glumes, comparing the effect of treatment with wheat which was without the glumes. The seeds were soaked for 24 hours in a 0.5 per cent solution, after which they were placed to germinate.

The effect of the treatment where the glumes were removed was apparent in the greatly reduced germinations of oats, the number falling from 91 to 53 in 28 days. Not only was the number greatly reduced, but the copper sulphate seemed to effect a retarding influence, a comparatively small number of seeds having germinated within the first week of the experiment. The germinations of oats from which the glumes had been removed, and wheat which was without any protective covering, showed but little difference when soaked in the solutions for the same length of time.

The browning of maize in France, V. DUCOMET (*Jour. Agr. Prat., n. ser., 5* (*1903*), *No. 16, pp. 507–511, figs. 4*).—A description is given of a disease of maize which has proved very destructive in the southwest of France, where this crop is extensively grown for green forage. The disease is characterized by the drying up of the leaves, and at first is quite localized, but spreads after a time, and in about 15 days the entire field may become completely browned and dried up. On account of the peculiar browning or burnt condition of the leaves the author has suggested the name "brûlure" for the disease.

The disease makes its appearance upon the leaves when the plants are from 20 to 30 in. in height as small discolored spots which rapidly increase until they attain a diameter of 2 cm. and a length of 6 or 7 cm. The spots are for a while limited by the veins in the leaves, the long diameter of the spot being parallel with the veins. Frequently the tips of the leaves are involved, and finally by the confluence of a number of spots the entire leaf is destroyed. About 15 days after the appearance of the first symptoms of the disease the spots occur in great abundance on both sides of the leaves, and from their centers appear numerous dirty, gray, cushion-like masses which are the reproductive organs of the fungus.

The life history of the fungus, which has been determined as *Helminthosporium turcicum*, is described at considerable length. In order to prevent the spread of this disease the author recommends the destruction of affected plants as soon as observed, and instead of sowing the grain closely to plant it at sufficient intervals to secure a better aeration of the plants.

A new disease of white sweet clover, R. LAUBERT (*Arb. K. Gesundheitsamte, Biol. Abt., 3* (*1903*), *No. 4, pp. 441–443, figs. 5*).—A description is given of *Ascochyta caulicola*, n. sp., a fungus which causes considerable injury to the leaves and stems of *Melilotus alba*.

A rosette disease of potatoes, A. D. SELBY (*Ohio Sta. Bul. 139, pp. 53–66, figs. 5*).—The author describes a disease of potatoes which is attributed to the sterile fungus Rhizoctonia. This fungus causes lesions on the stems below or near the surface

of the ground and results later in a peculiar branching or clustering of the leaves. This clustering, which is possibly secondary, is so conspicuous that it affords a sufficient means for the detection of a large percentage of the affected plants.

The disease has been under observation since 1900, and from the results obtained is apparently disseminated with the seed tubers. Attention was first called to it by the widespread occurrence through seed tubers that had been sent out from the station. Subsequent investigations seemed to prove that it spread from the station as a center, and methods of prevention were investigated. Tubers were treated with a solution of formalin before planting, and in 1902 there was practically no evidence of the rosette disease in the leaves of growing plants in the rows treated with formalin. Where the seed tubers had been given a treatment with corrosive sublimate previous to planting, there was no indication of immunity from disease. This method of treatment has been continued, and based upon 2 seasons' work the conclusion is drawn that formalin treatment will prevent Rhizoctonia disease to a very marked extent.

The author calls attention to the extreme diversity in injury among several varieties of potatoes grown at the station, and states that an average of from 6 to 20 per cent loss was due to this disease. For the practical prevention of the rosette disease, soaking the seed tubers for 2 hours in a solution of formalin composed of 0.5 pt. formalin to 15 gal. water is recommended. The bulletin concludes with citations to literature regarding Rhizoctonia diseases.

Remedies for the root disease of sugar cane (*Agr. News [Barbados], 2 (1903), No. 29, p. 162*).—The writer suggests preventive measures for combating the root disease of cane. The means suggested consist of selection of resistant varieties, planting healthy canes, careful cultivation and thorough drainage, rotation of crops, and the removal of diseased plants when discovered to prevent the fungus spreading to healthy ones. The diseased areas may be isolated by digging trenches a foot to 18 in. deep about the diseased plants, care being taken that the infested soil should not be thrown toward the healthy plants. In no case should the diseased canes be allowed to rattoon. The root disease, which is due to Marasmius, is said to have caused considerable loss to the planters of the West Indies during the past season.

Pests of garden vegetables, M. C. COOKE (*Jour. Roy. Hort. Soc. [London], 27 (1903), No. 4, pp. 801–831, pls. 3, fig. 1*).—Descriptions are given of a large number of the more common fungus diseases which attack garden vegetables, and, so far as known, methods are suggested for the prevention of their attack.

A new disease of beans, A. MAIGE (*Bul. Agr. Algérie et Tunisie, 9 (1903), No. 14, p. 334*).—A brief description is given of a disease of green beans which has proved very destructive in gardens during the past season. This disease is characterized by a development on the leaves of greenish-yellow spots which, extending little by little, finally involve the entire leaf. The fungus causing this disease has not been definitely determined, but reasoning from analogy of other diseases the author believes that this disease could be held in check by the use of standard fungicides.

The parasitism and development of Sclerotium cepivorum on onions, P. VOGLINO (*Staz. Sper. Agr. Ital., 36 (1903), No. 2, pp. 89–106, pls. 2, fig. 1*).—A study was made of the cause of the almost total loss of the onion crop in parts of Italy, and the results of investigations are given. The disease has been under observation since 1897, the last serious outbreak occurring in 1901 followed by a rare occurrence in 1902. The cause of the disease is attributed to *Sclerotium cepivorum*, which develops a conidial form, that has formerly been recognized as *Sphacelia allii*, upon the dead leaves and bulbs. The biology of the fungus is described and its parasitism affirmed. During hot weather the fungus develops with great rapidity in moist rich soils, particularly in those containing a large amount of humus. The only suggested means for preventing this disease is the abandonment of onion culture in infected soils.

Notes on a disease of black salsify, R. ADERHOLD (*Arb. K. Gesundheitsamte, Biol. Abt., 3 (1903), No. 4, pp. 439, 440, fig. 1*).—The author describes a disease of black

salsify which is due to the fungus *Sporidesmium scorzoneræ*, n. sp. This fungus attacks the leaves and stems of the black salsify, causing considerable injury. It is believed that it could be controlled by spraying the plants with Bordeaux mixture after its first appearance is noted.

The bitter rot of apples, H. VON SCHRENK and P. SPAULDING (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 44, pp. 54, pls. 9, figs. 9*).—A description is given of the bitter rot of apples, which is believed to have caused very serious losses to the apple crop of the United States, the loss in 1900 being estimated at $10,000,000. An account of the history, distribution, and a general description of the bitter-rot fungus is given. The fungus, the complete stage of which is known as *Glomerella rufomaculans*, is described and the relation of the cankers, which were discovered by an agent of the Department, to this disease is fully discussed. These cankers seem to be the centers from which the disease spreads in cone-like areas through the trees, and by inoculation experiments the authors have demonstrated that the conidial spores of the canker would produce the bitter rot on the apples, and cultures from diseased apples would produce the cankers on the tree branches. This fully demonstrates the relation between the cankers of the trees and the disease of the fruits.

The fungus is said to attack ripening apples during July and August, and is most virulent during moist hot summers. It is widely distributed over the eastern United States, being most active from Virginia to Oklahoma and southward. For the prevention of the disease the authors recommend the cutting out of the canker-like areas whenever discovered, and as a further precaution frequent spraying with Bordeaux mixture until the fruits are nearly ripe.

On the infection of apple trees with Fusicladium from species of Cratægus and Sorbus, R. ADERHOLD (*Arb. K. Gesundheitsamte, Biol. Abt., 3 (1903), No. 4, pp. 436–439, figs. 2*).—As a result of an extended investigation the author seems to be inclined to the belief that it is possible to reciprocally inoculate certain of these organisms from one host to another.

A cherry tree disease: its cause and prevention, R. ADERHOLD (*Arb. K. Gesundheitsamte, Biol. Abt., 3 (1903), No. 4, pp. 309–363, pls. 3, figs. 7*).—Since 1898 there has been noticed on the cherry trees along the Rhine River a very destructive disease that has been referred to various causes, but is now definitely determined as due to the fungus *Valsa leucostoma*. The fungus attacks the larger branches and main stems of the trees, gaining access, in part at least, through the injuries caused by late freezes. From these centers the fungus develops, causing a one-sided growth of the twig and presenting a cancer-like appearance accompanied by a copious flow of gum. By the subsequent growth and spread of the fungus the branch or stem becomes girdled, resulting in its destruction. The author discusses the history of the disease, the fungus and its parasitism, which has been definitely established by numerous inoculation experiments, and the relation of frosts to the disease, and suggests methods of control. The methods recommended include cutting and burning the dead and dying trees, cutting out infected areas where the attack is slight, and stimulating the tree growth in various ways.

The sooty mold of the olive, E. ZACHAREWICZ (*Rev. Vit., 20 (1903), No. 505, pp. 209–215; Bul. Agr. Algérie et Tunisie, 9 (1903), No. 8, pp. 179–186*).—A description is given of the sooty mold of olives which is due to the presence of the fungus *Fumago salicina* which develops over the various parts of the tree following the presence of the olive scale (*Lecanium oleæ*). In addition to the sooty mold the olive is frequently attacked at the same time by the fungus *Cycloconium oleaginum*. This fungus develops on both surfaces of the leaves, on the pedicels bearing the fruits, but rarely on the fruits themselves. To combat these diseases the author recommends the application of a combined insecticide and fungicide which is composed of soap 1 kg., petroleum 4 liters, copper sulphate 1 kg., and water 100 liters. Directions are given for the preparation of this mixture and suggestions for its application. Ordina-

rily 2 applications should be given the trees, the first about April 15 and the second about May 20. One hundred liters of this solution should not cost more than about 50 cts. and this would be enough to treat from 10 to 20 trees, depending upon their development.

Notes are given on a number of olive insects, with suggestions for their eradication and formulas for fertilizers which are recommended for use in connection with olive culture.

Cacao canker and its eradication (*Trop. Agr., 23* (*1903*), *No. 1, p. 31*).—Attention is called to the cacao canker in Ceylon and recommendations made for its eradication. The canker is said to have increased, and for its further eradication the author suggests that some legislation should be provided to protect private property from injury through the neglect of those who do not attempt to combat the disease. The disease may be prevented to a considerable extent by pruning and thinning out the shade so as to secure a better circulation of air through the trees, and by cutting out and burning all the dead trees and branches together with all the diseased areas shown on otherwise healthy trees. By concerted action of this kind it is believed that the disease can be almost entirely eradicated.

Black rot and its treatment, A. PRUNET (*Rev. Vit., 19* (*1903*), *No. 494, pp. 641–645; 20* (*1903*), *No. 498, pp. 14–19*).—A résumé is given of the author's investigations on the development and treatment of the black rot, the number, duration, and interval of the different invasions of the fungus being shown and the period of incubation being described. For the prevention of the disease the author recommends thorough spraying with Bordeaux mixture.

Treatment of black rot of grapes, A. PRUNET (*Rev. Vit., 20* (*1903*), *No. 499, pp. 39–42*).—According to the author, fungicides containing an equal amount of copper in solution have equal efficiency without reference to their acid or neutral reaction. When the cost of application is to be considered Bordeaux mixture, composed of 2 kg. of copper sulphate to 1 kg. of lime in a hectoliter of water is recommended. In spraying, all portions of the vines and leaves should be well covered with the fungicide and repeated applications should be made as conditions require.

This application, while it has some effect on the powdery mildew, does not entirely prevent it, and it is recommended that a special application of sulphur should be given during July as supplemental to the other treatments.

Black rot and grape mildew, J. CAPUS (*Rev. Vit., 20* (*1903*), *No. 500, pp. 70–74*).—An account is given of observations on the occurrence and treatment of black rot and downy mildew of grapes during 1902. The dates are given upon which the different diseases appeared, there having been 5 distinct attacks of each fungus. The period elapsing between the successive appearances of the 2 fungi was approximately the same, the exact period varying according to the atmospheric or other conditions. Suggestions are given for combating these diseases, spraying with Bordeaux mixture being recommended for both the black rot and the Plasmopara.

Notes on grape mildew, L. RAVAZ (*Prog. Agr. et Vit.* (*Éd. L'Est*), *24* (*1903*), *Nos. 21, pp. 629, 630; 22, pp. 658–660, pls. 2*).—Notes are given on the appearance of the downy mildew (*Plasmopara viticola*) and its effect upon the grapevine. The first attack of mildew is said to be rather insignificant, followed by more destructive attacks. The subsequent occurrence of the fungus may be controlled to a large extent by the thorough application of copper fungicides.

Grape mildew, J. DUFOUR (*Chron. Agr. Canton Vaud, 16* (*1903*), *Nos. 9, pp. 234–247; 10, pp. 274–280*).—A description is given of the mildew of grape due to *Plasmopara viticola*, and an account of the very destructive outbreak of this disease during 1902. Brief reports are given from a large number of grape growers on the occurrence and characteristics of the disease and upon the various means adopted to prevent the spread of the fungus. The different fungicides used are described and their formulas and directions for application given.

Grape mildew, J. Dufour (*Chron. Agr. Canton Vaud, 16 (1903), No. 17, p. 485*).—The author notes an unusual prevalence of grape mildew in many localities, and states that various treatments which have been recommended have given very unequal results. In order to study the question more fully a circular has been widely distributed from the experiment station at Lausanne asking for reports on the results of different methods of treatment. It is hoped from the data thus collected that some positive recommendation can be made for combating this disease.

Treatment of gray rot, E. Combemale (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 31, pp. 138–140*).—The author claims to have successfully used against *Botrytis cinerea* a mixture of triturated sulphur 50 kg., powdered quicklime 25 kg., and sulpho-steatite 25 kg. By the use of this mixture a considerable saving is effected over the ordinary use of triturated sulphur. The author uses this powder alone or as supplementing treatments of Bordeau mixture, in which case he has given 2 or 3 applications of the powder to 3 or 4 of the Bordeau mixture.

Treatment of gray rot of grapes, E. Zacharewicz (*Prog. Agr. et Vit. (Éd. L'Est), 24, (1903), No. 32, pp. 167, 168.*)—A description is given of a method of treatment of grapes for the prevention of attacks of *Botrytis cinerea* which has been successfully used by the author for a number of years. This consists of thorough application immediately after the first evidence of the disease of a powdered fungicide which consists of a mixture of gypsum 55 kg., powdered soap 5 kg., and sulpho-steatite containing 20 per cent copper sulphate 40 kg.

Combating grape chlorosis, G. Mottareale (*Bol. R. Scuola Superiore Agr. Portici, 2. ser., 1902, No. 6, pp. 3*).—An account is given of grape chlorosis, which is particularly destructive to the American stock used in Europe as a means of preventing phylloxera. The author summarizes the resistance of different stocks to chlorosis, and for the prevention of the disease he suggests treatment early in the spring by washing the vines with a 10 to 15 per cent solution of iron sulphate, by spraying the vines later in the season with a 0.5 to 1 per cent solution of iron sulphate, or by a third method, which is considered perhaps the most efficient, washing the vines after the fall of the leaves in autumn with a strong solution of iron sulphate to which is added 40 per cent sulphuric acid. If the treatment is neglected until later in the season it may be given the vines in January or a little later, but in this case the amount of sulphuric acid should be reduced to not more than 25 per cent.

The effect of sulphuric acid in retarding the growth of vines, J. D. Catta (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 12, pp. 356–358*).—Attention is called to the use of weak solutions of sulphuric acid as a winter wash for grape vines to prevent attacks of anthracnose. This has been recommended for a number of years, and dilute sulphuric acid, without the addition of iron sulphate, is extensively used in Algeria. It is shown that it exercises an important effect in retarding the early development of buds on the vines, and thus protects them from late spring frosts. The author has used solutions of sulphuric acid containing from 10 to 12 per cent of the acid upon grapevines, with the result that they were retarded in their development about 15 days. Where a weaker solution was used the vegetation was arrested 7 or 8 days.

A disease of clematis, F. Morel (*Rev. Hort. [Paris], 75 (1903), No. 15, pp. 364, 365*).—A description is given of a disease of clematis which has been variously attributed to improper cultivation, nematodes, fungi, etc. The author is convinced that it is of bacterial origin. The first indication of the presence of the disease may be noticed in the small openings which form in the stems, and these seem to spread with the increased humidity and temperature. Later a ring a few millimeters across is formed about the stem, when the plant dies beyond this infested region, while below it it does not seem to be injured. On account of the definite formation of these zones about the stem near the ground, the author does not believe that the disease is due to the nematodes, but that it is caused by bacteria which find entrance into

the stem. So far as the author's observations go, there does not appear to be any successful method of combating this disease.

A disease of tulips, caused by Botrytis parasitica, J. RITZEMA BOS and G. STAES (*Tijdschr. Plantenziekten, 8 (1902), pp. 177–202*).—The author describes the characteristics of a serious disease that causes annually a loss of from 5 to 30 per cent of the bulbs in some of the bulb-growing districts.

Tulips are most liable to be attacked by this disease, but hyacinths and Spanish iris also suffer. The disease does the greatest damage by attacking and destroying the flower bud before it has pushed through the ground; afterwards the decay extends to the entire old bulb and sometimes involves the new young bulb. The fungus also attacks the flower stalk and leaf, causing spots on the leaf and causing the blossom to fall over. The infection is spread by the cultivation of the ground, and also by the sclerotia being blown from one field to another with the sand during dry weather. Besides this soil infection there is an infection through the air by means of conidia. These give rise to the leaf spotting and to the diseased condition of the flower stalk resulting in its fall.

A number of methods for combating this disease were tried, but none proved both effective and practical except the use of creolin and carbolineum, and the latter being the cheaper was used for the field tests. The application of 50 liters of carbolineum per "are" (100 sq. meters) in the late summer destroyed all plant life. Bulbs could not be planted and even the following summer no weeds grew. The following autumn, however, tulip bulbs were planted, and of these not more than 2 per cent became diseased, and in some cases the disease was entirely absent, while in adjacent check beds 8 to 15 per cent of the bulbs was diseased. A more uniform distribution of the carbolineum was secured by mixing it with sand before applying.

Further tests are being made to determine the most efficient and economical methods of application of the carbolineum.—H. M. PIETERS.

Powdered fungicides, J. DUFOUR (*Chron. Agr. Canton Vaud, 16 (1903), No. 13, pp. 388–390*).—On account of the widely recommended use of fungicides in powdered form, the author has made a study of the different fungicides recommended, and he divides them into 2 classes—those composed of sulphur and sulphate of copper, and those composed of powdered sulphate of copper and some base, such as talc or steatite. Each of these forms has its advocates, and their relative efficiency is not commented upon. The formulas for the preparation of a number of the more common powdered fungicides are given.

Notes on the powdered sulphate of copper, J. DE GIRARD (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 26, pp. 773, 774*).—Attention is called to the recent recommendations of the use of powdered copper sulphate in combating the downy mildew of grapes and of its combination with sulphur against the powdery mildew. The author claims that powdered fungicides are less efficient than liquid ones, are more liable to injure foliage through their acidity, and are less adhesive and more troublesome to apply. To avoid the corrosive effect of the copper sulphate, talc is frequently used, the mixture being called copper steatite or sulpho-steatite. When pure magnesium silicate is used, the mixture will be found to contain a fairly constant amount of copper sulphate, but as much of the talc contains calcium carbonate the copper undergoes a change by oxidization and instead of 10 per cent copper sulphate, as claimed in some samples tested, the actual amount found to be present as sulphate was 0.78 per cent and the reaction was but very slightly acid. On the other hand, a sample said to contain 8 per cent copper sulphate when examined showed 5 per cent free sulphate and was very acid. This difference is said to account for the widely divergent results frequently obtained where these fungicides are used.

Sulphur and copper fungicides, J. M. GUILLON (*Rev. Vit., 19 (1903), Nos. 494, pp. 651–655; 495, pp. 681–684; 496, pp. 704, 705; 20 (1903), No. 498, pp. 9–14, figs. 5*).—Studies are reported upon the physical and chemical characteristics of a number of

fungicides which are grouped by the author into 4 classes—sulphur fungicides, liquid copper fungicides, powdered copper and sulphur, and liquid copper and sulphur mixtures. In all of these the fineness of the particles and thoroughness of application have a most important bearing upon their efficiency. In the case of the different forms of sulphur used the precipitated sulphur is preferred to the sublimed or triturated form, on account of its much greater fineness. Attention is called to some of the changes which take place in liquid fungicides when made up and allowed to stand for a considerable time. It is said to be sometimes necessary to apply a dressing of powdered sulphur between the sprayings with liquid fungicides to ward off severe attacks of the powdery mildew.

Some of the newer fungicides, B. D. Halsted and J. A. Kelsey (*New Jersey Stas. Bul. 167, pp. 15, pls. 2*).—The authors review different formulas for the preparation of Bordeaux mixture and give particular attention to the preparation and use of soda-Bordeaux. The use of this fungicide has been described in previous reports of the station, and in the present bulletin the authors recommend the following formula for its preparation: Soda (Lewis's Lye) 1 "pound" can, copper sulphate 3 lbs., lime 5 oz., and water 30 gal. This preparation has been successfully used not only in New Jersey, but elsewhere, and has the advantage of being equally as efficient as Bordeaux mixture made by the usual formula, but without the objectionable mechanical features of the ordinary Bordeaux mixture.

Attention is called to the use of formalin as a fungicide for disinfecting seed grain and for the prevention of potato scab, and notes are given on kerosene emulsion as a fungicide. A preliminary report on the use of kerosene emulsion in this way was given in the report of the station (E. S. R., 15, p. 579). These investigations have been continued, and it has been found that for the prevention of mildew on ornamental shrubs it is a very efficient treatment.

ENTOMOLOGY.

The elements of insect anatomy, J. H. Comstock and V. L. Kellogg (*Ithaca: Comstock Pub. Co., 1902, 4. ed. rev., pp. 145, figs. 11*).—In this volume the authors have outlined a course of study in the gross and microscopic anatomy of insects. The following topics discussed in the volume may be especially mentioned—external anatomy of locusts, internal anatomy of *Corydalis cornuta*, anatomy of the larvæ of the crane flies, external anatomy of beetles, mouth parts of insects, venation of the wings, and methods of insect histology.

Notes on economic entomology, F. V. Theobald (*Jour. Southeast. Agr. Col., Wye, 1903, No. 12, pp. 50–85, pls. 2*).—The author discusses the subject of injurious flea-beetles and their eradication. Notes are given on the damage caused by these insects, the method of invasion of beetles, and the effects of weather upon them. The more important genera of flea-beetles are briefly characterized and detailed notes are given on a number of specially injurious species, including *Haltica oleracea, Phyllotreta nemorum, P. undulata, P. crucifera, P. consobrina, P. atra, Crepidodera rufipes, C. aurata*, etc. The habits, life history, and means of combating sheep botfly are briefly discussed. The author recommends that tar should be smeared over the receptacles in which salt is kept, so that the sheep will come in contact with the tar in securing the salt. The tar serves as a deterrent to the sheep botfly. The author describes in considerable detail the life history of *Pemphigus spirothecæ*, which is reported as injurious to poplars. An article on the migration of the hop aphis, written by Plomley in 1849, is reproduced.

Injurious insects, E. Fleutiaux (*Agr. Prat. Pays Chauds, 3 (1903), No. 12, pp. 745–760*).—Notes on a weevil (*Sphenophorus sordidus*) injurious to the trunks of bananas; an enemy of beeswax (*Achroia grisella*); a species of grasshopper injurious to coffee; bean weevils; beetles injurious to mulberries, coffee, and other trees.

Royal Station of Agricultural Entomology of Florence, G. DEL GUERCIO (*Nuove Relaz. R. Staz. Ent. Agr., 1 ser., 1903, No. 6, pp. XXXVI+354, pls. 9, figs. 85*).—In this number of the report of the Royal Entomological Station the author presents a series of articles dealing with various injurious insects. A number of these articles may be briefly mentioned in this connection.

Notes are given on the gnats of the olive, with particular reference to *Clinodiplosis oleisuga*. The anatomy of these insects is described, together with an account of the development of various species. For combating these insects the author recommends that the infested bark be scraped off and burned. Some of the more important species of scale insects affecting the olive are discussed, including biological, descriptive, and economic notes on species of Pollinia, Philippia, and Lecanium. The conditions which are favorable or unfavorable to the distribution of these insects are described, together with insecticide experiments from 1896 to 1901. Good results were obtained by the use of a spray containing soap, oil of tar, and water. The cost and effectiveness of the insecticide methods are discussed by C. Campbell and G. Patriarca. Notes are given on the Diaspini of the olive, including a brief discussion of the anatomy and developmental stages of various species of Howardia, Leucaspis, etc. A description is given of peculiar alterations in the branches of pears and of a leaf miner in the branches of olives attacked with knot (pp. 116–125). A lepidopterous larva was found in knots caused by *Bacillus oleæ*, and another species of moth was found to cause peculiar wart-like enlargements on the branches of pear trees. A peculiar alteration of the branches of olives due to a species of thrips is noted.

Experiments were made to determine the action of calcium oxid on the larvæ and eggs of the cabbage butterfly. It was found that calcium oxid did not injure the larvæ of cabbage butterfly if they had been previously moistened with water. Small larvæ were quickly destroyed as a result of the process of dehydration when subjected to the action of this chemical. Oxid of lime was much less effective upon the eggs than upon the larvæ.

Notes are presented on a diseased condition of the grapevine and hazelnut and on experiments in combating it. The hazelnut is attacked by nematode worms, species of fungi, and mites. The buds, leaves, and flowers are subject to the attack of lepidoptera and various other insects. In destroying nematodes, mites, and insects upon the roots of the hazelnut, good results were obtained in the use of carbon bisulphid, alone or combined with a treatment with soluble wood tar. Arsenical poisons are recommended for the destruction of leaf-eating insects upon the hazelnut and grapevine. The anatomical details of the males of *Ceroplastes sinensis* are described.

Experiments were made to determine a method of protecting pear and apple trees against the attacks of apple maggot, scale insects, and lichens. The purpose of these experiments was to find a spray which would prove effective against all these enemies at once. The best results were had with the use of a mixture containing heavy oil of tar, soda, and water.

Brief notes are also given on a gall on rose stems, caused by an undetermined beetle; the protection of plantations of poplar and willow against the attacks of *Cossus cossus*, and *C. ligniperda;* on the common rose aphis *Siphonophera rosæ;* the destruction of grasshoppers in Argentina; galls on *Solanum sodomæum;* Thysonoptera injurious to grain fields in Italy; black peach aphis and experiments in combating it; various known and new species of plant lice imported into Italy; anatomical notes on Italian species of Phylloxera, and a general account of insects injurious to cereals in growing and stored condition.

The first annual report of the State nursery inspector, H. T. FERNALD (*Massachusetts State Bd. Agr. Rpt. 1902, pp. 287–293*).—A copy is given of the nursery inspection law of Massachusetts, together with a brief report on the work of inspection for the first year. During this period 80 nurseries were inspected, and of

this number 57 were found to be infested to some extent by injurious insects or diseases. The insect and fungus pests which are considered most important in Massachusetts are gypsy moth, brown-tail moth, San José scale, West Indian peach scale, peach yellows, pear blight, and black knot. As a rule infested stock was destroyed, and little use has thus far been made of the alternative of fumigating such stock rather than destroying it.

Report of the committee on gypsy moth, insects, and birds, A. PRATT ET AL. (*Massachusetts State Bd. Agr. Rpt. 1902, pp. 265–271, pl. 1*).—A brief account is given of the present status and distribution of the gypsy moth, together with a discussion of the depredations committed by the moth and the prospects of future damage from this insect. During the past year a number of the large colonies have defoliated considerable areas of trees and caused alarm in a number of localities.

Report on the work of the State entomologist for 1902, S. LAMPA (*Meddel. K. Landtbr. Styr. [Sweden], 1903, No. 85, pp. 60, fig. 1*).—Notes are presented on the insect outbreaks during the year throughout various parts of Sweden as reported by various observers and correspondents. Upon the whole, the insect outbreaks during the year were less pronounced than during the preceding year. Considerable injury was done to apple trees by *Cheimatobia brumata* and *Hibernia defoliaria*. A brief account is presented of the injuries caused to cereals by cockchafers, wireworms, and frit fly. Notes are also given on pea weevil and a number of miscellaneous insects injurious to garden vegetables and fruit trees.

Notes and practical suggestions relative to combating animals injurious to cultivated plants, G. DEL GUERCIO (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1903, No. 5, pp. 208, pls. 7, figs. 88*).—Descriptive, economic, and biological notes are presented on the more injurious insects of Italy, belonging to the following groups: Thysanoptera, Thrips, and Lepidoptera. The more important species are described in detail and notes are given on their habits, life history, food plants, natural enemies, and artificial remedies. The majority of the species considered are illustrated.

Injurious insects and other animals observed in Ireland during the year 1902, G. H. CARPENTER (*Econ. Proc. Roy. Dublin Soc., 1 (1903), IV, No. 9, pp. 195–218, pls. 2, figs. 7*).—Economic and biological notes are given on *Hepialus humuli*, crane flies, wheat-bulb fly, carrot fly, turnip fly, rose sawfly, Mediterranean flour moth, *Anobium domesticum*, *A. paniceum*, *Oniscus asellus*, *Syagrius intrudens*, etc.

The Hessian fly in Ohio, C. E. THORNE (*Ohio Sta. Bul. 136, pp. 24, pls. 2, figs. 10*).—During the past season the damage from Hessian fly is said to have exceeded that of any previous attack of this insect. Detailed notes are given on the previous important outbreaks of Hessian fly in Ohio. From a consideration of these outbreaks it appears that a warm autumn is favorable to the prevalence of the fly, but that the rainfall has little effect upon its relative abundance. In general the climatic conditions which favor the growth of wheat also favor the increase of the Hessian fly. In a few instances continuous October frosts appeared to check the development of the Hessian fly. The liberal use of manure or fertilizers assisted in some instances in saving wheat from total destruction. According to statistics extending over a long period of years it appears that it is not safe to sow wheat earlier than from September 23 to October 10, according to the latitude of different parts of the State. It is stated, however, that while it is possible to avoid injury from the Hessian fly by late seeding, "in average seasons the risk of winter injury to wheat sown sufficiently late to avoid the fly appears to be quite as great as the risk from the fly." It is recommended that a part of the crop be sown moderately early in order to determine whether the Hessian fly prevails to an unusual extent during any particular season, or that several sowings be made a few days apart in order to induce the insects to make their main attack upon the earlier sowing.

Hessian fly in Missouri, J. M. STEDMAN (*Missouri Sta. Bul. 62, pp. 131–149, figs. 6*).—The Hessian fly is found throughout Missouri and is considered to be second only to

the chinch bug in the destruction of wheat. Notes are given on the habits, life history, and food plants of this insect. In controlling the pest the author recommends late sowing of fall wheat and the burning or plowing under of all infested stubble.

The eggs of insects which are frequently found on sugar cane, W. VAN DEVENTER (*Meded. Proefstat. Suikerriet West Java, 1903, No. 63, pp. 10, pls. 2*).—Descriptive, economic, and biological notes on a number of insects injurious to sugar cane, including *Euproctis minor*, *Procodeca adara*, *Chilo infuscatellus*, and *Diatræa striatalis*.

Enemies of tobacco, G. D'UTRA (*Bol. Agr. São Paulo, 4. ser., 1903, No. 3, pp. 111–122, figs. 3*).—Notes are given on the habits, life history, and means of combating *Protoparce carolina*, *Epitrix parvula*, *Dicyphus minimus*, and other less important insects.

Insect enemies of stored grain, POSKIN (*Bul. Agr.* [*Brussels*], *19* (*1903*), *No. 4, pp. 532–557*).—The author presents descriptive, biological, and economic notes on granary weevil, Angoumois grain moth, and a number of other insects injurious to stored grain, together with a detailed discussion of the artificial remedies which are usually recommended in combating these insects. These remedies include mechanical shock and the application of heat, cold, and poisonous gases.

Insects that damage wheat and other food stuffs, W. W. FROGGATT (*Agr. Gaz. New South Wales, 14* (*1903*), *No. 6, pp. 481–492, pl. 1*).—Notes on the habits, life history, and means of combating rice weevil, granary weevil, flour beetle, saw-toothed grain weevil, bean weevil, Mediterranean flour moth, Angoumois grain moth, etc.

The pests and blights of the tea plant, G. WATT and H. H. MANN (*Calcutta: Supt. Govt. Printing, 1903, 2. ed., pp. XV+429, pls. 24, figs. 44*).—This handbook on the insect and fungus pests of the tea plant has been largely rewritten in the present edition. The purpose of the volume is to present a general account of cultural methods adapted to preventing the attacks of insects and fungus enemies, and to furnish biological and economic accounts of the chief pests of tea. As stated by the authors, the purpose of the cultural suggestions made by them is to furnish data regarding methods which "should necessarily accompany more specific efforts to battle with the pests and blights." About one-third of the volume is occupied with cultural details, while the remaining two-thirds is devoted to a discussion of insects and fungus enemies. The insects are classified into natural orders and discussed in a systematic manner. The majority of the species are well illustrated. Among the numerous species which are discussed mention may be made of a few of the more important ones, including *Lachnosterna impressa*, *Diapromorpha melanopus*, *Amatissa consorta*, *Brachytrypes achatinus*, *Helopeltis theivora*, *Chlorita flavescens*, *Ceylonia theæcola*, *Termes taprobanes*, and *Tetranychus bioculatus*. A number of fungus diseases of tea is considered (pp. 392–416). The more important of these are due to the following species: *Stilbum nanum*, *Cephaleuros mycoidea*, and *Nectria ditissima*.

White fly (Aleurodes citri), H. A. GOSSARD (*Florida Sta. Bul. 67, pp. 595–666, pls. 6, figs. 3*).—A general account is given on the family Aleurodidæ, with special reference to the white fly. The original home of this insect is not definitely known, but it is believed to be Florida. It is also found in Louisiana, Georgia, North Carolina, Texas, and the District of Columbia. The insect is described in detail in its various stages. It is considered to be the worst orange pest of Florida, and is known to be established in 14 counties of that State. There are 3 broods, which occur from March to May, June to August, and September to November, respectively. The eggs are deposited upon the leaves. The insect is distributed greatly by nursery shipments, wind currents, and various vehicles. The chief natural enemies of the insect are brown fungus, *Aschersonia aleurodis*, and other species of parasitic fungi as well as ladybirds. In experiments to discover the effect of cold storage the white fly was killed by subjection to temperatures of 10 to 20° F. for periods varying from 1 to 48 hours. Notes are given on the food plants of this insect. Among the insecticides discussed by the author mention should be made of resin sprays, kerosene

emulsion, whale-oil soap, Montgomery's insecticide, tobacco decoction, sulphur dust, and hydrocyanic-acid gas. The most favorable time for spraying is during the winter period; at least 2 thorough applications should be made. Fumigation with hydrocyanic-acid gas proved effective, but is not generally recommended. Resin wash is considered to be a very satisfactory spray and potash whale-oil soap may also be used with good success and with little injury to the trees.

The white fly, H. A. GOSSARD (*Florida Sta. Farmers' Inst. Bul. 1, pp. 29–50*).—The white fly is described in its various stages and notes are given on its habits and life history. A number of remedies have been tried in combating this insect, and good results are reported from the use of resin wash and other similar insecticides. A parasitic fungus is believed to help appreciably in the destruction of this insect.

Fiddler beetle (*Jour. Jamaica Agr. Soc., 7 (1903), No. 7, pp. 275–277*).—The roots of orange trees are said to be greatly injured by a beetle which was identified as *Exophthalmus vittatus*. The beetle is most injurious in its larval condition. The adult beetles may be jarred from the orange trees in the early morning and captured.

An enemy of olive grafts, TRABUT (*Bul. Agr. Algérie et Tunisie, 9 (1903), No. 13, pp. 308, 309, fig. 1*).—Considerable injury to the grafts of olives is reported as due to the attacks of *Otiorhynchus crebricollis*. The young grafts may be protected by spraying with arsenical insecticides.

Lecanium oleæ, TRABUT (*Bul. Agr. Algérie et Tunisie, 9 (1903), No. 11, pp. 258, 259*).—This insect is considered one of the worst pests of the olive. Since certain of the enemies of the olive scale live on fig trees, it is recommended that the latter trees be planted in the vicinity of olive groves.

A new destructive scale insect, TRABUT (*Bul. Agr. Algérie et Tunisie, 9 (1903), No. 13, pp. 289, 290, fig. 1*).—Notes are given on *Ceroplastes sinensis*, which is considered one of the most important enemies of the orange in Algeria.

The San José scale: its native home and natural enemy, C. L. MARLATT (*U. S. Dept Agr. Yearbook 1902, pp. 155–174, pls. 6, figs. 3*).—A discussion of the history, distribution, natural enemies, and home of the San José scale. As a result of the author's travels in the Orient it is believed that China is the original habitat of this insect. Considerable assistance may reasonably be expected from *Chilocorus similis* in the destruction of the scale. This ladybird was introduced from China and has been distributed in a number of localities in the United States.

A catalogue of the Coccidæ of the world, MARIA E. FERNALD (*Massachusetts Sta. Bul. 88, pp. 360*).—The number of species of Coccidæ recognized in this bulletin is about 1,500. The preferred specific name is given in each case, followed by full bibliographic references and synonyms. A detailed index contains the names of subfamilies, genera, subgenera, species, and subspecies. This index enables the entomologist to make rapid references to the names and synonymy to the various species as contained in the text of the bulletin.

Some wood-boring beetles and their habits, W. W. FROGGATT (*Agr. Gaz. New South Wales, 14 (1903), No. 5, pp. 414–417, pl. 1*).—Descriptive, biological, and economic notes on *Bostrychus cylindricus*, *Xyleborus solidus*, *Lyctus brunneus*, and *Gracilia pygmæa*. Xyleborus was reported as causing considerable injury to apple and peach trees. The apple trees were most affected. In some cases limbs 1 in. in diameter were so badly eaten that they readily broke off.

Some of the principal insect enemies of coniferous forests in the United States, A. D. HOPKINS (*U. S. Dept. Agr. Yearbook 1902, pp. 265–282, pls. 2, figs. 10*).—An account is presented of the habits, life history, and means of combating *Dendroctonus piceaperda*, *D. frontalis*, *D. ponderosa*, and other injurious species of this genus. The author briefly indicates the remedies which may be employed in checking the spread of these insects.

The narcissus or daffodil fly, W. WILKS (*Jour. Roy. Hort. Soc. [London], 27 (1902), No. 1, pp. 181–185, fig. 1*).—A study was made of the life habits and history of

Merodon equestris, which is reported as greatly injurious to daffodils. According to the observations of the author, the eggs are deposited in the scales near the top of the bulb, and the larva after hatching eats its way down through the bulb and finally emerges at the base. No practical remedies for this pest have been discovered.

Locust destruction, W. H. Bushby (*Agr. Jour. and Min. Rec.* [*Natal*], *6* (*1903*), *No. 13, pp. 457–464*).—This is the report of the chief locust officer for the Natal government and contains a report of the operations conducted by the government in the destruction of these insects. The formula for the insecticide which was successfully used in various parts of Natal is as follows: 1 lb. arsenic, 0.5 lb. soda, 0.8 lb. sugar, 16 gal. water. The solution was found to be quite harmless to stock except when considerable quantities were taken at one time. The country was divided into districts for the purpose of securing a more effective extermination of the locusts, and each district was placed in charge of a local officer who was made responsible for the destruction of the young locusts. Calls for aid from natives in locust-infested districts were not always met enthusiastically and the author complains that in many instances too much was expected from the government operations along this line.

The invasion of locusts in Charente, J. Ricard (*Ann. Inst. Nat. Agron., 2. ser., 2* (*1903*), *No. 1, pp. 145–179, figs. 6*).—The species of locust which is reported as having caused most damage in Charente is *Caloptenus italicus*. Notes are given on the distribution of the insect and the depredations committed in 1901 and 1902. Little success was had from the use of ordinary chemical remedies in combating this insect, and the author believes that the main reliance must be placed upon the proper use of mechanical remedies, such as large hopperdozers combined with the employment of a considerable force of men armed with small branches of trees to be used in driving the young locusts. Among the natural enemies of locusts the author mentions parasitic fungi and unfavorable climatic conditions.

Cicadas and their habits, W. W. Froggatt (*Agr. Gaz. New South Wales, 14* (*1903*), *No. 5, pp. 418–425, pls. 2*).—Notes are given on the following species of Cicada: *Tibicina curvicosta, Macrouistria angularis, Psaltoda flavescens, Melampsalta melanopygia, M. encaustica, Tettigarcta tomentosa, Cystosoma saundersii,* and *C. vitripennis*. A bibliography of the subject is appended to the article.

Spraying crops, C. M. Weed (*New York: Orange Judd Co., 1903, 4. ed., pp. 136, pls. 5, figs. 53*).—In this edition an attempt has been made to bring the discussion of insecticides and fungicides up to date by inclusion of some of the newer formulas which have been recommended by entomologists and botanists.

Insecticide studies, J. K. Haywood (*U. S. Dept. Agr., Bureau of Chemistry Bul. 76, pp. 63*).—An investigation was made of pyrethrum powders containing poisonous metals. It was found that in some localities the public demands that pyrethrum powders be bright yellow. This color is produced by the addition of lead chromate. Since this chemical is poisonous to man, attention is called to the dangers from using pyrethrum powders containing lead chromate, and a number of cases of poisoning are reported from the literature on the subject. During this investigation 105 samples were analyzed, and 18 per cent were found to be colored by lead chromate. It is believed that where pyrethrum powders are sprinkled about houses for the destruction of fleas, cockroaches, and other household pests the pulverized lead chromate might produce serious cases of poisoning by inhalation.

A compilation of analyses of insecticides and fungicides was made from the publications of agricultural experiment stations and is presented in a tabular form, with comments on the methods used and on the results obtained. Copies are given of the State laws governing the composition and sale of insecticides.

Paris green, T. Macfarlane (*Lab. Inland Rev. Dept. Ottawa, Canada, 1903, Bul. 88, pp. 11*).—A tabulated statement is presented describing 169 samples of Paris green which were submitted for analysis, and showing the amount of arsenious acid, cupric oxid, and other constituents of the various samples. From these analyses it

appears that improvement has been made during recent years in Canada in the quality of Paris green sold on the market.

The fauna of British India, Hymenoptera, C. T. BINGHAM (*London: Taylor & Francis, 1903, vol. 2, pp. 506, pl. 1, figs. 161*).—In this volume the author presents an account of the ants and cuckoo wasps. The anatomy of these insects is described in detail, and brief notes are given on their food plants and distribution.

The destruction of ants by calcium carbid, DEFONTAINE (*Agr. Prat. Pays Chauds, 2 (1903), No. 12, pp. 742–744*).—Three species of ants (*Atta sexdens*, *Camponotus rufipes*, and *Dinoponera grandis*) were found to be injurious to cassava in certain plantations in South America. For the destruction of these ants the author recommends the use of calcium carbid for the purpose of producing acetylene gas in the burrows of the ant colonies. The gas is then ignited and the ants are destroyed by the rapid combustion and explosion of the gas.

Destruction of white ants by means of sulphurous acid, P. LESNE (*Jour. Agr. Prat., n. ser., 6 (1903), No. 30, pp. 116, 117*).—An apparatus devised for the production of sulphurous acid in combating various insect pests is briefly described. As a result of his observations and experiments the author believes that this remedy furnishes an excellent means of destroying ants, white ants, and other underground insects.

Foul brood and ants, DELÉPINE (*Jour. Agr. Prat., n. ser., 5 (1903), No. 22, pp. 691, 692*).—The author advises against the use of salicylic acid as a remedy for foul brood. This remedy is not readily soluble in honey and exercises injurious effects upon the bees. The remedy recommended by the author consists in the use of naphthaline, which is hung in small sacks in various parts of the hives.

In localities where ants prove to be a nuisance to bee raisers, from their habit of crawling into the hives, the author recommends that hives be surrounded with troughs of water for a limited period, so that the ants are unable to reach the entrance to the hives and finally go elsewhere for their food.

The A B C of bee culture, A. I. and E. R. ROOT (*Medina, Ohio: A. I. Root Co., 1903, pp. 482, pls. 34, figs. 397*).—A revised edition of this cyclopedia of bee culture, including a discussion of recent experimental work in the management of bees, the treatment of honey, together with a discussion of the diseases and enemies of bees, etc.

The book of the honeybee, C. HARRISON (*London and New York: John Lane, 1903, pp. 132, pls. 13, figs. 29*).—The author presents an account of the arrangement of the apiary, bee pasturage, appliances and apparatus in use in bee raising, the practical operations involved in caring for bees and honey, and also an account of the diseases and enemies of bees. The volume is well illustrated from photographs by J. C. Douglas, and contains such information as is required by the practical bee raiser.

Apiculture (*Jour. Jamaica Agr. Soc., 7 (1903), No. 5, pp. 184–187*).—A brief discussion of the production and composition of beeswax, together with notes on the adulteration and importation of this substance. On account of the abundance and cheapness of Muscovado sugar in the West Indies it is suggested that this material might profitably be fed to bees throughout the season for the purpose of furnishing them material with which to make wax.

Modern apiculture, A. REINHOLD (*Apicultura Moderna. Buenos Aires: Author, 1903, pp. 56, figs. 142*).—A description of the beehives commonly used in North America, together with other apparatus necessary for the successful management of bees.

The breeds of mulberry silkworm and their selection, D. ROWSINSKI (*Selsk. Khoz. i Lyesov., 209 (1903), May, pp. 375–413*).—Notes are presented on the various races of mulberry silkworms as raised in various countries and the comparative merits of the different races for different purposes are shown in tabular form. The general subject of silkworm culture is also discussed.

Silk culture in France, J. C. COVERT (*U. S. Consular Rpts., 72 (1903), No. 273,*

pp. 237–239).—The author presents a detailed account of the extent of mulberry culture in France and the methods employed in this industry. Mulberries are planted either in orchards, with or without other crops between the trees, or in hedges. It has been found important to pick the leaves in a dry condition, since they keep longer than when picked wet, especially if prevented from being folded in handling.

Silk culture in Greece, D. E. McGinley (*U. S. Consular Rpts., 72* (*1903*), *No. 273, pp. 239, 240*).—In Greece silkworms are not given any other food than mulberry leaves. Mulberry trees are transplanted from January to March, and the maximum age of mulberry trees varies from 50 to 70 years. The silkworm eggs used in Greece are largely imported from foreign countries.

Silk culture in Syria, G. B. Ravndal (*U. S. Consular Rpts., 72* (*1903*), *No. 273, pp. 165, 166*).—Silk raising is reported as in a less prosperous condition than in former years. Notes are given on the culture of the mulberry in Syria and on the utensils and methods used in the production of silk.

FOODS—NUTRITION.

Dietary studies in Boston and Springfield, Mass., Philadelphia, Pa., and Chicago, Ill. (*U. S. Dept. Agr., Office of Experiment Stations Bul. 129, pp. 103*).—Dietary studies carried on in a number of American cities are reported in this bulletin, which was edited by R. D. Milner.

Dietary studies at the Boston School of Housekeeping, 1901–2, Lydia Southard (pp. 7–26).—The first of the 4 dietary studies was made under the usual living conditions, to determine the cost and nutritive value of the diet ordinarily eaten and to compare with this dietaries of medium, low, and high cost, menus being planned beforehand. The general purpose was to learn something of the factors which influence the cost of food, the relation between cost and an attractive menu, and the possibility of applying practically the results of nutrition investigations. The range in cost, nutrients, and energy in the different dietaries is shown by the following summary:

Summary of results of dietary studies at Boston School of Housekeeping.

	Cost.	Protein.	Fat.	Carbohydrates.	Energy.
	Cents.	*Grams.*	*Grams.*	*Grams.*	*Calories.*
Usual diet	28.1	93	156	349	3,156
Diet of medium cost	23.1	94	131	289	2,700
Diet of low cost	16.3	79	94	257	2,183
Diet of high cost	51.1	118	115	390	3,057

The diet in every case was adequate, but the more expensive menu was the one generally relished.

"The results of the investigation as a whole show plainly the impossibility of providing a universally satisfactory bill of fare, as long as the attitude of people toward their food is so largely a question of personal whim. They do show, however, that it is possible to provide a diet of a definite cost which may vary within rather wide limits and which shall at the same time supply the protein and energy called for by the commonly accepted dietary standards."

A dietary study at the Boston School of Housekeeping, 1901, Susannah Usher and Bertha M. Terrill (pp. 27–30).—For instruction in the practical application of dietary studies a class in the Boston School of Housekeeping planned their dietary for one week, the attempt being made to supply an adequate diet costing not over 25 cents per person per day. The menu provided, which was fairly satisfactory, cost 22.6 cents and furnished 94 gm. protein, 127 gm. fat, 317 gm. carbohydrates, and 2,776 calories per woman per day. From this, according to the authors, it seems fair

to say that the cost of the daily fare may be often diminished by intelligent planning of the menu in such a way that a reasonable proportion of moderate-priced foods is used and other justifiable economies are practiced without making the diet so plain that it is unattractive.

Dietary study at the Bible Normal College, 1902, Bertha M. Terrill (pp. 31-36).—The students of the Bible Normal College, situated then at Springfield, Mass., determined to save a certain sum of money which was desired, by diminishing the cost of food, the diet being planned beforehand in such a way that though of low cost it would supply the needed protein and energy. The cost of foods (not including preparation) was only 9.4 cents per woman per day. The diet supplied 75 gm. protein, 78 gm. fat, 312 gm. carbohydrates, and 2,243 calories of energy per woman per day, and was regarded as fairly palatable. The study is regarded as "an excellent illustration of what can be done when it seems desirable to make the cost of the daily fare as low as is consistent with a reasonably palatable diet."

Dietary studies in Philadelphia and Chicago, 1892-93, Ellen H. Richards and Amelia Shapleigh (pp. 37-98).—Twenty-four dietary studies were made in the thickly congested districts of Philadelphia and 32 in similar localities in Chicago. Information was desired in order that charitable work might be carried on intelligently, especially as regards instruction in the selection and preparation of food, household management, etc. In Philadelphia the average cost of the diet was 22.8 cents per person per day, and it furnished 115 gm. protein, 102 gm. fat, 476 gm. carbohydrates, and 3,308 calories per person per day. In Chicago the cost of the daily food was 26.8 cents per person per day, the protein, fat, and carbohydrates supplied being 127, 149, and 457 gm., respectively, and the fuel value being 3,664 calories. The individual dietaries are discussed in detail and in many cases suggestions are made for improving the diet without materially increasing its cost.

"Considering the net results of these dietary studies they were of undoubted value to the settlement associations under whose auspices they were made. They furnished more accurate information than could have been gained otherwise regarding the ways of living, the adequacy of the diet, and the faults in methods of purchasing, cooking, and serving food. The information gained, it is believed, has been utilized in many ways to the advantage of all concerned."

The cost of food as related to its nutritive value, R. D. MILNER (*U. S. Dept. Agr. Yearbook 1902, pp. 387-406*).—The relative value of different foods is discussed, the fact being emphasized that the amount of nutritive material present determines the real value of the food rather than its cost per pound. Common food materials are divided into groups designated cheap, medium, and expensive, as regards sources of both protein and energy. The relative value of a number of common foods is discussed and ways suggested in which the results of nutrition investigations in general may be made of practical use.

Inorganic salts in relation to nutrition (*British Med. Jour., 1903, No. 2219, pp. 93, 94*).—A discussion summarizing data on value of different inorganic salts in the nutrition of man and animals.

The dietetic values of food stuffs prepared by plants, G. HENSLOW (*Jour. Roy. Hort. Soc. [London], 27 (1903), No. 4, pp. 968-976, figs. 2*).—The author summarizes and discusses data regarding the food value of plants and the forms in which the nutritive material occurs.

The physiological action of betaïne extracted from raw beet sugar (*British Med. Jour., 1903, No. 2224, p. 380*).—A brief note on a recent investigation by Waller and Plimmer which showed that betaïne has a marked physiological effect. In view of this the need of careful purification of beet sugar is pointed out.

The victualling of the royal navy: Past, present, and future, A. TURNBULL (*London: Elliot Stock, 1903, pp. 31*).—A compilation of data regarding the rations issued to the British navy in the past and at the present time, together with a sum-

mary of the report of a committee appointed by the Lords of the Admiralty which proposes a number of changes.

The food factor in education (*British Med. Jour., 1903, No. 225, pp. 424, 425*).—The diet commonly found in British schools is discussed and suggestions for improvement are made, as it is regarded as inadequate.

Composition of the principal proteids in foods, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 6 (1903), No. 33, pp. 205, 206*).—A brief summary.

Food and food adulteration, J. B. WEEMS (*Dietet. and Hyg. Gaz., 19 (1903), No. 9, pp. 513–518*).—The extent of food adulteration, the need of legislation to restrain it, and similar topics are discussed.

Chemical composition of foods and condiments, J. KÖNIG and A. BÖMER (*Chemische Zusammensetzung der menschlichen Nahrungs- und Genussmittel. Berlin: Julius Springer, 1903, vol. 1, 4. ed., pp. XX+1535, figs. 4*).—It is stated that the revision of the new edition of this valuable handbook has been prepared by Professor Bömer. The original form of reporting the analytical data in considerable detail has been adhered to, the large amount of recent analyses published since the earlier editions being included, in addition to the older material. The introductory chapter on the theory of nutrition has not been retained, as it is planned to elaborate this subject in a subsequent volume.

Seventh report on food products, A. L. WINTON ET AL. (*Connecticut State Sta. Rpt. 1902, pt. 3, pp. 179–325, figs. 36*).—In the introduction to this report, by E. H. Jenkins, it is stated that during the year 1,205 samples of foods and food products purchased by the station, or submitted to it, were examined, as well as 662 collected by the State Dairy Commission, making a total of 1,867 samples.

Milk, A. L. Winton, M. Silverman, and E. M. Bailey (pp. 183–195).—Of the 292 samples of milk purchased from milkmen, 10.9 per cent were found to be adulterated, in 4 cases by the use of added preservatives, in 7 cases by dyes, and in the remainder by watering and skimming. Analyses are also reported of a sample of preserved cream and a number of samples of milk which were not collected by the station.

Carbonated nonalcoholic beverages and fruit flavors, A. L. Winton, A. W. Ogden, M. Silverman, and E. M. Bailey (pp. 195–215).—Two hundred and eleven samples of sirups, fruit juices, and carbonated beverages were analyzed, and 72 were found to be unadulterated. The majority of them contained coal-tar dyes. Added preservatives were also common. A sample of lemon extract and 3 samples of vanilla extract were examined and were all free from adulteration.

Sweet pickles, A. L. Winton and A. W. Ogden (pp. 216–221).—Only 1 of the 18 samples of sweet pickles (cucumbers and other vegetables) examined was free from glucose, saccharin, or chemical preservatives. Most of the pickles contained small quantities of alumina and sulphuric acid, and 1 sample was colored with copper. The methods of examination are described.

Lard, A. L. Winton and A. W. Ogden (pp. 221–227).—During the year 166 samples of lard were examined, 55 of which were adulterated.

Cheese, A. L. Winton and E. M. Bailey (pp. 228, 229).—The fact that various soft cheeses sold in jars, tin-foil packages, etc., differ in keeping qualities led to an examination for added preservatives with the result that borax was found in 7 samples. Fourteen samples were not adulterated.

Maraschino cherries, A. L. Winton and E. M. Bailey (pp. 229, 230).—Six brands of Maraschino cherries were examined and coal-tar dye found in all.

Ground spices, A. L. Winton and E. M. Bailey (pp. 230–245).—During the year 233 samples of spices were examined, of which 40 were found to be adulterated.

Coffee, A. L. Winton (pp. 246–248).—Only 3 of the 33 samples of coffee examined were found to be adulterated. A marked decrease in the adulteration of this class of goods during the last 7 years is noted.

Cocoa, A. L. Winton, M. Silverman, and E. M. Bailey (pp. 248–255, 257–263).—Cocoa

products and methods of examination are described and analyses reported of samples of 45 brands. Of these 12 were found to be adulterated and 7 to be compound cocoa.

Miscellaneous samples, A. L. Winton, M. Silverman, and E. M. Bailey (pp. 255, 256).—Proximate analyses are reported of gluten bread and a preservative for yeast, as well as examinations for the detection of adulterants of cream of tartar, sage, granulated sugar, butter, curd, canned beets, green tea, preserving mixture, baking powder, and vinegar, and the alcohol content of several samples of liquors.

Food products examined for the dairy commissioner in the twelve months ending July 31, 1902 (pp. 264, 265).—A number of samples of butter, molasses, honey, and vinegar were examined for the State commissioner in dairying, the results being briefly reported.

The effects of roasting on the chemical composition of cocoa beans, A. L. Winton, M. Silverman, and E. M. Bailey (pp. 265–269).—Taking into account the work of earlier investigators, the changes brought about in cocoa beans by roasting are discussed and analyses reported of a test made with raw and roasted Caracas cocoa beans, one sample being roasted at a lower heat than is customary, a second in the usual manner, and a third at an abnormally high heat. The operation of roasting was conducted in a chocolate factory by skilled workmen in the presence of a representative of the station. So far as could be judged by the analyses, the chemical composition of the cocoa nibs was altered little, if at all, by roasting. Apparently no starch was converted into dextrin or other soluble carbohydrates, nor were the percentages of fat or the fat constants changed, nor the theobromin, caffein or other nitrogenous substances altered. The crude fiber content in the roasted samples was slightly increased, probably owing to the presence of a little finely-divided charcoal from the shells which was constantly present.

"These results do not by any means prove that only the mechanical condition of the nibs is affected by roasting and no chemical change whatever takes place during the process. As a matter of fact, the flavor of roasted beans is materially different from that of the raw beans, and this must be due to some difference in chemical constitution, but this difference would appear to be slight and justifies the adoption of standards of composition based on analyses of beans roasted at a medium heat."

Analyses of authenticated samples of cocoa beans, A. L. Winton, M. Silverman, and E. M. Bailey (pp. 270–287).—Analyses are reported of a number of samples of roasted cocoa nibs, roasted cocoa shells, and roasted unshelled cocoa beans. Methods are described and the analytical data discussed with reference to its bearing upon the composition of chocolate and the fixing of standards of composition.

The anatomy of edible berries, A. L. Winton (pp. 288–325).—Extended studies are reported of the following American edible berries: Cultivated strawberry, American field strawberry, American red raspberry, black raspberry, blackberry, dewberry, red currant, black currant, American gooseberry, European gooseberry, American cranberry, and huckleberry; and of some European species, including the forest strawberry, European raspberry, and mountain cranberry.

While the special purpose was to accumulate data for use in the examination of jams, preserves, etc., the author's investigations furnish a large amount of information regarding the macroscopical and microscropical appearance of the different berries and their normal structure, the text being supplemented by numerous drawings. Detailed directions are given for the examination of jams and preserves made from the various berries, attention being called in every case to the more striking features which may be expected.

A German translation[a] of this article has previously appeared.

Canned meats, A. McGill (*Lab. Inland Rev. Dept. Ottawa, Canada, 1903, Bul. 85, pp. 3, 4*).—Ninety-nine samples of canned meats were examined. With the exception

[a] Ztschr. Untersuch. Nahr. u. Genussmtl., 5 (1902), pp. 785–814.

of 5 samples they were in good condition. Boric acid was found in 21 samples, but in no case "has it exceeded the limit fixed by the British Parliamentary Commission, viz, 0.5 per cent, and in most cases it has fallen markedly below this amount."

American corn meal and hominy in France, T. Haynes (*U. S. Consular Rpts. 73 (1903), No. 276, pp. 101, 102*).—In order to secure any extended market for American corn meal the author believes that it must be marketed in more satisfactory packages, sold for a more reasonable price, and methods of preparation suggested which are in keeping with the dietary habits of the French people.

Arrowroot, C. T. Musson (*Agr. Gaz. New South Wales, 14 (1903), No. 5, pp. 452, 453, figs. 2*).—Directions for extracting starch on a small scale from *Canna edulis* are given.

Canned vegetables, A. McGill (*Lab. Inland Rev. Dept. Ottawa, Canada, 1903, Bul. 87, pp. 9*).—With 2 exceptions all of the 100 samples of canned vegetables examined were found to be in good condition and in no case were added preservatives found. Traces of copper were found in 2 samples of canned peas and a larger amount in a sample of French peas.

The principal vegetables used as food in the French Colonies, Balland (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 15, pp. 934–936*).—The composition is reported of peanuts, *Cajanus indicus*, several varieties of beans, and the so-called African peanut (*Voandzia subterranea*).

The chemical composition of nuts used as food, J. B. Weems and Alice W. Hess (*Proc. Iowa Acad. Sci., 10 (1902), pp. 108–111*).—Analyses of a number of native and foreign nuts are reported and their food value discussed.

Coffee substitutes (*Agr. News [Barbados], 2 (1903), No. 36, p. 281*).—A note on the use of soy beans as a coffee substitute.

Sources of sugar, C. A. Kern (*Dietet. and Hyg. Gaz., 19 (1903), No. 9, pp. 522–524*).—A popular article discussing the manufacture of sugar from various sources, a number of which are unusual.

Preservation of cane sirup, W. R. Dodson (*Louisiana Stas. Bul. 75, 2. ser., pp 236–249*).—Believing in the desirability of preserving cane sugar as a means of increasing its home consumption and sale, tests were undertaken to learn the value of various methods. Attempts to preserve sirups in small quantities by the ordinary household methods employed in preserving fruit were entirely successful, but attempts to preserve sterilized sirup of 22° Baume density in large quantities in sterilized kegs did not succeed. However, sirup of 36° density so preserved fermented very little, while similar sirup not sterilized fermented very badly. The author believes, therefore, that "thick sirup, sterilized in tight wooden vessels, can be kept practically without fermentation during the entire summer."

The belief is rather widespread that filtering cane juice through Spanish moss materially increases the keeping qualities of sirup made from it and prevents crystallization. As shown by a number of experiments there is no foundation for this belief.

A number of tests which had to do with the causes of fermentation are reported, leading to the conclusion that cane fermentation is due to micro-organisms introduced from without and not to enzyms present in the cane. Freezing the cane facilitated the entrance of the micro-organisms causing fermentation.

The enzyms of the sugar cane, C. A. Browne, Jr. (*Louisiana Stas. Bul. 75, 2. ser., pp. 249–256*).—The presence of enzyms was demonstrated in sugar cane, including a catalase, an oxidase, and a peroxidase, the first 2 being always and the latter sometimes present.

Special device for keeping sirup in a sterile condition, W. R. Dodson (*Louisiana Stas. Bul. 75, 2. ser., pp. 256–258, fig. 1*).—A modified form of faucet is described which was designed to permit the withdrawing of a small quantity of sterilized sirup from a large vessel without disturbing the sterile condition of that which remains.

Relation of bacteria to the inversion of crystallized sugars, W. R. DODSON (*Louisiana Stas. Bul. 75, 2. ser., pp. 259–263*).—Recognizing the fact that unrefined sugars are subject to inversion during storage or transportation over long distances, bacteriological studies were undertaken, and a bacterium isolated which is regarded as the cause of the inversion. The test led to the following conclusions:

"Sugar that was sterilized and not inoculated with any organism did not deteriorate in purity. Sugar sterilized and inoculated with pure cultures of organisms found in inverting sugars show a decided inversion. There is no reason to believe that any other agent than the organism introduced was responsible for this inversion."

The character of the bacterium was not fully determined, but it is planned to continue the work.

Preservation of eggs, R. GUENTHER (*U. S. Consular Rpts., 73 (1903), No. 276, pp. 66, 67*).—A note on the successful use of water-glass solution for preserving eggs.

Preserving eggs (*Agr. Gaz. New South Wales, 14 (1903), No. 5, pp. 472, 473*).—A number of experiments carried on in Germany are briefly quoted, which show that the best results were obtained when eggs were either varnished with vaselin, immersed in limewater, or in water-glass solution.

Hens' eggs, E. CARPIAUX (*Bul. Inst. Chim. et Bact. Gembloux, 1903, No. 73, pp. 39–51*).—Noted from another publication. (E. S. R., 15, p. 64.)

ANIMAL PRODUCTION.

The value of oak leaves for forage, W. W. MACKIE (*California Sta. Bul. 150, pp. 21, figs. 10*).—Having noted that live stock readily eat the leaves of certain oaks, the author studied the chemical composition and food value of the leaves of a number of species found in the northern coast ranges of California, and also the leaves of poison oak. In addition to the usual data the tannin in the leaves was determined.

The results of analyses of the different kinds of foliage follow, the leaves being gathered in every case in the fall when they were fully mature:

Composition of oak and poison oak leaves.

Species.	Water.	Protein.	Ether extract.	Nitrogen-free extract.	Fiber.	Tannin.	Ash.
Live oaks:	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Scrub oak (*Quercus dumosa*)	3.90	9.16	5.26	31.41	26.79	14.06	9.12
Cañon live oak (*Q. wislizeni*)	3.51	10.95	5.86	30.89	29.48	9.62	9.66
Maul oak (*Q. chrysolepis*)	6.53	8.32	3.50	31.52	30.35	10.16	9.62
Deciduous oaks:							
Blue oak (*Q. douglasii*)	5.21	8.32	4.25	34.55	33.35	5.00	9.32
Black oak (*Q. californica*)	5.10	8.15	7.06	40.50	19.22	10.62	9.35
Mountain white oak (*Q. garryana*)	4.59	15.05	5.47	40.18	16.26	9.01	9.44
Poison oak (*Rhus diversiloba*)	5.39	6.85	6.50	41.05	25.13	6.42	8.66

It was observed that the poisonous oil of poison oak is apparently volatile at a comparatively low temperature, as samples dried at ordinary room temperature did not produce poisonous effects.

In general all the leaves examined possessed a high crude fiber content and less nitrogen-free extract than leguminous crops. The resins present "have pungent and disagreeable flavors, which render them distasteful to stock. A good example of this is seen in the *Quercus californica*. The leaves of the young trees and shrubs of this species contain no more tannin than those of most of the other species, are only 1¼ per cent below alfalfa in nitrogen-free extract, have a fair amount of protein, are low in crude fiber, and are large and soft. These qualities should produce a feed superior to oat hay. This is not the case, however, for stock avoid it to a great extent on account of the resins and waxes in the dense tomentum covering the leaves. These

waxes and resins serve as a protection against drying winds and severe weather, and all the oaks have more or less of them.

"As compared with the crude fiber and resins, tannin of oak leaves, as before stated, is not only bitter and astringent, but interferes with digestion. . . . In summing up the value of the forage oaks, from chemical analyses and observations in the field, the conclusion is reached that the facts observed in the field coincide in most cases with those determined by analysis. For instance, the deciduous oaks possess a higher nutritive value than the live oaks and are, as would be expected, more readily eaten by horses, cattle, sheep, and goats. In some cases, however, certain physical conditions modify these relations. This is true in the case of the live oaks. These contain a sufficiently high proportion of nutrients, and yet only sheep and goats thrive upon them. This is due to the thick, harsh leaves with their spinescent teeth, which prevent horses and cattle from relishing them.

"Although all stock prefer the deciduous oaks of the higher altitudes, yet indiscriminate pasturing causes much damage to the forests and ground-cover. When sheep and goats are allowed to browse on the deciduous oaks of the timbered area, they kill the seedling conifers by nibbling and trampling, kill the shrubs by overbrowsing, and cut up the slopes in trails which become deep gullies during the rainy season. This could be avoided by pasturing the sheep and goats on the 'live oaks' of the lower chapparal or brush areas, the only necessary precaution being to prevent too many congregating in one place, thus avoiding too much trampling and gullying.

"Since cattle and horses are unable to thrive on the live oaks, and since they do not browse close enough to kill shrubs, never browse on young conifers, nor cut up slopes by trails, they may profitably be pastured on the timbered areas and on the higher altitudes. Thus, this oak area, comprising half the whole State, can, by a conservative and well-regulated system of browsing, be made to pasture sheep and goats throughout the year, and all stock during the summer months; and also during seasons of drought or when winter conditions make other feed inaccessible."

Feeding stuff inspection, C. D. WOODS and J. M. BARTLETT (*Maine Sta. Bul. 92, pp. 53–68*).—In accordance with the State feeding stuff law, analyses were made of a large number of samples of concentrated feeding stuffs sent by correspondents and collected by the Station, including cotton-seed meal, linseed meal, flax meal, gluten meals and feeds, Fourex (dried distillers' grains), bran, red dog flour, meat meal, animal meal, beef scraps, bone and meat meal, mixed feeds, proprietary feeds, cereal breakfast food by-products, and calf meal. In general it is noted that the amount of impure cotton-seed meal sold in the State was a very small percentage of the whole, and that the feeding stuffs compared favorably with the guaranteed composition.

"In the fall of 1899 the State was flooded with low grade, adulterated wheat brans and mixed feeds. Because of the publicity given to these fraudulent goods and the cooperation of the best of the large dealers, they have quite largely disappeared, or are sold under a proper guaranty. There is so much profit in selling ground corn cobs and broom corn at the price of wheat bran that the consumer must ever be on the watch against this fraud. The safest thing is to buy only well-known reliable brands of this class of goods."

The feeding value of the dried distillers' grains was tested with 6 cows, all in milk, for about 3 months. They had been fed a mixture of wheat bran, cotton-seed meal, and linseed meal, 2 : 2 : 1, in addition to corn silage and mixed hay. Dried distillers' grain mixed with bran in the proportion of 30 to 5 was gradually substituted for this and fed for 22 days, and was then gradually replaced by the first ration. The total milk yield for 22 days on the oil meal ration (comprising 11 days before and 11 days after the period on dried distillers' grain) was 2,879.2 lbs. The total milk yield in the same time on distillers' grain was 2,989.8 lbs. In other words, the cows maintained their milk yield on the dried distillers' grains. This feed, according to

the authors, "has about the same composition as gluten meal. It is readily eaten by stock and is a safe food for milch cows when fed by itself or in combination with other grain feeds."

Concentrated feeding stuffs, L. A. VOORHEES and J. P. STREET (*New Jersey Stas. Bul. 165, pp. 47*).—The feeding stuffs analyzed this season under the State law included cotton-seed meal and feed, linseed meal, germ meal, gluten meals and feeds, hominy meal, maizeline feed, cerealine feed, corn brans, distillers' grains, malt sprouts, dried brewers' grains with and without molasses, mixed commercial feeds, cereal breakfast food by-products, calf meal, animal meal, poultry feeds, wheat brans, feeding flour, rye and wheat middlings, rye chop, buckwheat bran or middlings, barley feed and meal, and peanut bran, middlings, and vines.

"Of the 214 samples which are guaranteed and of which an examination has been made, 69 fail in their promises, 50 of these being deficient in protein. Among the 242 samples of feeds not required to be guaranteed, 215 are found to be of normal composition, about 24 vary from the same, for various reasons, and 3 are adulterated. Particularly to be avoided are the materials which contain hulls of other seeds or of their own in excess of that normally present."

Analyses of concentrated commercial feed stuffs, W. FREAR (*Pennsylvania State Dept. Agr. Bul. 107, pp. 61*).—During the year 1902 analyses were made under the State feeding stuff law of 263 samples of cattle feeds, including cotton-seed meal and feed, linseed meal, rye chop and feed, malt sprouts, dried brewers' grains, rice feed, oat feeds, corn chop, hominy feeds, gluten meals and feeds, cerealine feeds, corn bran, germ oil meal, sugar feed, maizeline, mixed feeds, breakfast food by-products, condimental feeds, animal meal, wheat bran, middlings, feed, chop, screenings, and germ middlings. The different classes of feeds are discussed at some length as regards their quality. A general failure to comply with legal requirements as to guaranty was observed.

The composition and digestibility of prairie hay and of buffalo-grass hay, J. T. WILLARD and R. W. CLOTHIER (*Trans. Kansas Acad. Sci., 18 (1901–2), pp. 59, 60*).—Noted from another publication (E. S. R., 13, p. 480).

The feeding value of rice products, C. A. BROWNE, Jr. (*Louisiana Planter, 30 (1903), Nos. 24, pp. 383–385; 25, pp. 398–401*).—In a paper presented before the Louisiana Sugar Planters' Association, rice products are described, their feeding value discussed, and investigations carried on at the Louisiana Station briefly reported. The latter include determinations of the composition of rice bran, polish, meal, hulls, and straw, and digestion experiments with steers.

On an average rice bran was found to have the following coefficients of digestibility: Dry matter 58 per cent, protein 64.7 per cent, fat 54.8 per cent, crude fiber 13.8 per cent, nitrogen-free extract 78.1 per cent, and ash 33 per cent; and rice polish, dry matter 82.5 per cent, protein 65.6 per cent, fat 73.6 per cent, crude fiber 22.1 per cent, nitrogen-free extract 92.7 per cent, and ash 31.4 per cent. A number of rations for mules are suggested which contain rice products. The paper is followed by a discussion.

Dried sugar beets as food for farm animals, G. H. MURPHY (*U. S. Consular Rpts., 73 (1903), No. 276, pp. 108, 109*).—A brief note quoting statements published in the *Blätter für Zuckerrübenbau* on methods of drying beets and the value of the product as a feeding stuff.

White beans as a stock food, C. S. PLUMB (*Breeders' Gaz., 43 (1903), No. 14, p. 679*).—According to the experience of a number of farmers in Michigan, waste beans not suitable for market are a satisfactory feeding stuff for farm animals. The opinion was generally held by local feeders that beans could be given to all classes of stock. In the experience of one of the feeders quoted, a mixture of corn, oats, and ground beans 2 : 1 : 1 gave good results with horses, cattle, sheep, and pigs.

"The beans are fed cooked to pigs, but to other classes of stock in the dry and

ground or unground condition, as the feeder sees fit, though to cattle ground." Bean pods are commonly used as coarse fodder and are highly praised as a food for sheep. "The universal testimony seemed to be that beans and pods both acted as a laxative and should be fed with great discretion. When fed with care, however, good results were secured."

Waste beans as stock feed (*Pacific Rural Press, 65 (1903), No. 17, p. 262*).—The use of stained beans by local dairy and poultry feeders is noted and statements regarding the feeding value of beans are quoted from the article noted above.

The anatomy of the fruit of certain cultivated sorghums, A. L. WINTON (*Connecticut State Sta. Rpt. 1902, pt. 3, pp. 326–338, figs. 8*).—Microscopical studies are reported of the seeds of a number of sorts of sorghum with a view to accumulating data for use in detecting the materials used to adulterate cattle feeds. A German translation [a] of this article has previously appeared.

American wheat screenings, A. L. WINTON (*Connecticut State Sta. Rpt. 1902, pt. 3, pp. 339–358, figs. 14*).—Noted from another source (E. S. R., 14, p. 1101).

Rôle of albuminoids in the nutrition of animals, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 6 (1903), No. 34, pp. 240, 241*).—A brief discussion of the nutritive value of protein and the protein requirement of different animals.

Feeding experiments with materials containing the pyrimidin group, H. STEUDEL (*Ztschr. Physiol. Chem., 39 (1903), No. 2, pp. 136–142*).—A brief account of an experiment in which a dog was fed pseudouric acid, isouric acid, etc.

Subcutaneous alimentation and bile formation, A. G. BARBERA (*Arch. Ital. Biol., 38 (1902), No. 3, pp. 447–455; abs. in British Med. Jour., 1903, No. 2229, Epit., pp. 43, 44*).—From experiments made with dogs the conclusion is drawn that the subcutaneous injection of nutritive material is of little value and does not compare at all favorably with the results obtained with rectal feeding.

The relation between body size and nutrient requirements in the case of dogs at rest and at work, B. SLOWTZOFF (*Arch. Physiol. [Pflüger], 95 (1903), No. 3–4, pp. 158–191*).—Experimenting with dogs the author determined the respiratory quotient under various conditions, with the special object of securing data regarding some of the fundamental principles of nutrition in relation to the production of work. The following conclusions were drawn: For motion of forward progression the work required for a uniform weight and distance is inversely proportional to the size of the animal. Metabolism is directly dependent upon the surface area of the animal in a condition of rest, although it appears that metabolism is not determined by this factor alone. During forward progression the energy expenditure is only approximately proportional to surface area and is affected by other factors which are not well understood. In climbing an incline the energy expenditure varies with different animals and no direct connection between it and body size was noted.

The effect of speed, body temperature, and training upon metabolism during rest and work, N. ZUNTZ (*Arch. Physiol. [Pflüger], 95 (1903), No. 3–4, pp. 192–208*).—On the basis of the experiments of B. Slowtzoff, noted above, and additional data from the author's experiments and those of other investigators, the effects on metabolism of speed, body temperature, and skill gained by practice are discussed, and the results obtained with man and the lower animals compared. According to the author it appears that with dogs speed does not markedly affect the amount of material required for unit distance covered, dogs differing in this respect from man and horses. When body temperature is increased the amount of material required for the resting body and for the work of respiration is also increased. On the other hand the muscles perform a definite piece of work with the same expenditure of force as at normal temperature.

[a] Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), p. 337.

The material required by the muscles for the performance of a definite piece of work is very markedly diminished by training. However, training does not induce a like saving when other sorts of work are performed. Any considerable training of the muscular system increases metabolism while the subject is at rest in the same way as does the consumption of an excessive amount of protein. The author notes that in the case of man and horses the amount of nutritive material required to raise 1 kgm. 1 meter in climbing an incline is about the same as in the case of dogs, being 2.96 kgm. as compared with 2.91 kgm.

Beef production in New England, J. W. SANBORN (*Massachusetts State Bd. Agr. Rpt. 1902, pp. 61–84*).—The possibilities for the development of the beef industry in New England are pointed out and considerable data are summarized. The paper is followed by a discussion.

Sheep, cattle, pigs, H. H. CHAPMAN (*Minnesota Sta. Bul. 81, pp. 239–244*).—In this discussion of the feeding and management of sheep, cattle, and pigs under local conditions, the experience gained at the Northeast Experiment Farm is especially drawn upon. Attention is particularly directed to the value of sheep for clearing brush from new land, and the fact is pointed out that although they will live entirely upon brush they can not make satisfactory gains under such conditions. In the experience of the station, sheep on brush alone become poor, lambs will not grow well, and the ewes fall off in milk yield, yet they will destroy it more quickly than when supplied with other feeds in addition. When it was desired to supplement brush, the sheep have been hurdled on such crops as corn, oats, clover, timothy, winter rye, and rape, grown in small fields in 5-year rotation.

Lamb feeding, J. W. WILSON and H. G. SKINNER (*South Dakota Sta. Bul. 80, pp. 3–22, fig. 1*).—The relative value of some grains recently introduced, namely, spelt and macaroni wheat, as compared with more staple grains, was studied with 9 lots each containing at the beginning of the trial 9 lambs weighing about 81 lbs. each and all about 9 months old. The advantage of grinding grain was also taken into account in the case of the spelt and the macaroni wheat, but as it was observed that when finely ground they were not relished, these grains were only cracked during the greater part of the trial. No attempt was made to feed a balanced ration, "but the conditions in every respect were such as should be provided by the average farmer." For the first 88 days of the trial all the lambs were fed prairie-grass hay in addition to grain and *Bromus inermis* hay during the remainder of the test. All the lots were kept in sheds with yards.

On the different grain rations the average daily gain per head during the 109 days of the trial were as follows: Corn 0.35 lb., wheat 0.37 lb., macaroni wheat 0.35 lb., whole spelt 0.35 lb., ground spelt 0.31 lb., corn and bran 0.37 lb., whole macaroni wheat and bran 0.34 lb., ground macaroni wheat and bran 0.31 lb., and whole spelt and bran 0.34 lb. The amount of grain eaten per pound of gain ranged from 4.6 lbs. with the lot fed corn to 6.8 lbs. with the lot fed whole spelt and bran; and the cost of a pound of gain from 4.1 cts. with the corn-fed lot to 6.5 cts. with the lot fed ground spelt.

Toward the close of the trial the lambs were sheared, the fleece ranging from 59 lbs. with the lot fed ground macaroni wheat and bran to 69 lbs. with the lot fed whole wheat. That shearing apparently had an effect on the gains made is shown by the fact that after shearing the average daily gain was 0.64 lb. per head as compared with 0.28 lb. per head before shearing. The lambs were sold in Chicago and were regarded as of superior quality. Some of the principal conclusions follow:

The gain was most cheaply made on whole corn, but the most uniform gain was made with whole wheat. Macaroni wheat and bread wheat proved of equal value as regards the gains made, but gain was more cheaply made on the former when fed whole than on the latter. Adding bran to the ration increased the cost of gain. Grinding grain was not profitable as it decreased the palatability of the ration and

therefore interfered with the gains. Less grain was consumed with *Bromus inermis* hay than with prairie-grass hay. The lambs were dipped before the feeding test and this was regarded as beneficial since it killed external parasites and improved the quality of the wool. Analyses are reported of the spelt and the wheats fed.

Fattening sheep on grass, J. W. WILSON and H. G. SKINNER (*South Dakota Sta. Bul. 80, pp. 23–27*).—To learn something of the possibility of utilizing partially dried pasturage, with and without grains, in the fattening of lambs for the early winter market, 6 lots of 10 common-grade ewes, from 1 to 6 years old and weighing about 120 lbs. each, were pastured from September 6 to November 2, each lot having the run of 2 acres of native prairie grass which had not that season been pastured or cut for hay. All the lots except one were fed grain, the sheep on corn and on oats each making an average daily gain of 0.44 lb. per head, those on bread wheat 0.31 lb., on spelt 0.29 lb., and on barley 0.38 lb. The grain eaten per pound of gain ranged from 3.9 lbs. with the corn-fed lot to 7.2 lbs. with the sheep on spelt, and the cost of a pound of gain from 3 cents on oats to 5.3 cents on bread wheat. With the sheep fed no grain there was a total loss of 52 lbs. During the last 2 weeks of the trial it was noted that the losses were about twice as great as during the preceding 2 weeks and that the gains made by the other lots were correspondingly lower during the same period. This was accounted for in part by the fact that the grass had been considerably injured by frost.

The authors state in effect that the natural condition of grasses in an average season is well suited to the economical production of mutton; but that when sheep are turned on a partially dried up prairie-grass pasture a gradual decrease in weight is to be expected in case there are unusually heavy rains during the fall, unless they are fed grain. The grains giving the best results (corn, oats, and barley) also give the largest yield and are widely grown.

Sheep feeding at Jemalong, A. A. DUNNICLIFFE (*Agr. Gaz. New South Wales, 14 (1903), No. 5, pp. 385–399, figs. 16*).—Under government supervision an experiment was carried out on a large scale, which demonstrated the possibility of profitably feeding sheep on crops grown on irrigated land in time of drought. In the test over 1,600 sheep were used. For 18 weeks they were fed alfalfa twice a day, an acre supplying the fodder for 75 sheep. The cost of production, including irrigation, cutting, interest on capital, etc., was found to be 25 cts. per ton of green fodder. The water for irrigating the alfalfa fields was pumped from a small stream.

Rearing and fattening of pigs, S. SPENCER (*Jour. Bd. Agr.* [*London*], *10 (1903), No. 1, pp. 1–16*).—A general summary.

Selecting and judging horses for market and breeding purposes, W. J. KENNEDY (*U. S. Dept. Agr. Yearbook 1902, pp. 455–468, fig. 1*).—The author discusses the possibilities of horse breeding in this country, and points out that under existing conditions there are at least four classes of horses which farmers can profitably produce—namely, heavy draft horses, carriage or coach horses, roadsters, and saddle horses.

Horse breeding in South Africa, C. H. BLACKBURNE (*Transvaal Agr. Jour., 1 (1903), No. 4, pp. 57–59, figs. 2*).—The need of high-grade sires is spoken of and methods of improving horses proposed, which include government aid. South Africa, in the author's opinion, affords a fine opportunity for extensive horse breeding.

Some inexpensive ways of making farm poultry more profitable, J. H. ROBINSON (*Massachusetts State Bd. Agr. Rpt. 1902, pp. 395–407*).—A general discussion.

Poultry culture in Ireland, H. DE COURCY (*Reliable Poultry Jour., 10 (1903), Nos. 5, pp. 534, 535; 6, p. 601; 7, p. 669; 7, Sup. p. VI, figs. 9*).—The poultry industry in Ireland is discussed with especial reference to the efforts made by the Irish agricultural societies for its development.

Distribution and magnitude of the poultry and egg industry, G. F. THOMP-

SON (*U. S. Dept. Agr. Yearbook 1902, pp. 295–308, dgm. 1*).—A statistical article based largely on publications issued by the U. S. Census Office.

Squab raising, W. E. RICE (*U. S. Dept. Agr., Farmers' Bul. 177, pp. 31, figs. 11*).—On the basis of personal experience pigeon raising is discussed with special reference to breeds and breeding, feeds, management, dressing, and marketing, and diseases, parasites, and remedies. Profitable pigeon raising, it is said, depends upon securing the right kind of stock, careful attention, and proper management. Homing pigeons and Dragoons are regarded as the best breeds, while a cross between the two is also favorably mentioned. A large house is better and more economical than several small ones, but in no case should accommodate more than 200 pairs. Pigeons require feed twice a day, the best sorts being cracked corn, red wheat, Kafir corn, millet, peas, hemp, and rice. The importance of varying the diet is insisted upon as well as plenty of pure water for drinking and bathing, and attention to the sanitary condition of houses, nests, and yards.

The educational value of live-stock exhibitions, G. M. ROMMEL (*U. S. Dept. Agr. Yearbook 1902, pp. 259–264*).—A general discussion of the subject emphasizing the fact that well-conducted exhibits are profitable both to the exhibitor and the spectator.

DAIRY FARMING—DAIRYING.

Records of individual cows on dairy farms, A. J. GLOVER (*Illinois Sta. Bul. 85, pp. 44, figs. 23*).—Farm tests were made of 8 different herds, containing in all 176 cows, records of 144 cows being obtained for a full year. Composite samples, representing 14 consecutive milkings, were obtained every seventh week and tested with the Babcock test. The necessary apparatus was furnished by the station. The different herds are described and illustrations are given of many of the cows. The rations fed are also given and commented upon.

The best individual record was 8,949 lbs. of milk and 472 lbs. of butter, and the poorest 1,482 lbs. of milk, and 68 lbs. of butter. With the exception of one improved herd the average production, considered as representing that of the ordinary cows in Illinois, was 4,721 lbs. of milk and 173 lbs. of fat, equivalent to 202 lbs. of butter. The most profitable cow gave a net return of $57.22, and the poorest was kept at a loss of $17.83. The average net profit per cow was $9.96.

Comparative feeding experiment with palm-nut cake and shea-nut cake, M. RIPPER (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 7, pp. 620–627*).—In a test with 8 cows lasting 6 weeks palm-nut cake was compared with shea-nut cake, the residue from the manufacture of shea butter from the seed of *Bassia latifolia*. The two feeding stuffs had practically equal value. No injurious effects upon the health of the cows due to feeding the shea-nut cake at the rate of 1.5 kg. per day were observed.

Jersey cattle, their feeding and management (*London: Vinton & Co., Ltd., 1903, 2 ed., rev. and enl., pp. 97*).—This book is compiled from information received from members of the English Jersey Cattle Society. The additions in this edition relate mainly to diseases, especially parasitic gastro-enteritis.

Experiments on the influence of different methods of milking on the yield and quality of milk, H. MITTELSTÄDT (*Abs. in Centbl. Agr. Chem., 32 (1903), No. 3, pp. 197–201*).—The experiments confirmed the results obtained in Denmark as to the value of the Hegelund method of milking, which is warmly recommended.

The milk supply of two hundred cities and towns, H. E. ALVORD and R. A. PEARSON (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 46, pp. 210*).—This bulletin gives descriptions of the milk supply of the 161 cities in the United States having a population of over 25,000 each, and of 39 selected cities and towns of smaller size. The statistical data collected are presented in a series of tables, and the legal

requirements relating to market milk in the different States and Territories are also compiled.

There is some supervision of the milk supply in practically all the cities of the United States having a population of over 50,000, while in the smaller cities and towns supervision is the exception rather than the rule. The methods followed vary widely as well as the character of the work performed. The inspection work consists for the most part of testing samples of milk for the content of fat and other solids. So far as the composition of the milk is concerned laws, ordinances, and regulations are considered quite well enforced, but beyond that their enforcement is very imperfect. In the discussion of the information presented in the bulletin many suggestions are made for the improvement of present conditions.

Economical methods for improving the keeping qualities of milk, C. F. Doane (*Maryland Sta. Bul. 88, pp. 117–164*).—The author discusses the source of bacteria in milk and practical means for controlling their growth, including in the bulletin the results of considerable original work consisting for the most part of tests of methods in common use.

Bacteria in milk are derived from the interior of the udder, from the exterior of the cow, from the milker, from the air, and from dairy utensils, nearly all of which sources can be regulated to a certain extent. The value of dampening the udder and flank before milking was shown by bacterial determinations in several trials. In cleansing utensils where steam is not available the author recommends the use of washing powders, the efficiency of this method having been shown in experiments reported in an earlier bulletin of the station.

In the purification of milk several tests were made with filters and separators. Milk filtered through animal charcoal which had been thoroughly washed in water was turned black, illustrating a difficulty in purifying milk by filtration as compared with purifying water. The use of separators for purifying milk by 2 city dairies failed to give satisfaction to consumers, the main objection being that milk so treated soured sooner than untreated milk. In 4 out of 5 trials made at the station the acidity of fresh samples of separated milk was found to be higher than that of unseparated samples, the difference in one instance being 0.03 per cent. The cause of this variation was not investigated. It is suggested, however, that it may be due to a change in the content of carbon dioxid, due to the process of separation. The results of the tests indicate that the use of the separator for purifying milk tends to lessen rather than improve its keeping qualities.

Determinations were made of the number of bacteria and the percentage of acid in aerated and unaerated milk. At the end of 24 hours there was no noticeable difference in the acid content, as shown by 11 trials conducted under ordinary dairy conditions. The development of bacteria was also unaffected to any marked extent by aeration. It is therefore believed that the keeping qualities of milk are not improved by aeration.

In a series of experiments the effect of cooling milk in different ways was studied. As the temperature of the well water in the State is commonly 60° F, this temperature was used as a basis for comparison. Milk cooled immediately to 60° was compared as regards acidity and germ content with milk cooled gradually by setting in running water at 60°. At the end of 5 hours the milk kept in running water had a temperature of about 64° when it was cooled quickly to 60° and both lots were kept at that temperature. In one of the four trials the milk cooled immediately remained in a condition fit for use 15 hours longer than the milk cooled gradually. In all trials the keeping qualities of the milk were improved by prompt cooling.

In the second experiment the keeping property of milk cooled immediately to 60° was compared with that of milk in a 5 gal. can set in a half barrel of water at 60°. At the end of 15 hours the milk set in standing water had a temperature of 66 to 74°, varying with weather conditions. It was then cooled to 60° and kept at that

temperature. The milk thus treated soured from 6 to 18 hours sooner than the control lots. Practically all the samples cooled immediately were fit for use at the end of 48 hours. In a third experiment milk cooled immediately to 60° was compared with milk cooled after standing for 2 hours, the results showing that the milk cooled immediately remained sweet for about 12 hours, on an average, longer than the milk not cooled until 2 hours after milking, illustrating the importance of prompt cooling.

Practical experiments were also made with the use of ice. A five gallon can of milk was set about 1 hour after milking in a half barrel of water to which a large piece of ice had been added, the temperature of the water being about 40°. This milk was compared with milk cooled within 15 minutes from the time of milking to 60° and kept at that temperature, the results showing no great advantage from the use of ice under these conditions. In other experiments it was found that from 2 to $2\frac{1}{2}$ hours were required for milk set in ice water to cool to 60°, and that such milk soured in some instances as much as 5 hours sooner than milk cooled immediately to 60°. In a second series of experiments similar to the above a temperature of 65° was used for comparison. Milk cooled immediately and kept at that temperature remained sweet for 30 to 35 hours, while milk not cooled other than by setting in water at 65° did not keep over 24 hours. The results of the work at 65° show the importance of prompt cooling and also that under ordinary conditions this temperature can not be depended upon in producing milk for city markets.

Milk set in a shotgun can in a refrigerator at 60° was found to have a temperature of 68 to 74° at the end of 15 hours, at which time the milk was on the point of turning. On the other hand, milk cooled immediately to the temperature of the refrigerator and kept at that temperature remained in good condition for about 50 hours.

After showing by the above practical experiments the need of keeping milk at a low temperature and particularly the need of cooling it immediately after milking, the author discusses the use of milk coolers, giving the results of several tests and also considers the use of refrigerators, preservatives, and the acid test.

During several weeks in the summer of 1902 determinations were made of the temperature, acidity, and bacterial content of milk as received at a large dairy in Baltimore, the data being tabulated and discussed along with observations on the shipping of milk over one of the railroads entering Baltimore.

Milk transportation: Freight rates to the largest fifteen cities in the United States, E. G. Ward, Jr. (*U. S. Dept. Agr., Division of Statistics Bul. 25, pp. 60*).—This bulletin contains not only transportation charges relating to milk, but descriptions of the different means of transportation employed and some general information regarding the milk supply of each city. About 850,000 gal. of milk and cream are required daily to supply the 15 cities. Considerable lack of uniformity was observed in the freight rates.

Clean milk, S. D. Belcher (*New York: Hardy Pub. Co., 1903, pp. 146, pls. 24*).—In the introduction to this book by W. H. Park the improvement of the milk supply and the transportation of milk are briefly discussed. The book itself is written from the standpoint of the bacteriologist and deals with means for lessening or preventing the contamination of milk. Such subjects as the construction and care of stables, the management of cows, milking, cleansing dairy utensils, handling and sale of milk, etc., are considered.

The sugar in the milk of the buffalo, C. Porcher (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 15, pp. 828–830*).—An examination of 2 samples from Italy and 2 from Egypt led the author to conclude that the sugar in buffalo's milk is identical with that in milk from other animals.

Butter industry in the Argentine Republic, E. W. Ames (*U. S. Consular Rpts., 73 (1903), No. 276, pp. 115–119*).—The exports in 1902 amounted to 9,021,020 lbs., nearly all of which was shipped to the United Kingdom.

Annual report of the experiment station for cheese making at Lodi, 1902 (*Ann. R. Staz. Sper. Caseif. Lodi, 1902, pp. 116*).—This contains a review of the work of the station during the year, the results of experiments on the utilization of skim milk in the feeding of calves, an account of the manufacture and composition of a full cream cheese of Lombardy designated Mascarpone, a discussion of the food value of margarine cheese, and notes on milk with inseparable fat on an instrument designated the coaguloscope, and on the progress of the dairy industry in Sardinia. Under the title of Milk with Inseparable Fat, G. Fascetti refers to a method of forcing milk through capillary spaces under a pressure of 250 atmospheres, which reduces the size of the fat globules and renders them incapable of rising to the surface on standing. In a sample of milk thus treated the fat showed no tendency to separate at any time, while an analysis showed the milk to be normal in composition. It is announced that a plant for the treatment of milk by this method is to be established at Lodi.

Dairying at home and abroad, H. E. Alvord (*U. S. Dept. Agr. Yearbook 1902, pp. 145–154, pls. 6*).—Dairying in different countries of Europe and in the United States are compared as regards breeds of dairy cattle, stabling, and feeding of cows, care and sale of milk, butter making, cheese making, etc. "While too much can not be said in praise of the industry, frugality, and thrift of most of the dairymen of Europe, a close comparison leads one to feel that the conditions of this industry in the United States are decidedly more satisfactory in almost every particular."

Dairying in Belgium (*Bul. Agr.* [*Brussels*], *19* (*1903*), *No. 3, pp. 327–389*).—This includes several papers as follows: History of the Dairy Industry, and Commerce in Dairy Products, by A. C. Bovy; Instruction in Dairying, by Devuyst; Cooperative Dairies, by O. Bolle; The Dairy Station of the Agricultural Institute, by M. Henseval; Construction of Dairy Apparatus, by J. Vandervaeren; and Notes on Breeds of Cattle, by G. Mullie.

Study of the societies for dairy control in Denmark and their possible organization in Switzerland, C. Bauverd (*Jour. Soc. Agr. Suisse Romande, 44* (*1903*), *No. 3, pp. 43–114*).

Elements of dairying, J. W. Decker (*Columbus, Ohio: Author, 1903, pp. 115, figs. 21*).—Introductory notes are given on the history and present status of the dairy industry, following which the secretion, composition, and physical properties of milk; butter and cheese; contamination of milk; testing cows; market milk; and dairy refrigeration are discussed in a popular manner, the results of considerable experiment station work being incorporated.

VETERINARY SCIENCE AND PRACTICE.

Text-book of veterinary medicine, J. Law (*Ithaca: Author, 1903, vol. 5, pp. 532*).—This constitutes the final volume of the author's text-book of veterinary medicine and is devoted to a discussion of parasites and parasitism. The general subject of parasitism is briefly discussed by way of an introduction to the volume. The various parasitic fungi and insects are arranged according to their systematic position and each parasite receives an elaborate discussion, together with an account of the symptoms of disease produced by it and the best treatment to be adopted in combating it. The plant parasites discussed in this volume include the organisms of ringworm, thrush, and Actinomycosis, as well as various forms of Aspergillus. The parasitic insects which are discussed in the volume include the majority of important forms recognized as injurious to domestic animals.

Elementary lectures on veterinary science, H. Thompson (*New York: W. R. Jenkins, 1903, pp. 397, pls. 51*).—This volume contains 12 lectures, together with 3 appendixes, and is intended for use in veterinary instruction in all institutions offer-

ing veterinary courses. The classification of the lectures is as follows: Introductory, including various anatomical and physiological data; bones; muscles; hoofs and shoeing; digestive organs; dentition; circulatory and lymphatic systems; respiratory organs; nervous diseases, including those of the special senses; skin diseases; and urinary diseases. The number of specific diseases of various sorts which are mentioned in the volume is sufficient to include all the more important ones. In the appendixes valuable information is furnished in a brief form regarding the nature of various diseases and treatment to be given; the nature of various medicines; formulas for preparing veterinary medicines, and a tabulated list of medicines with the usual size of doses for horse, sheep, pig, and dog.

Treatise on surgical therapeutics of domestic animals, P. J. Cadiot and J. Almy (*Traité de thérapeutique chirurgicale des animaux domestiques. Paris: Asselin & Houzeau, 1903, vol. 2, 2. ed., pp. 744, figs. 310*).—In this volume the authors present a detailed and critical discussion of diseases of the withers, back, loins, chest, abdomen, tail, legs, and feet. The diseases of the abdomen are classified according to the organ or parts affected. The pathological conditions and surgical instruments used in the treatment of these affections are well illustrated.

The formation of precipitates during agglutination, M. Löwit (*Centbl. Bakt. u. Par., 1. Abt., 34 (1903), Nos. 2, Orig., pp. 156–166; 3, Orig., pp. 251–259, pl. 1*).—The author attacked the problem of determining the nature of agglutination in bacterial cultures. It was found that a homogeneous connecting substance in varying quantities was always to be demonstrated in cases of agglutination. This connecting substance exhibited a considerable affinity for eosin and certain other stains, and could therefore be demonstrated with considerable ease. The author believes, therefore, that he has furnished morphological proof of the fact that the agglutination of bacteria is to be considered as essentially a process of precipitation. The author concludes that in cases of agglutination precipitates are formed in and upon the bacteria concerned and perhaps also in the surrounding fluid. The substance necessary for the formation of the precipitate is believed to come from the bacterial cells.

On the protective substances of immune sera, E. W. A. Walker (*Jour. Hyg. [Cambridge], 2 (1902), No. 1, pp. 85–100*).—The experiments reported in this paper were made with typhoid bacillus upon guinea pigs. The following results were obtained: The quantity of immune body required for protection against a given number of minimum lethal doses of the bacterial organism is in general an equal number of cubic centimeters of the immune serum. The complement is a leucocytic ferment not strictly specific. It is increased by the process of immunization.

The relationship between toxin and antitoxin, P. Eisenberg (*Centbl. Bakt. u. Par., 1. Abt., 34 (1903), No. 3, Orig., pp. 259–283*).—The literature of this subject is critically reviewed in connection with a bibliography. The author found during his investigations that the relative amount of toxin required for the neutralization of the antitoxin varied according to the total amount of the mixture. Where large quantities of each were used a relatively larger amount of toxin was required for the neutralization of the antitoxin.

Further contributions to the theory of bacteriolytic immunity, R. Pfeiffer and E. Friedberger (*Centbl. Bakt. u. Par., 34 (1903), No. 1, Orig., pp. 70–84*).—The authors' experiments as reported in this article were concerned chiefly with the formation of immune bodies antagonistic to bacteriological amboceptors, with special reference to the vibrio of cholera. During these experiments it was found that in the serum of an animal treated with the immune serum of cholera, antiamboceptors arise which attack the cytophilous group of the amboceptors. The antiamboceptors possess no affinity for the receptors of the cholera vibrio. Antiamboceptors are relatively stable bodies which are not destroyed by subjection to 60° C. for ½ hour.

Experimental studies on disinfection by means of formaldehyde and steam, H. Herzog (*Centbl. Bakt. u. Par., 1. Abt., 34 (1903), No. 2, Orig., pp. 170–187, figs. 2*).—

During the experiments reported in this paper it was found that the disinfectant action of steam was considerably increased by the presence of formaldehyde fumes. Spores of *Bacillus mesentericus*, which resisted the action of steam for a period of 145 minutes, were destroyed within 10 to 15 minutes when a 0.1 per cent formaldehyde solution was allowed to act simultaneously with the steam. Similar results were obtained in experiments with anthrax spores. Attention is called to the fact that by the use of a combination of steam and formaldehyde it is possible to destroy the most resistant spores at a temperature which is harmless for substances such as leather, silk, etc.

The parasites of man and domestic animals, E. PERRONCITO (*I parassiti dell 'uomo e degli animali utili. Milan: Francesco Vallardi, 1901, pp. 632, pls. 25, figs. 276*).—A brief account is given of parasitism in general with notes on the pathogenic bacteria of greatest importance. The greater part of the volume is occupied with a discussion of animal parasites, the diseases caused by them, and methods of prevention and cure of infestation by these parasites. Animal parasites are discussed in a systematic manner according to their position in the usual scheme of zoological classification. The groups which are discussed include protozoa of various families, tapeworms, fluke worms, nematodes, mites, insects, etc. The more important species are illustrated and reference to the various subjects is made easy by means of a subject and author index.

The dry-rot fungus, a pathogenic parasite of man and animals, with special regard to its action in causing cancerous tumors, A. KLUG (*Der Hausschwamm ein pathogener Parasit des menschlichen und tierischen Organismus, speziell seine Eigenschaft als Erreger von Krebsgeschwülsten. Freiheit-Johannisbad: Author, 1903, pp. 139, figs. 44*).—An elaborate investigation was made for the purpose of determining the relationship between *Merulius lacrymans* and cancerous tumors in man and animals. A large number of cancerous growths of various forms were studied in human patients and the spores of this fungus were found in the tumerous growths. Experiments were made in inoculating rabbits, 15 of these animals being used during the progress of the investigation. All of the rabbits were killed within from 14 to 240 days after inoculation and were subjected to careful post-mortem examination. It was found as a result of these experiments that the dry rot fungus is capable of living as a parasite in animal tissue and that the meruliocytes obtained from tumors thus produced were identical with those obtained from the germination of basidiospores of the dry-rot fungus.

Observations on the flagella of the tetanus bacillus, S. DE GRANDI (*Centbl. Bakt. u. Par., 1. Abt., 34 (1903), No. 2, Orig., pp. 97–108, figs. 11*).—A detailed description is given of the flagella of the tetanus bacillus as they appear after treatment by various staining methods, and notes are presented on the microscopic technique which is required for demonstrating the flagella.

A means of preventing tetanus, E. THIERRY (*Jour. Agr. Prat., n. ser., 6 (1903), No. 27, pp. 23, 24*).—It was found that the antitetanic serum could be desiccated to the form of a powder and that its active properties could be preserved in this form for a long period.

A short historical report on the veterinary service from 1898 to 1903 and on the veterinary sanitation in St. Petersburg, S. I. SAMBORSKI (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), No. 4, pp. 417–442*).—In this article the author presents an account of the organization of veterinary service and sanitation in St. Petersburg, with special reference to the prevention of the spread of animal diseases to man through the uncontrolled prevalence of animal plagues and through the use of the meat and milk of diseased animals.

Division of veterinary science, J. A. GILRUTH (*New Zealand Dept. Agr. Rpt. 1902, pp. 219–326, pls. 25, figs. 7*).—A short account is given of the equipment of the laboratory of the bacteriologist and on the work done in this laboratory during the

season. The author discusses the slaughtering and inspection act of New Zealand and describes a number of abattoirs and the methods of slaughtering and inspecting meat. Notes are given on the condition of horses selected for military service and on the chief defects found in these animals. The author advocates the compulsory registry of all veterinary practitioners in the Colony.

During the year three outbreaks of anthrax occurred at widely separated localities. It is feared that unless special care is exercised to prevent the further introduction of anthrax in bones used for fertilizing purposes and otherwise New Zealand will become extensively infested with this disease.

The total number of cattle inspected during the year was 80,987, and of this number 3,919, or 4.8 per cent, were found to be tuberculous. This percentage of tuberculosis was found among cattle which had never been stabled or handled, and indicates the possibility of the spread of the disease under range conditions. Notes are given on tuberculosis of the larynx in cattle and on tuberculosis in fowls. A number of outbreaks of the latter kind was observed during the year. Considerable loss was suffered from abortion, and this was believed to be of a contagious nature in every case and not due to ergot.

Hog cholera had not been observed for a year, but broke out again under conditions which precluded a knowledge of the source of infection. Notes are given on blackleg and pseudotuberculosis in sheep. The pathological anatomy and symptoms of pseudotuberculosis are described in detail, and an organism was isolated with which inoculation experiments were made in sheep, guinea pigs, rabbits, and calves. The disease affects all these animals and also goats. In its pathology the disease resembles tuberculosis and glanders.

An outbreak of a disease resembling braxy occurred among sheep which were fed on turnips. Post-mortem examinations were made, and the symptoms and lesions of the disease are described. An organism was isolated from diseased animals and inoculation experiments were made on sheep and guinea pigs. The disease is apparently due to a specific micro-organism which differs from any other previously observed by the author. The chief symptoms of braxy are not present. There is no striking odor immediately after death, and very little gas in the cultures of the bacilli.

A form of gangrenous mammitis was observed in sheep. It proved to be contagious and due to a specific micro-organism. No curative treatment was successful. Notes are given on a number of parasites of sheep, including lung and stomach worms, botflies, tapeworms, liver flukes, *Cœnurus cerebralis*, etc. The predisposing causes of infestation by these parasites are considered to be the following: Drinking stagnant water; constitutional weakness of the sheep; presence of the parasites in swampy, undrained lands; want of care in weaning; overstocking, and insufficient nutrition. Experiments with intratracheal injections of carbolic acid, turpentine, chloroform, olive oil, and doses of turpentine and oil indicated that these remedies are of little use.

The author believes that the most rational method of prevention and cure for the lung and stomach worms consists in the provision of a generous diet. Cirrhosis of the liver in horses and cattle was investigated by the author, and was found to be connected in some way with the ingestion of *Senecio jacobæus*. The disease appeared only in animals which had eaten this plant. Notes are also given on a number of diseases, including among others the following: Omphalitis in colts, paralysis in salmon and trout, epithelioma of salmon, septic pleurisy in sheep, actinomycosis and a considerable variety of tumors in domesticated animals.

Semiannual report of the chief of the cattle bureau, A. Peters (*Massachusetts State Bd. Agr. Rpt. 1902, pp. 321–378*).—As usual in these reports, the author presents a financial statement showing the expenses of the cattle bureau in the work of eradicating infectious diseases, the payment of indemnities for animals, etc. A large number of tuberculin tests were made for the purpose of determining the extent

of tuberculosis in the State. During the progress of this work 898 cattle were condemned, killed, and indemnities paid to the owners. A few experiments were made bearing upon the question of identity of human and bovine tuberculosis. These experiments were made by Dr. Theobald Smith. Four young cattle were inoculated with tubercle bacilli of human and bovine origin. The autopsies indicated that the disease in the animals which were inoculated by bacilli of apparently bovine origin was much more virulent than in the others. The experiments, while not completed, indicated that the disease in children from which tubercle bacilli were obtained was of bovine origin. A number of cases of actinomycosis is reported.

An elaborate review is recorded of the outbreak of the foot-and-mouth disease which has recently prevailed in Massachusetts and neighboring States. In the warfare which was waged for the eradication of this plague the Massachusetts cattle bureau cooperated with this Department. Copies are presented of the various orders which were issued by the cattle bureau and by the Bureau of Animal Industry. The number of animals killed by the Bureau of Animal Industry was 1,848, and the indemnity paid for these animals was $62,050.25. This indemity was estimated at 70 per cent of the value of the cattle killed. A few cases of Texas fever occurred at Wellesley, the animals having been imported from Michigan. No outbreak of anthrax was reported, but a few cases of blackleg occurred.

Considerable attention is devoted to a discussion of the problem of glanders in Massachusetts. This disease appears to be on the increase in spite of all the efforts which are being put forth to control it. It is estimated that the annual loss in the State from this disease is about $60,000. The total number of cases on record is 1,027, which is an increase of more than 100 over the number reported for the previous year. Mallein has been used more extensively than ever in the identification of the disease. Brief notes are also presented on contagious diseases of swine, nodular disease of sheep, stomach worms in sheep, and rabies.

Governmental protection against animal plagues, B. Plehn (*Der staatliche Schutz gegen Viehseuchen. Berlin: August Hirschwald, 1903, pp. 549*).—In this volume the author has brought together copies of German laws and regulations regarding the control and eradication of rinderpest, swine plague, influenza of horses, and other dangerous contagious diseases of domesticated animals, together with a discussion of the importance and effects of these laws. Reference to the various subjects discussed in the laws is made easy by the addition of a detailed index. In an appendix to the volume, Froehner gives an account of the nature, symptoms, and treatment of the various diseases mentioned in the German laws.

Some diseases of cattle, C. A. Cary and F. G. Matthews (*Alabama College Sta. Bul. 125, pp. 105–168, figs. 15*).—Notes are given on the nature, symptoms, and economic importance of cow pox, varicella, furunculosis, obstructions to the flow of milk, dysentery in young animals, acute indigestion in cattle, abortion, milk fever, and mammitis. Feeding experiments were made with *Kalmia latifolia*. A cow, a calf, and one horse were fed various quantities of the leaves of this plant, and all of the animals manifested decided symptoms of poisoning. The symptoms included an increase in the rate of pulse and respiration, together with disturbances of temperature and muscular convulsion. Whisky is recommended as a stimulant in cases of poisoning from this plant, and Epsom salts as a purgative. Similar symptoms were produced as a result of eating the leaves of *Æsculus pavia*. Brief notes are given on poisonous plants which contain hydrocyanic acid. These plants include various species of the genus Prunus, as well as sorghum. A number of cases of poisoning are reported from Alabama. *Phytolacca decandra* is said to produce symptoms of poisoning, which include chills, fever, and headache. When applied to the skin a decoction of this plant acted as a blister.

Extensive experiments in the antiseptic treatment of aborting cows indicated that this method is of little avail in the control of abortion. It is suggested that the bac-

terial organism which causes the disease is located in the uterus as well as in the vagina, and that therefore the ordinary antiseptic washes are insufficient for destroying infection. It is suggested that the expensive method of gradually establishing immunity in a herd of cattle may in the end be the cheapest method of controlling this disease.

Studies on natural and artificial immunity to anthrax, O. BAIL and A. PETTERSSON (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), Nos. 5, Orig., pp. 343–353; 8, Orig., pp. 610–612; 10, Orig., pp. 756–762; 34 (1903), No. 2, Orig., pp. 167–170*).—An elaborate study was made of the reactions observed in the blood of different animals to infection with anthrax. Special attention was given to the study of the antagonistic action of rabbit and dog serum toward anthrax bacillus. Notes are given on the location of the complement in the body of rabbits. As a result of experiments carried on by the authors it was found that the mere power of the serum to undergo an increase in its immunizing properties by the addition of normal rabbit serum containing some complement has no apparent connection with natural immunity to anthrax on the part of the animal from which the blood was obtained. A test was made to determine whether the serum of various animals could be fortified by the addition of leucocytes and tissue cells from rabbits. In these experiments it was found that the organs of rabbits from which the blood had been removed exercised no influence in an indifferent fluid upon anthrax bacilli. The authors believe, therefore, that the immune body and the complement do not exist simultaneously in rabbits, or at least not to a high degree. The property of fortifying the sera of other animals appears to exist chiefly in the blood and to a less degree in the polynuclear leucocytes. A study was also made of the reaction of horse and rat sera to anthrax bacilli, and of the quantity of immune body in the normal sera of different animals.

Anthrax, A. R. WARD (*California Sta. Circ. 4, pp. 3*).—Brief notes on the symptoms and post-mortem appearances of this disease, with an account of vaccination.

Blackleg, A. R. WARD (*California Sta. Circ. 2, pp. 3*).—Brief notes on the symptoms, post-mortem changes, etiology, treatment, and vaccination for this disease.

The inoculability of human tuberculosis upon bovines, D. J. HAMILTON (*British Med. Jour., 1903, No. 2228, pp. 565, 566*).—This article is of a controversial nature and in it the author presents arguments in support of the correctness of the results obtained in his previous experiments, during which it was shown that cattle could be inoculated with tubercle bacilli of human origin.

The present warfare against tuberculosis of domesticated animals, O. MALM (*Norsk Vet. Tidsskr., 15 (1903), No. 2, pp. 33–75*).—In this article the author presents a summary account of the methods employed in combating bovine tuberculosis in Denmark, Norway, Sweden, Finland, Germany, and other parts of Europe, and the United States. The method of immunization recently proposed by Behring is critically discussed. The author concludes from his review of this subject that no system of immunization thus far suggested can be relied upon to give satisfactory results under ordinary conditions. It is recommended, therefore, that the warfare against bovine tuberculosis be continued along present lines, viz, by the extensive use of tuberculin and quarantining infected animals.

Foot-and-mouth disease, D. E. SALMON (*U. S. Dept. Agr. Yearbook 1902, pp. 643–658, fig. 1*).—The author presents a historical account of the recent outbreak of this disease in the United States. Notes are given on the distribution of the disease at various times during the outbreak, and on the measures which were adopted for controlling it. The disease was confined to Massachusetts, New Hampshire, Vermont, and Rhode Island, and affected 220 herds of cattle containing 4,175 animals. The total compensation paid by the Government as indemnity for slaughtered animals of all kinds was $120,007.47.

Foot-and-mouth disease, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 22 (1903), No. 6, pp. 681–684*).—The symptoms, cause, means of distribution, and treatment of

this disease are briefly discussed, with special reference to recent outbreaks of the disease.

Serum therapy in foot-and-mouth disease, E. NOCARD (*Jour. Agricole* [*Paris*], *14* (*1903*), *No. 161, pp. 137–141*).—This is a copy of the report made at a general agricultural congress in Paris. The method of applying this treatment is outlined and the advantages and disadvantages are mentioned. It is stated that the immunity persists for not longer than 15 days, and that at the end of that time the animals are as susceptible to the disease as before treatment.

The serotherapy of foot-and-mouth disease, E. NOCARD (*Bul. Agr. Algérie et Tunisie, 9* (*1903*), *No. 12, pp. 275–280*).—Brief notes are given on the successful application of serotherapy in the treatment of various diseases of animals and man. In the treatment of foot-and-mouth disease the results from the use of serum have been much less satisfactory, but the author believes that a more lasting immunity will ultimately be produced by this method.

Report on the cattle disease in southern Rhodesia, R. KOCH (*Agr. Jour. and Min. Rec.* [*Natal*], *6* (*1903*), *Nos. 10, pp. 313–319; 12, pp. 401–405*).—A careful investigation of the virulent form of Texas fever, or redwater, which has long been known in Rhodesia, led the author to the conclusion that this disease, while closely related to Texas fever, is quite distinct from it.

The author observed a number of constant differences between Texas fever and the form of the disease which prevails in Rhodesia. In the latter form of the disease the red blood corpuscles are more abundantly infected with the blood parasites, but the destruction of the blood corpuscles is very slight as compared with that which is observed in cases of Texas fever. It was only in a few instances that the number of red blood corpuscles per cubic millimeter was reduced to 4,500,000.

An examination of animals dead of the Rhodesian fever discloses certain post-mortem changes which are absent in cases of Texas fever. These changes consist in lesions in certain organs which indicate that parasites become accumulated in these parts in enormous numbers. In a number of cases it was possible to determine definitely that the animals were simultanously affected with Texas fever and Rhodesian fever. The small parasites of the Rhodesian, or African Coast fever, as the author calls it, were present in the blood, together with larger pyriform organisms of Texas fever.

Another striking difference between Texas fever and Rhodesian fever was observed in the fact that direct inoculation of healthy animals with the blood of animals affected with Rhodesian fever does not produce infection from the first inoculation but only after a second inoculation. It was observed that the animals which were immune to Texas fever were very subject to Rhodesian fever, but it was found possible to produce immunity to the Rhodesian form of the disease by inoculation with the blood of animals infected by this form.

The cattle disease in southern Rhodesia, R. KOCH (*Transvaal Agr. Jour., 1* (*1903*), *No. 4, pp. 112–117*).—A circumstantial account is given of the conditions which prevail in the infested territory. The symptoms of the Rhodesian tick fever are said to be very similar to those of Texas fever. The rate of mortality is very high, in some outbreaks 80 to 90 per cent. The blood parasites are considerably smaller than in the case of Texas fever and in the early stages of the disease are not very numerous. The destruction of red corpuscles is by no means so great as in Texas fever. There is therefore a much less pronounced anemia than is usually observed in Texas fever. Extensive experiments have been planned for the purpose of developing a successful method of inoculation and the author hopes for satisfactory results from these experiments.

The Rhodesian tick fever, A. THEILER (*Transvaal Agr. Jour., 1* (*1903*), *No. 4, pp. 93–110, pl. 1*).—The name "Rhodesian tick fever" is proposed to differentiate this form of protozoan disease from the less malignant Texas fever of the United

States. A historical account is given of the occurrence and distribution of the disease in South Africa. The organism of the disease is a species of pyroplasma closely related to that of Texas fever and exhibiting bacillary and coccal forms. The organism was readily found in the blood of infected animals. The shortest period of incubation observed was 10 days and the longest 20 days. The average course of the fever occupied about 13 days, and the period from infection to death about 25 days. The symptoms and post-mortem lesions are described in detail and notes are given on the history of various cases and on extensive inoculation experiments with the blood of affected animals. The tick which is believed to be instrumental in carrying the disease is *Rhipicephalus shipleyi*, commonly known as the brown tick. Inoculation experiments were unsuccessful on account of the fact that under ordinary circumstances the blood of affected animals does not produce the disease when inoculated into healthy ones. In a few instances it was observed that animals which had recovered from one attack of Rhodesian tick fever were still susceptible to the disease.

The new form of redwater in the Transvaal, D. HUTCHEON (*Transvaal Agr. Jour., 1 (1903), No. 3, pp. 45–57*).—A brief account is presented of the work of Koch and Theiler on this subject. Notes are also given on the history of the disease in Rhodesia and the Transvaal. The disease is undoubtedly carried by ticks and the author recommends quarantining known infected centers and the use of an arsenical dip for the destruction of ticks. While little good can be expected from the use of drugs in the treatment of this disease, fairly satisfactory results have been observed by the author in a number of cases from the use of carbolic acid and certain coal-tar derivatives. Carbolic acid was given, thoroughly mixed with raw linseed oil. Attention is called to the failure which has attended attempts to immunize cattle by inoculation with the blood of animals recovered from Texas fever. It is necessary to use blood from animals recovered from the more virulent form of the disease which prevails in South Africa.

Rinderpest and redwater in cattle, S. STOCKMAN (*Transvaal Agr. Jour., 1 (1903), No. 4, pp. 59–63*).—The author conducted an elaborate series of experiments for the purpose of determining whether animals could be infected with these 2 diseases simultaneously and whether the lesions caused by the 2 diseases could be readily distinguished. As a result of these investigations it was found that animals are frequently attacked by both diseases at the same time, and that the extensive intestinal lesions which had been attributed by some writers to an attack of redwater were really the result of infection by rinderpest. During experiments made by the author in the production of rinderpest serum a number of animals was inoculated with the virus of rinderpest and one of these animals developed redwater in addition to rinderpest. Inoculation of other animals with the blood of these animals produced rinderpest only in animals which were immune to redwater, while both diseases developed in animals which were susceptible to both. The author concludes from his experiments that the possible coexistence of rinderpest and redwater must be admitted, and that this fact should be borne in mind in experiments with rinderpest serum, or in inoculation experiments for the purpose of preventing redwater.

Redwater inoculation, L. D. GILSON (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 10, pp. 310–312*).—Excellent results are reported from inoculation experiments during which the defibrinated blood of diseased animals was used for inoculating susceptible animals.

Virulent redwater in the Transvaal, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 23 (1903), No. 1, pp. 39–60*).—The author presents a detailed report of his investigations regarding the history, distribution, cause, nature, and treatment of the virulent form of Texas fever observed in the Transvaal. It is believed that this disease is identical with that reported in Rhodesia. The author observed that cattle which had been immunized against Texas fever were still subject to the virulent

form of the disease prevailing in the Transvaal. It is believed, however, that healthy animals may be successfully immunized against the virulent form of the disease, by using blood of animals which have recovered from this disease, under the usual precautions which are recognized as necessary to the success of such inoculation experiments.

Rinderpest in Cape Colony (*Agr. Jour. Cape Good Hope, 23 (1903), No. 1, pp. 70–82, pls. 5*).—This article deals chiefly with an account of the serum station at Aliwal North. Two extensive outbreaks of rinderpest have occurred in Cape Colony and the disease has been stamped out in both instances with considerable rapidity by inoculation of healthy animals with the serum or bile of recovered or diseased animals. Detailed notes are given on the methods employed at the Aliwal North station in preparing serum and bile, and of the treatment and management of infected herds.

A note on tick infestation, C. P. LOUNSBURY (*Transvaal Agr. Jour., 1 (1903), No. 4, pp. 11, 12*).—Experiments are in progress to determine the species of ticks which are concerned in carrying the virulent form of Texas fever which prevails in South Africa. According to determinations made by G. Neumann, *Rhipicephalus shipleyi* and *R. simus* are instrumental in carrying this disease. The author believes, however, that these determinations are only preliminary and may be shown to be incorrect after a larger amount of material is examined.

A bacterial form of bovine piroplasmosis, A. LAVERAN (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 11, pp. 648–653, figs. 18*).—The bacterial form of *Piroplasma bigeminum* was sent from Rhodesia to the author by Theiler. This organism is described in detail and notes are given on its prevalence in the cases of Texas fever which have recently been investigated in Rhodesia. The form of Texas fever which prevails there is unusually virulent. The organism is considered as a variety of the ordinary specific form. The possibility is suggested of this being a new species of piroplasma and the suggestion is based on the fact of its unusual virulence and peculiar symptoms manifested in affected cattle.

Spirillosis in Bovidæ, A. LAVERAN (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 16, pp. 939–941, fig. 1*).—A species of Spirillum was found in the blood of cattle in the Transvaal. The author describes this organism in detail. The cattle in which the organism was found were also affected with Texas fever and the pathogenic action of the Spirillum therefore remains doubtful.

Lamziekte and impaction of the third stomach, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 23 (1903), No. 1, pp. 25–28*).—Lamziekte is described as a lameness or nervous affection in cattle which may be due to congestion of the liver. The symptoms of the disease are described in detail. Impaction of the third stomach is described with especial reference to the cause and treatment of this trouble.

Indigestion and diarrhea in calves, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 22 (1903), No. 6, pp. 669–681*).—The author describes in detail the symptoms, etiology, and treatment of diarrhea due to sudden changes of diet or to intestinal parasites, as well as infectious diarrhea or so-called white scour in calves. A brief discussion is also presented on the subject of liver disease in calves.

Contagious abortion in cows, J. LAW (*California Sta. Circ. 5, pp. 13*).—A popular account of the forms of abortion, together with a discussion of the etiology, symptoms, prevention, and treatment of this disease.

Sterility in cattle and sheep (*Agr. Jour. Cape Good Hope, 22 (1903), No. 6, pp. 658–661*).—A brief discussion is given on the possible action of salt in causing sterility. It is not believed that any such effect can be produced by salt under ordinary conditions. Brief notes are also given on the veterinary use of Stockholm tar.

Plants injurious to stock, C. W. PETERSON (*Rpt. Dept. Agr. Northwest Territories, 1902, pp. 33–44*).—Notes are given on *Pulsatilla hirsutissima*, spear grass, common horsetail, oat smut, ergot, larkspur, corn cockle, Thermopsis, lupines, loco weed, chokecherry, water hemlock, sneezeweed, death camas, *Solanum triflorum*, and

other plants which are known or suspected of having caused poisoning among cattle, sheep, and horses.

Loco weed, L. E. SAYRE (*Trans. Kansas Acad. Sci., 18 (1901–2), pp. 141–144*).—A number of experiments are reported in which feeding tests were made with *Astragalus mollissimus.* The plant was not found to be uniformly poisonous—in fact, in some instances, no effects whatever were produced by eating it. A brief account is given of the various theories which have been suggested in explanation of loco disease.

Rot in sheep (*Jour. Bd. Agr. [London], 10 (1903), No. 1, pp. 22–26, fig. 1*).—Brief notes on the life history of the liver fluke, together with an account of the symptoms of infestation by this worm, and a discussion of preventive and remedial measures.

Contagious gangrenous mammitis in sheep, J. A. GILRUTH (*New Zealand Dept. Agr. Leaflets for Farmers, No. 63, pp. 4*).—An investigation of this disease disclosed the fact that it is of an infectious nature and is caused by a specific organism of the Coccus type. Inoculation experiments showed that the disease could be transmitted through the milk sinus. No direct curative treatment is practical and the only method of controlling the disease consists in stamping out the infection and the use of preventive remedies.

Parasites in sheep, J. A. GILRUTH (*New Zealand Dept. Agr. Leaflets for Farmers, No. 64, pp. 10*).—Notes on stomach and lung worms, tapeworms, liver flukes, and other parasitic worms of sheep, together with a discussion of the predisposing factors of the infection by these worms and a brief statement of the remedies commonly recommended for destroying the pests.

Damaged wool and its relation to sheep dips, S. B. HOLLINGS (*Bradford, England: William Byles & Sons, 1903, pp. 15*).—The author made an extensive investigation of the relationship between sheep dips and damaged wool. These investigations covered the greater part of Europe, Australia, Tasmania, etc. It was found that as a rule the low prices paid for inferior grades of wool were due to injury from the use of certain dips. The lime and sulphur dip is condemned as always injurious. It was found to cause trouble in scouring, dyeing, and weaving of the wool. This dip is said to have been abandoned in Australia, Tasmania, the Argentine Republic, Ireland, and certain other sheep-raising countries.

Tobacco dips were found to stain the wool in a large percentage of cases, except where sheep were dipped immediately after shearing. Tobacco dips are objected to furthermore on the ground of injurious action upon the sheep. Carbolic dips, and especially pitch oil, formerly used in Scotland, are condemned as causing considerable injury to the wool staple, except when properly made. The author believes that arsenical dips are effective in curing scab, and his investigations indicate that these dips cause the least injury to wool when properly prepared and applied. If, however, an excess of either alkali or arsenic be present in the dip as a result of careless preparation or inaccurate measurements of ingredients, great harm results to the wool.

The author recommends that no home-made arsenical or carbolic dips be used, on account of the careless methods which are so frequently observed on farms and ranches. On the other hand, arsenical dips, when accurately made, so as to avoid any excess of either alkali or arsenic, are recommended as safe and as least liable of all dips to cause serious harm to the color or structure of the wool fiber.

Takosis, a contagious disease of goats, J. R. MOHLER and H. J. WASHBURN (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 45, pp. 44, pls. 5*).—An extensive outbreak of an apparently new disease occurred among Angora goats in Pennsylvania during December, 1901, and was investigated by the authors. While the common goat is comparatively refractory to ordinary diseases, the authors believe that the

Angora has developed "a perceptible retrogradation in vitality and power of resistance against diseases."

An outbreak occurred on premises where goats had been maintained for a number of years, but the greater part of the flock had recently been purchased in Texas. The symptoms of the disease were great emaciation and weakness, combined with diarrhea, pneumonia, and a considerable elevation of temperature. Rumination continued and the appetite persisted fairly good. The disease assumed either a subacute or chronic type, and its course varied from 8 days to 6 or 8 weeks. Young goats appeared to be most susceptible. The visible mucous membranes are pale in cases of this disease, and the lungs exhibit an extensive inflammation. The heart is pale and shows inflamed areas. The spleen is somewhat atrophied.

Cultures made from the heart, lungs, spleen, liver, and mediastinal lymphatic glands showed the presence of a new organism, which is described under the name *Micrococcus caprinus.* It occurs either singly or in chains of 2, 3, or 4 elements. No capsules were observed on the organism. This organism develops as an aerobe, but may also occur under anaerobic conditions. The growth of the organism on various culture media is described in detail. It did not produce gas, and the indol test gave negative results. The organism was killed by exposure for 6 minutes at a temperature of 62° C. and desiccation for 12 hours, and subsequent exposure to diffuse light for 9 days, destroyed its virulence. Low temperatures had no effect upon the organism. It was killed, however, by exposure for 26 minutes to a solution of bichlorid of mercury in the proportion of 1 to 2,000, or for 57 minutes to a 1 per cent solution of carbolic acid, or for 31 minutes to a 2 per cent solution of formalin. Inoculation experiments showed that the organism was pathogenic for goats, chickens, rabbits, guinea pigs, and white mice, but not for sheep, dogs, or rats.

A toxin was obtained from cultures of the pathogenic organism, which was destroyed by subjection to heat, but which, when inoculated without being subjected to heat, produced considerable immunity in the animals thus treated. The number of red blood corpuscles was not diminished during the progress of the disease. Medicinal treatment was as a rule unsatisfactory, but in certain cases encouraging results were obtained from the administration of calomel, followed by powders containing arsenic, iron, and quinine. The authors believe that the method of immunization devised by them will give good results on a large scale when further perfected.

Hog cholera, A. R. WARD (*California Sta. Circ. 3, pp. 6*).—A short account of the symptoms, methods of distribution, treatment, and quarantine regulations for hog cholera.

Glanders in the camel under conditions of natural and artificial infection, A. P. PETROVSKI (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), Nos. 2, pp. 103–150; 3, pp. 274–295; 4, pp. 383–416; 5, pp. 511–539*).—The eradication of glanders among camels is an important economic problem in certain parts of the Russian Empire on account of the large numbers of camels which are raised and the considerable percentage of infection with glanders. The author made an extended investigation of the conditions under which natural infection takes place in camels, and conducted a number of experiments in artificial infection for the purpose of determining the susceptibility of camels to the disease, and the possibility of protecting them by means of repeated injections of mallein and serum of glanderous horses. The experiments have thus far not led to results which can serve as a practical working basis regarding the treatment of glanders.

Experiments in the treatment of glanders, and immunization of cats and guinea pigs against this disease, M. LAVINOVICH (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), No. 3, pp. 211–226*).—The author discusses the subject of the treatment of glanders, in connection with a bibliography of 34 titles. The experiments reported by the author indicate that a considerable degree of immunization may be conferred upon cats and guinea pigs by repeated injections of the serum from glanderous ani-

mals. The author believes that the methods which he employed may be extended to the treatment of horse and man for the same disease.

Disinfection of stables in cases of glanders, A. THEILER (*Transvaal Agr. Jour., 1 (1903), No. 3, pp. 16, 17*).—The recommendations offered by the author include the immediate isolation and quarantine of glanderous horses, the thorough cleaning and disinfection, by burning and the use of various antiseptic substances, of all bedding, harness, stalls, and utensils which may have become infected from the glanderous animals.

Contagious skin diseases of the horse, A. THEILER (*Transvaal Agr. Jour., 1 (1903), No. 3, pp. 14–16*).—Notes on Sarcoptes, Dermatocoptes, and Dermatophagus as causes of different kinds of mange in horses. The remedies recommended for the treatment of mangy horses include carbolic acid, creolin, benzine, kerosene, tar, tobacco, sulphur, etc.

Post-mortem diagnosis of rabies according to the method of Nélis, A. V. BYELITZER (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), Nos. 4, pp. 347–382; 5, pp. 463–492, figs. 3*).—During the experiments recorded in this paper, the author found that by the method of Nélis it is possible to make a rapid diagnosis of rabies in dogs in all cases of natural death from this disease and in the majority of cases in which the animals were killed during the progress of the disease. In horses, cattle, sheep, and hogs dead of rabies the changes in the ganglion nodosum, although sufficiently conspicuous to permit a diagnosis, are of less importance than they are in dogs. A post-mortem diagnosis of the early stages of rabies in the larger domesticated animals from an examination of the ganglion nodosum is exceedingly difficult. The superior cervical ganglion is commonly affected in rabies less extensively than the ganglion nodosum, although the changes in it are identical with those which occur in the latter. The alterations in the nerve ganglia in cases of rabies do not begin with a proliferation of the endothelial capsule of the nerve cells, but with an infiltration of cellular elements of connective tissue. The author believes that all positive results obtained in examination of supposed cases of rabies according to the method of Nélis may be confidently relied upon.

Experimental investigations in the diagnosis of rabies, A. AUJESZKY (*Veterinarius, 25 (1902), No. 18, pp. 550–554*).—The author made a study of the brain of 63 animals and 1 man suspected of being infected with rabies. Of the 64 cases, the investigation was without results in 12, while in 10 it was shown that the animals were not affected with rabies. The incubation period in the 42 cases in which positive results were obtained averaged 16 days after subdural inoculation and 19 days after intramuscular inoculation. The course of the disease after the appearances of pronounced symptoms was from 3 to 6 days. It was shown during these experiments that subdural inoculation is much more certain than intramuscular.

Trichorrhexis nodosa, with special regard to its etiology and treatment, TENNERT (*Ztschr. Veterinärk., 14 (1902), No. 8–9, pp. 361–372, figs. 5*).—The literature of this subject is reviewed in connection with a brief bibliography. The author believes that the name of this disease has been used incorrectly in many instances in cases of other closely related skin diseases. Detailed notes are given on the pathological anatomy of the disease and on the symptoms by which it may be recognized. The disease is due to the attacks of a micro-organism similar to that which produces favus.

Some diseases of poultry in South Africa, HUNEBERG (*Transvaal Agr. Jour., 1 (1903), No. 4, pp. 65–67*).—Serious digestive disturbances are said to occur in fowls after excessive feeding with corn or fermented cereals. Notes are also given on roup, gapes, and eye diseases in young chickens.

An epizootic among ducks with diphtheria bacilli upon the conjunctiva, KAMPMANN ET AL. (*Centbl. Bakt. u. Par., 1 Abt., 34 (1903), No. 3, Orig., pp. 214–[illegible]*).—A report is made upon an outbreak of an apparently new disease among ducks. This

disease affected a large number of ducks and was fatal in about 25 per cent of cases. One of the more characteristic symptoms of the disease was an intense conjunctivitis with the formation of a purulent discharge. An organism was isolated from the material obtained from the eyes of affected ducks and it was found to resemble closely the diphtheria bacillus. Notes are given on the growth of this organism on various nutrient media. Inoculation experiments with white mice and other experimental animals were without positive results.

The chicken mite, J. J. Repp (*Iowa Sta. Bul. 69, pp. 285–294, figs. 2*).—*Dermanyssus gallinæ* is said to be one of the most formidable enemies of chickens in Iowa. Sitting hens often die on the nest from excessive infestation with this mite, and a mortality as high as 90 per cent is reported in young chicks. The mite is described in its various stages. The author tried experiments in ridding henhouses by means of fire applied with a torch. The attempt, however, was unsuccessful, since it is impossible to apply sufficient heat to kill the mites without running the risk of setting the henhouse on fire. The best results were obtained from spraying with kerosene emulsion diluted with 10 volumes soft water. Three applications should be made in succession on the same day. After 2 or 3 days, when the eggs have hatched, another crop of mites will appear and the spraying should be repeated. The extermination of the mites may be hastened by dusting the fowls with pyrethrum powder while the spraying experiments are going on. Incidentally it was observed that all of the eggs of the chicken mite which are moistened by the kerosene emulsion are killed by this insecticide.

The fowl tick, C. P. Lounsbury (*Agr. Jour. Cape Good Hope, 23 (1903), No. 3, pp. 261–273, pls. 3*).—The fowl tick of South Africa is *Argas persicus*. The author worked out anew the details of the life history of this pest and describes the tick in its various stages. All stages of the tick were found to be capable of living many weeks without food or drink. The tick infests chickens, ducks, geese, and turkeys, and is believed to cause more serious depredations than has been supposed. The remedies recommended for controlling the tick include destruction by insecticides applied to infested birds, insecticide methods applied to roosts and to poultry houses, and isolation of roosts and nests by means of special methods of construction or by the use of repellants.

Index-catalogue of medical and veterinary zoology, C. W. Stiles and A. Hassall (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 39, pts. 3, pp. 199–324; 4, pp. 325–403; 5, pp. 404–435*).—An alphabetical list of authors whose names begin with the letters C, D, and E.

Bibliotheca veterinaria, R. Klee (*Leipzig: Hermann Seemann Nachfolger, 1901, pp. 247*).—In this volume the author has made an attempt to present a list of veterinary works produced in Germany, either in a book form or in periodicals, up to the present time. The list is arranged alphabetically according to authors, and the volume is provided with an alphabetical list of important catchwords with references to the main text of the book.

AGRICULTURAL ENGINEERING.

Some engineering features of drainage, C. G. Elliott (*U. S. Dept. Agr. Yearbook, 1902, pp. 231–244, pl. 1, figs. 2*).—A discussion of some general features of drainage illustrated by plans made by the author for the drainage of lands near Greeley, Colo., swamped by excessive irrigation. "Sufficient work has been done in Colorado to demonstrate that judicious drainage will reclaim lands already saturated; that it will prevent the rise of alkali, and that land which has become water-logged and injured by alkali may by this means be restored to its former productiveness."

Drainage of irrigated land, E. McCullough (*Engineer. News, 50 (1903), No. 8,

pp. 158–160).—Referring to the work of this Department the author discusses the need and methods of drainage to relieve the land of excess of alkali and water.

The proper disposal of sewerage wastes in rural districts so as to prevent the spread of intestinal parasitic diseases, J. NELSON (*New Jersey Stas. Bul. 166, p. 15*).—This bulletin discusses sewerage and earth-closet systems of sewage disposal, kinds of sewage wastes, decomposition of sewage as a natural method of disposal, bacterial parasites, how disease germs are spread, the biology of parasitism, prevention of dissemination of parasitic germs, cesspool *v.* sewer gas, disease caused by improper disposal, and the proper construction of an earth closet.

The irrigation commission's report, C. SCOTT-MONCRIEFF ET AL. (*Indian Agr., 28* (*1903*), *No. 9, pp. 277–280*).—The concluding chapter, which summarizes this report, is quoted. The report describes "the present state and the extent of irrigation in India, its use and value in increasing the produce of the land and in affording protection against famine, the scope that still remains for its future expansion, both by public and private works, and the limitations to such expansion which are imposed by physical and financial considerations . . . [as well] as the possibility of utilizing artesian sources of supply, the classification and financing of State irrigation works, the provision of the additional establishment required for their construction and subsequent maintenance, the methods of charging for canal water, the value of agricultural experiments in connection with practical irrigation, and the future preparation and maintenance of programmes of famine relief works."

After considering the present status and future extension of large and small State works, private works are taken up and it is shown that "out of a gross area of 44 million acres annually irrigated in British India 25½ millions, or 58 per cent, are irrigated by private works." It is maintained that as great an increase in the irrigated area may be effected "by assisting and stimulating the development of private works as by constructing new State works. For greater protection against famine reliance must be placed, not only on new State irrigation works, but also on the extension of irrigation by means of private works. . . .

"The general geological conditions of India, and the results attained by the utilization of artesian waters in other countries where the conditions are more favorable, render it certain that the area which can be irrigated from these sources must always be comparatively insignificant." Programmes of relief works are outlined and administrative measures required are discussed.

Practical irrigation a success in Florida (*Forestry and Irrig., 9* (*1903*), *No. 9, pp. 435–442, figs. 3*).—"The districts in which irrigation is practiced are widely scattered. Commencing in the extreme northwestern portion, they extend through the central part, with numerous areas on the east and Gulf coasts. In northwest Florida irrigation is applied in the growing of Sumatra tobacco, while in other sections it is utilized in the cultivation of truck and small-fruit farms, orange groves, pineries, and nurseries. The water for irrigation is obtained from streams, lakes, and nonflowing wells, by various pumping devices, or from artesian wells having a strong surface flow. . . .

"In 1902 irrigation was reported from 405 farms, the irrigated area being 3,772 acres and the irrigation systems representing a constructive outlay of $512,859. The total artificially watered area producing crops was 3,313 acres and the value of the crops grown thereon was $1,432,530, an average of $432 per acre. The irrigation systems cost $446,569, an average of $135 per acre. There were 56 farms, having an irrigated area of 459 acres, which did not produce crops in 1902, the land being in young orange trees. The cost of constructing irrigation systems supplying these farms was $66,290. There were also reported 25 irrigation plants, costing $26,658, that were not operated in 1902."

Irrigation at Bundaberg (*Queensland Agr. Jour., 12* (*1903*), *No. 6, pp. 373–384,*

pls. 9).—A report of an irrigation reconnoissance of this district of Queensland, showing present status and possibilities of future development.

The use of alkaline and saline waters for irrigation, T. H. MEANS (*U. S. Dept. Agr., Bureau of Soils Circ. 10, pp. 4*).—Observations are reported which show that in the Algerian oases artesian water containing as high as 800 parts of soluble salts (largely sodium chlorid) per 100,000 is successfully used in the irrigation, not only of dates, but also of deciduous fruits, garden vegetables, and alfalfa. Accumulation of alkali in the soil is prevented by frequent and large applications of water. Analyses of 3 samples of the artesian water are reported.

The water supply of Australia, W. G. COX (*Proc. Roy. Colon. Inst., 33 (1901–2), pp. 35–49*).—In summing up the author states "that, as regards rainfall, Australia is similarly conditioned to other semitropical and tropical countries; that, as regards irrigation from rivers, the Darling-Murray system—which never runs dry—affords the best promise of future success; that the other rivers, and the creeks of the great plains of the interior, are not so well adapted for irrigation, unless at a cost for conservation reservoirs, which will be, in all probability, prohibitive for a long time to come; that, as regards subterranean supplies, the official figures given show the great present outflow, the bulk of which has been running continuously for years—in one State alone; and when the enormous quantity of water stored up in the ground at disposal is considered, and that that water is being tapped at a comparatively low cost for its value, and that it can be obtained in self-discharging quantities at any point required within the artesian areas, thus obviating expensive pumping from rivers or reservoirs and long-distance channeling, it is . . . . fair to claim that Australia can not be deemed . . . . a drought-stricken land. In the near future, when a much larger flow is obtained from artesian sources, the effects of droughts will be further neutralized."

Use of mineral oil in road improvement, J. W. ABBOTT (*U. S. Dept. Agr. Yearbook 1902, pp. 439–454, pls. 3, figs. 4*).—Experience in California is described, the general applicability of the use of oil is discussed, and methods are described. The use of oil is said to be applicable wherever "through long, hot, dry summers the roads become very dusty, and where water can be kept out of their foundations in the winter, so that they will remain firm and not give way beneath the oiled surface in the spring."

Thrashing machinery in Russia, C. J. ZINTHEO (*Amer. Thresherman, 6 (1903), No. 5, p. 4, figs. 4*).—A brief account of primitive methods still largely in use, of the introduction of English machines, and of the chance for the introduction of American machinery.

MISCELLANEOUS.

Yearbook of the Department of Agriculture, 1902 (*U. S. Dept. Agr. Yearbook 1902, pp. 912, pls. 87, figs. 62*).—The Yearbook for 1902, prepared on the same general plan as previous Yearbooks, includes the report of the Secretary on the operations of the Department during the year, 37 miscellaneous articles noted elsewhere, and an appendix consisting of the usual summary of information on various subjects of interest to the farmer.

Some practical results of experiment station work, W. H. BEAL (*U. S. Dept. Agr. Yearbook 1902, pp. 589–606*).—A large number of specific examples are given to show the character and extent of the influence of the experiment stations in the United States upon agricultural practice.

Systems of farm management in the United States, W. J. SPILLMAN (*U. S. Dept. Agr. Yearbook 1902, pp. 343–364, figs. 4*).—The author describes types of farm management designated live-stock farming, grain and hay farming, and nonhumus farming, and discusses their distribution in the United States. Selected farms repre-

senting subtypes of live-stock farming are described. These include a general live-stock farm in Illinois, a dairy farm in Indiana, and a sheep farm in Ohio. "The study commenced in this paper will be continued, and publications showing the methods of management pursued on different types of farms in all the principal agricultural sections of the country are under consideration."

Statistics of the land-grant colleges and agricultural experiment stations in the United States for the year ended June 30, 1902 (*U. S. Dept. Agr., Office of Experiment Stations Bul. 128, pp. 38*).—These statistics relate to the courses of study at the agricultural colleges, number of students in attendance, value of permanent funds and equipment, revenues for the year, etc.; and the lines of work and publications of the experiment stations, their revenues, additions to equipment, and classification of expenditures for the fiscal year. The total number of experiment stations in the United States is 60, exclusive of substations, and of these 55 receive the benefit of the Hatch Act. The total income of the stations during 1902 was $1,328,847.37, of which $720,000 was received from the National Government. In addition to this, the Office of Experiment Stations had an appropriation of $139,000, including $12,000 each for the Alaska, Hawaii, and Porto Rico experiment stations, $20,000 for nutrition investigations, and $50,000 for irrigation investigations.

The stations employ 710 persons in the work of administration and inquiry, 364 of whom do more or less teaching in the colleges with which the stations are connected. During the year they published 373 annual reports and bulletins, which were supplied to over half a million addresses on the regular mailing lists.

Instruction in agronomy at some agricultural colleges, A. C. TRUE and D. J. CROSBY (*U. S. Dept. Agr., Office of Experiment Stations Bul. 127, pp. 85, pls. 17, figs. 22*).—This bulletin contains a brief review of the work of the committee on methods of teaching agriculture of the Association of American Agricultural Colleges and Experiment Stations, with extracts from the reports of that committee, and detailed descriptions of the courses in agronomy in the agricultural colleges in Alabama, Illinois, Michigan, Minnesota, Nebraska, and Ohio, and the agricultural institute of the University of Göttingen, Germany.

Progress in secondary education in agriculture, A. C. TRUE (*U. S. Dept. Agr. Yearbook 1902, pp. 481–500, pls. 2*).—This is a review of the progress that is being made in secondary education in agriculture in the United States. The present status of the high schools as regards industrial education is set forth, the schools of agriculture of the universities of Minnesota and Nebraska and the agricultural high schools in Wisconsin and other States are described, and suggestions are made for courses in agriculture in the public high schools.

The serious problem of obtaining teachers properly qualified to give instruction in agriculture in high schools is also considered, and the advantages to be derived from high school courses in agriculture are pointed out. "Technical education has proved a sure road to commercial development and greatly increased wealth in connection with every industry which has received its benefits. It will prove equally so as regards agriculture. The tremendously productive results which have already come from the work of the agricultural colleges and experiment stations may be multiplied a hundredfold by the education of hundreds of thousands of the flower of rural youth in secondary schools in which there is definite and systematic teaching of the technique and scientific principles of agriculture."

Primary commercial education in Germany, E. L. HARRIS (*U. S. Consular Rpts., 72 (1903), No. 273, pp. 190–199*).—Statistical information on this subject.

NOTES.

Connecticut State Station.—E. Monroe Bailey has been appointed assistant chemist.

Florida College and Station.—F. S. Stringer and F. M. Simonton have succeeded J. D. Callaway and L. Harrison on the governing board. F. C. Reimer has succeeded Miss Lucia McCulloch as assistant in botany; and W. E. Worthington has been appointed assistant in field and feeding experiments, and R. H. Lichtenthaeler second assistant chemist.

Hawaii Federal Station.—Jared G. Smith, director, has returned to Washington for a few weeks for conference on the work of the station.

Hawaii Sugar Station.—An additional laboratory building has been erected and equipped for analytical work on sugarhouse products. Firman Thompson, formerly of the Queensland Sugar Experiment Station, and A. E. Jordan have been added to the station staff as assistant chemists.

Idaho College and Station.—H. T. Condon has resigned as clerk of the station, and is succeeded by W. G. Harrison. It has been decided to add an agronomist to the station staff, to take up work in plant breeding and soil physics; and a bacteriological laboratory will soon be established in connection with the department of botany. A number of Shorthorn cattle will be purchased in the East to increase the present herd, the last legislature having made an appropriation of $3,000 for this purpose.

Illinois College.—The enrollment for the fall term includes a total of 290 students in the agricultural courses, an increase of more than 75 over last fall. The majority come better prepared this year and a larger number will take the four-year course. The graduating class this year will be as large, if not larger, than the entire number of agricultural students five years ago.

Iowa College and Station.—Thomas S. Hunt has been appointed assistant in field experiments to succeed Alfred Atkinson who resigned some months since to take up editorial work. Howard R. Watkins is now assistant in agricultural chemistry in the college. The new live-stock and grain-judging pavilion is nearing completion. The building is octagonal in form, 65 ft. in diameter, 2 stories high, and built of pressed brick, with steel girders and slate roof. The lower floor will be used for animal husbandry work, and the upper floor connected with the agronomy rooms of the experiment station barn and used for corn and grain judging and demonstration. The cost of this building when completed will be about $15,000.

Kentucky Station.—E. P. Taylor, assistant agriculturist and botanist, has resigned.

Minnesota College and Station.—John Thompson, assistant in agriculture at the college and station, has resigned to take up editorial work on a farm paper at Des Moines, Iowa. F. J. Wojta, assistant in agriculture at the college, has also resigned.

Montana College and Station.—V. K. Chesnut, of the Bureau of Plant Industry, this Department, has been selected to succeed F. W. Traphagen as chemist to the college and station, and will enter upon his work there in January or February; and W. J. Elliott, a graduate of the Ontario Agricultural College, who has spent some time in Minnesota in connection with the dairy industry, has been appointed assistant in the dairy work of the college and station.

Nebraska Station.—W. P. Snyder has been appointed assistant in animal husbandry in the station. The substation in the western portion of the State provided for by the last legislature has been located at North Platte, on a tract of 1,920 acres of land lying 3 miles south of the city. The function of the substation under the law is to conduct experiments on the adaptability of the arid and semiarid portions of the State to agriculture, horticulture, and forest tree growing. Tests will also be made of the effect of resting pastures and of summer and winter grazing on the carrying capacity of the range, about 1,500 acres of the tract acquired being rough grazing land. Work will be taken up at the substation early next spring.

New Hampshire College and Station.—J. C. Bridwell, recently connected with the Division of Entomology of this Department, has become instructor in botany and zoology in the college and assistant entomologist in the station. New greenhouses for the department of horticulture are in process of construction, an appropriation of $7,000 having been made by the State for this purpose.

New Jersey Stations.—George A. Billings has succeeded C. B. Lane in the position of dairy husbandman.

Cornell University.—In connection with the reorganization of the college of agriculture, John L. Stone has been made assistant professor of agronomy, S. W. Fletcher assistant professor of extension teaching in agriculture, and James E. Rice assistant professor of poultry husbandry. The latter is believed to be the first professorship of poultry husbandry established in this country.

Ohio University.—The enrollment of the college of agriculture is 207, an increase of 20 over the fall term of last year. Of these 101 are new students and 123 are in the long course, 75 being in the short course, 7 special students, and 2 post graduates.

Rhode Island Station.—B. L. Hartwell, formerly first assistant chemist of the station, has been made associate chemist.

South Dakota College and Station.—W. A. Wheeler, formerly connected with the Minnesota College of Agriculture, has been appointed botanist in the college and station to succeed D. A. Saunders, who has been granted indefinite leave of absence. Investigations in making macaroni and curing it under different conditions have been recently undertaken by the chemical department of the station.

Texas College and Station.—F. S. Johnston has been elected station agriculturist, vice B. C. Pittuck, who, as previously noted, has gone to Louisiana; and F. R. Marshall, recently of the Iowa College and Station, has been elected associate professor of animal husbandry. J. K. Robertson has been made superintendent of the Beeville Station, vice S. A. McHenry; and W. S. Hotchkiss, of Illinois, superintendent of the Troupe Station, which for some months past has been under the direction of E. C. Green, of the horticultural department. H. H. Harrington has been given a year's leave of absence for travel and study in Europe. R. L. Bennett, recently director of the Arkansas Station, has been elected superintendent of farmers' institutes. The contract has been let for a dairy barn to cost $8,000.

Washington College.—R. K. Beattie has been appointed acting professor of botany, vice C. V. Piper, who, as previously noted, has accepted a position in this Department.

Wisconsin University.—G. N. Knapp has been appointed assistant professor of agricultural engineering in the college of agriculture, in accordance with provision made for this new department by the last legislature. He is now connected with the United States Geological Survey, but will enter upon his new duties next March.

West Virginia Station.—T. C. Johnson has been appointed assistant horticulturist of the station.

Cotton Boll Weevil Convention.—A convention attended by 1,200 officials, farmers, and business men, with delegates from the Southern States and from Chicago and New York, was held at Dallas, November 5–6. The object of the convention was to consider ways and means of averting the danger to the cotton interests from the ravages of the cotton-boll weevil. The Secretary of Agriculture, B. T. Galloway, A. L.

Quaintance, S. J. Hunter, H. J. Webber, and others from this Department, delivered addresses, and stereopticon lectures were given during the evening on the boll weevil, the bollworm, and root rot. There were numerous testimonials as to the effectiveness of proper cultural methods. Resolutions were adopted urging intensive culture of cotton by approved methods and diversification, and calling on organizations of the State to encourage the adoption of tested methods by farmers. A permanent organization was formed with George N. Aldredge, of Dallas, as president, and J. H. Connell, secretary. The proceedings of the convention are to be published.

Meeting of American Public Health Association.—The thirty-first annual meeting of this association was held in this city October 26–30. A number of the papers had a more or less immediate bearing upon agriculture, and are briefly noted.

D. E. Salmon presented a report of the committee on animal diseases and food, the main part of which was occupied with a discussion of the relationship between human and bovine tuberculosis. The conclusion from the paper and from the discussion which followed was that these forms are mere varieties of one disease and are intertransmissible between man and animals. M. P. Ravenel pointed out that the transmission of tuberculosis from man to animals, and vice versa, had been shown by numerous direct experiments and clinical observations. The bovine bacillus was stated to be from 25 to 30 times as virulent as the human bacillus as a rule, although human bacilli have been found of considerable virulence for various animals. Successful experiments by the speaker in transmitting the disease from man to various species of animals were reported. Thirty-eight cases were cited in proof of the possibility of infection of man through ingestion of tuberculous milk and meat, and post-mortem statistics on intestinal tuberculosis in children as related to the drinking of tuberculous milk were discussed. The speaker briefly referred to experiments, the results of which have not yet been published, which show that infection of the lungs and lymphatic glands may be produced by ingestion of tubercle bacilli without the development of intestinal lesions. In dogs fed on butter mixed with tubercle bacilli, the bacilli were found in the chyle within 3½ hours after feeding in 8 out of 10 cases.

Problems connected with the disposal of garbage and other refuse were discussed by a number of speakers. The use of these materials for feeding pigs and for fertilizer was shown to be quite common, especially in small cities. Several of the speakers spoke favorably of the use of garbage for feeding pigs, but the general opinion seemed to be that for large cities the burning of such materials is often less expensive and preferable from a sanitary standpoint. In Memphis, where a furnace 50 ft. long has been constructed for destroying garbage, the expense thus far has averaged 15 cts. per ton, which is believed to be cheaper than feeding it to pigs. Attention was called to the utilization of heat from burning garbage and waste material in the form of steam power. From statistics obtained in England it appears that 1 ton of such refuse furnishes 40 horsepower hours of energy. The temperature in the destructors should not be 400 or 500° F., but preferably 3,000° F. It was pointed out that certain animal refuse may yield considerable revenue when treated for the extraction of oil, and that in Cleveland a digestor is in use for the removal of fats from fish refuse, which yields a revenue of from $30 to $40 a ton, the residue being burned or sold as a fertilizer.

The purification of water by filtration was discussed by M. O. Leighton. The speaker gave a historical account of filtration, and stated that the results have shown that most impurities, including typhoid bacilli, are removed by it. His conclusions regarding the value of filtration were based on analytical evidence and on the eradication of typhoid fever in different localities. Statistics from European and American cities were favorable to filtration. It was stated that many filter plants in America are defective in construction.

Considerable attention was given to a general discussion of the yellow-fever problem, with special reference to the agency of *Stegomyia fasciata* in carrying the disease, the habits and life history of this mosquito, its location in different parts of the world, and the means of destroying it.

The general subject of disinfectants was discussed and attention was called to the importance of killing insects in infected premises as a part of the process of disinfection after the prevalence of infectious diseases. Steam, formalin, hot carbonate of soda, and tobacco were recommended, and also hydrocyanic-acid gas. The latter has proved very effective in the destruction of bedbugs, cockroaches, mosquitoes, fleas, rats, and mice. Quite striking differences were reported in the resisting power of different insects and animals to this gas. For most insects it was recommended that 20 gm. of potassium cyanid be used per cubic meter of space. Certain enamel paints have been found to possess a considerable germicidal power which persists for a long period.

Havana, Cuba, was chosen as the next place of meeting, and the following officers were elected: President, C. J. Finlay; first vice-president, J. R. Monjaras; second vice-president, W. C. Woodward; treasurer, F. W. Wright; and secretary, C. O. Probst.

New Experiment Station in the Philippine Islands.—Press reports state that Governor Taft has issued a proclamation setting aside Government land adjacent to the towns of Trinidad and Baguio, in the province of Benguet, for an experiment station. This action is in accordance with the recommendations of Prof. F. L. Scribner in his report last year. Attention has repeatedly been called to the exceptionally fine climate and other natural advantages of this province, which make it well suited to the growing of a great variety of agricultural plants. An especially fine coffee is produced there, the bushes coming into bearing in 3 years. Professor Scribner says: "In the gardens of the governor of the province one sees healthy coffee trees loaded with berries, vigorous growing tea plants, hothouse gardenia, caladiums, dracænas, frangi pani, and mango trees, all plants of the Tropics; also phila tree ferns, scarlet hibiscus, passion fruit, begonias, hydrangeas, and many others of the subtropical regions, while near by are potatoes and other garden vegetables, monthly roses and pines, strictly plants of the temperate zone. Probably in no other part of the world could there be grown side by side the gorgeous vegetation of the Tropics and the pines of temperate regions, orchards of coffee, celery, and Irish potatoes."

Lord Rosebery's Experiment Station at Dalmeny Park.—It appears from information furnished by Mr. D. W. May that the Earl of Rosebery has for several years maintained a private experiment station at his estate of Dalmeny Park, 6 miles from Edinburgh. The experiments are carried on in the interest of the estate, which comprises about 6,000 acres. The work is mainly of a quite practical character and is carried on by the men in charge of the various departments, no trained specialists being employed. Experiments are made with fertilizers for different crops, especially in the use of lime and in studying the residual effects of fertilizers. The combating of plant diseases also receives attention. Plant selection is practiced, especially with the potato to develop varieties, as the whole crop of potatoes is sold for seed. Considerable work is done in feeding cattle for the market and in crossing Aberdeen Angus and Galloway with the Shorthorn, pure-bred stock being used in all cases. While not of a scientific character, the results of the station's work have proved very helpful as a guide to good practice. No publications are issued.

Improvement of Agriculture in Bombay.—An influentially signed memorial on the subject of the improvement of agriculture was recently sent to the government of Bombay, and is summarized by *Nature* from the *Pioneer Mail*. The memorialists propose that two botanic gardens should be established, one at Poona and one near Bombay, the former as the center of investigation for the Deccan, and the latter for the Konkan and Gujarat. Each garden should be provided with a herbarium and

with chemical and botanical laboratories, and to each should be attached a farm for agricultural and horticultural experiments. It is suggested that the number of the experiment stations should be increased and the scope of the experiments extended; that local bodies should be encouraged by grants to aid in conducting experiments on lines prescribed by the department; that publicity should be given to the work of the department, and results of practical interest should be communicated through leaflets printed in the vernacular; that further measures for the improvement of agricultural stock should be taken by the State; and that the forest department should be invited to cooperate with the agricultural department in the work of experimenting with products likely to succeed in forest areas.

New Horticultural and Agricultural Terms.—This subject is discussed by H. J. Webber in a recent article in *Science*, who points out the need of a suitable term to apply to plants which are propagated vegetatively by buds, grafts, cuttings, suckers, runners, slips, bulbs, tubers, etc. "The plants grown from such vegetative parts are not individuals in the ordinary sense, but are simply transplanted parts of the same individual, and in heredity and in all biological and physiological senses such plants are the same individual." Last year he suggested the word "strace," a combination of the words "strain" and "race," but he now recommends the term "clon," which he believes to be better suited to the purpose. The generic term variety would then include in cultivation groups known as "races," "strains," and "clons." He also believes the phrase "transmitting power," as applied to the faculty which an individual organism has of transmitting its individual peculiarities to its progeny, to be preferable to "prepotency," which has several other meanings.

Training of Rural Teachers.—The legislature of Michigan at its last session provided for the establishment of 10 county normal schools for the training of rural teachers in that State. The first of these schools is to be established at Standish, Arenac County.

Personal Mention.—Prof. E. W. Hilgard, of the California University and Station, celebrated the fiftieth anniversary of his graduation as doctor of philosophy on October 7. On that occasion he received from the University of Heidelberg a new diploma reconferring the title and giving a general summary of the scientific work done by him, with the congratulations of the faculty. Professor Hilgard was also presented with a congratulatory address from his colleagues of the University of California.

Frederick Law Olmsted has been appointed to the chair of landscape architecture in Harvard University known as the Charles Eliot professorship, in honor of President Eliot's son.

Otto Luebkert, Assistant Forester and Chief of the Division of Records of the Bureau of Forestry, who has been connected with the forestry work of this Department for the past 13 years, has resigned his position to engage in commercial lines.

We note from *Science* that W. J. Palmer, a graduate of the Ontario Agricultural College, has been appointed director of agriculture in the Orange River Colony at a salary of $6,000 per annum.

H. Maxwell Lefroy has, according to *Nature*, been appointed entomologist to the government of India, and will be stationed at Surat, in the Bombay Presidency, pending the establishment of the permanent headquarters of the imperial agricultural department now being organized under the orders of Lord Curzon.

Prof. L. H. Uillier has been made director of the meteorological observatory at Nantes.

S. I. Kuwana, who recently spent several years in study in this country, has been appointed entomologist at the Central Agricultural Experiment Station at Nishigahara, near Tokyo.

Prof. Julius Stoklasa, formerly director of the plant-physiological institute at Prague, has been called to the technical high school at Vienna.

Prof. A. D. Hall, director of the Rothamsted Experiment Station, is delivering a course of lectures to advanced students in the University of London on the subject of The Relation of the Composition of the Plant to the Soil in which it Grows.

Miscellaneous.—A State hygienic laboratory has been organized in Wisconsin in accordance with the legislative enactment of last winter. The laboratory is located at Madison, in connection with the bacteriological department of the university, and is under the directorship of Dr. H. L. Russell. G. J. Marquette has been appointed first assistant in the new laboratory.

By recent legislation certain powers relative to the fishing industry in Great Britain have been transferred to the Board of Agriculture, which will hereafter be known as the Board of Agriculture and Fisheries. An additional assistant secretary is provided for to have charge of the fishery interests, and Walter Edward Archer, formerly chief inspector of fisheries under the Board of Trade, has been appointed to that position.

Announcement is made that the first meeting of the Society for Horticultural Science will be held in St. Louis during convocation week, in connection with the meeting of the American Association for the Advancement of Science.

The American Conference on Tuberculosis will be held at Washington, April 4–6, 1905, and not at St. Louis in 1904, as previously arranged. This will avoid clashing with the International Congress on Tuberculosis to be held in Paris in 1904.

An international competition of apparatus for the pasteurization of milk is to be held at the Imperial Agricultural Museum, in St. Petersburg, in the spring of 1904, under the direction of the minister of agriculture and imperial domains. The competition is open to apparatus of foreign make. Prizes of 1,500 rubles ($772.50) and 500 rubles ($257.50) are offered.

Our Farmer Youth and the Public Schools is the title of an article by Prof. Willet M. Hays, of Minnesota, in the *American Monthly Review of Reviews* for October. The article deals with the movement to provide better educational facilities for the country boy, especially in the things which pertain to his prospective vocation. The plan of consolidated rural schools and agricultural high schools is described, and, leading out from these, the collegiate courses in agriculture. One of the benefits mentioned which may be expected to result from this system of education for the farmer is successful cooperation in many matters of mutual interest. The possibilities in this direction are illustrated by the cooperative enterprises carried on by associations of graduates from such schools and colleges in a number of States. "With the assistance of a large body of ex-students, organized to promote cooperative business, social, and other merged efforts among farmers, the agricultural college, agricultural high schools, and experiment stations would be profoundly influential in civic as well as in educational affairs."

An Introduction to Nature Study, by E. Stenhouse, is a new book on the teaching of nature study, or elementary agriculture and rural economy, intended primarily for the orientation and systematic guidance of teachers who take up this subject. It is designed for teachers who are lacking in training for this work and who have not gained from previous books on the subject a true conception of what nature study is. It serves as a guide to the methods to be followed, and gives detailed directions for carrying out simple experiments within the reach of school-teachers. The book is published in London by Macmillan & Co., and contains over 400 pages.

O

EXPERIMENT STATION RECORD.

VOL. XV. DECEMBER, 1903. No. 4.

The report of the Secretary of Agriculture should prove an interesting document to all who are concerned, even in a general way, with the progress of agriculture in the fields of both investigation and education. It gives more attention to matters relating to agricultural education and the training of specialists than any previous report. The opening paragraph deals with the Department as a training ground or post-graduate institution for experts and specialists. The supply of these men fitted to the Department's special lines of work has not been equal to the demand, and has necessitated training them in its laboratories and offices. Since 1897, 496 students have been admitted to the Department for instruction as experts, 249 of whom have remained in its service and 185 gone elsewhere to teach, to experiment, or to demonstrate in private enterprises what they have learned.

This educational work has increased from year to year, and may now be said to form a feature of no little importance. The Department is concerning itself with practically every phase of agricultural instruction, from the assistance of the farmers by demonstration tests, popular bulletins and correspondence, the promotion of farmers' institutes, and the development of agricultural courses for various classes of institutions, to the post-graduate training of specialists.

The Weather Bureau officials have taken an active part in education along meteorological lines at colleges, universities, and schools, and the Secretary announces that the new meteorological laboratory at Mount Weather, Bluemont, Va., which is to be very completely equipped for scientific research in problems pertaining to weather phenomena, will provide facilities for a school of instruction in advanced meteorology.

The movement in the direction of improving and strengthening the courses of instruction at the agricultural colleges, and the accompanying increase in the number of students pursuing agricultural courses is commented upon, and reference is made to the developments in secondary and elementary schools of agriculture, and to the growth of interest in popular agricultural instruction.

Referring to the success of the experiment stations "in leading the way to the improvement of agricultural practice on a grand scale," the Secretary points out the need of larger funds for these institutions, and commends the matter of additional aid from the National Government for consideration. Frequent mention is made in the report of cooperation with the stations, as a means of carrying the field of observation and experiment and the influence of the Department to the various sections of the country. The Bureau of Plant Industry is cooperating with more than 40 stations in the improvement of forage crop conditions, the extension of the work on cereals, the testing of new seeds and plants, demonstration work in the treatment of plant diseases, and numerous other lines. Announcement is made that the Department is considering the wisdom of undertaking systematic cooperation with the stations in the development of types of domestic animals suited to varying latitudes and conditions, with a view to greater economy in production. This would serve to round out the work of the Bureau of Animal Industry, and would furnish the initiative and the means which are necessary for entering upon work of this character in a scientific manner.

There are many indications that the Secretary regards the stations as important agencies through which the Department should operate in extending its work throughout the country, and appreciates the mutual aid which these closely related agencies can render each other.

Referring to the aid which the Department is preparing to extend to the farmers' institute organizations of the various States, the Secretary states that "it is difficult to realize the extent and importance of the farmers' institute movement and its vital relation to the successful incorporation of the results of scientific investigations in our agricultural practice," and points out that "it is of the greatest importance that our adult farmers shall receive definite information regarding improved methods of agriculture and the principles which lie at the foundation of progress in agricultural practice."

The main part of the report is occupied with a brief survey of the scientific work of the Department and its administrative functions. This indicates not only the broad field the Department is covering in its investigations of problems related to agriculture, but the extent to which its work is at present specialized. The latter constitutes an element of strength and is one of the important developments in the recent reorganization.

Some of the larger enterprises which are prominently mentioned are the eradication of the foot-and-mouth disease in New England, which was accomplished in a little over five months at a total expense of less than $300,000, the aid which is being rendered in the introduction of forestry methods on public lands and in the management of

private tracts and wood lots, the continuation of the soil survey over nearly 15,000,000 acres during the year, irrigation investigations, and the work on the cotton boll-weevil in Texas.

The Secretary points to the results with macaroni wheats as an indication of what may be accomplished in plant introduction. It is estimated that 10,000,000 bushels of this wheat were harvested the past season, and at least 20 mills are now handling it. Tests of the bread-making qualities of macaroni wheat flour at several of the experiment stations and on a large scale by the Department have shown that a very good quality of bread can be made from such flour.

The application for advice and working plans for forest lands increases steadily, indicating the widespread interest which has at length been aroused in improved methods of management. This work, however, should not obscure the investigations which the Bureau of Forestry is conducting along other lines, among which may be mentioned tests of the strength of timber, the preservation of wood by cheap means, the control of forest insects, and a new method of gathering crude turpentine, which within a single year has revolutionized the naval stores industry, nearly doubling the yield of turpentine with practically the same labor, and greatly prolonging the life of the tree.

The studies of the duty of water form an indispensable basis for a more economical use of water in irrigation, the excessive use of which not only reduces the yield of crops and ruins large areas of fertile lands, but deprives other lands equally fertile of a water supply. An area of approximately 10,000,000 acres is now under irrigation, and canals already built cover an added area of at least 5,000,000 acres. The studies already made lead to the belief that the application of better methods would make possible the cultivation of the added 5,000,000 acres now under ditch, with very little expense for canal construction. In Oregon it is estimated that there are 3,000,000 acres of land whose products can be greatly increased by the adoption of proper methods for conserving the moisture which falls outside of the irrigation period, and equally good results are probable in other States. The Secretary refers to the importance of undertaking work in agricultural engineering, especially on the application of power to farm machinery, and recommends that the irrigation work be enlarged to include both irrigation and agricultural engineering.

Much attention is given in the report to the ravages of the cotton boll-weevil in Texas, which menaces cotton production in that and adjoining States; and a plan is outlined for combating the invasion of this insect. An appropriation of half a million dollars for this purpose is recommended, to become immediately available, in order that the campaign may be made comprehensive and effective.

The publications of the Department during the past year, which in a way may be taken as an indication of its activity, far exceeded those of

any other year. In all, 938 publications were issued, as against 757 in any previous year, and 375 of these were new publications. The total number of copies of all the publications issued aggregated nearly 12,000,000, 7,000,000 of which were Farmers' Bulletins and were distributed quite largely through members of Congress. It is a striking evidence of the general appreciation of the publications of the Department that over 30,000 copies were sold by the Superintendent of Documents, in the face of the enormous free distribution, the supply of copies for sale being inadequate to the demand.

Plans for the new buildings authorized by the last Congress have been adopted and are being worked up in detail. These plans provide ultimately for the erection of a series of ten buildings, connected by pavilions in such a way as to make practically one harmonious structure. The central feature of this series is an administrative building, and grouped about it are the laboratory buildings to be used by the various bureaus in their research work. The amount authorized by Congress ($1,500,000) will suffice for the erection of three of the laboratory buildings, which will provide a floor space of about 100,000 square feet, and will enable compliance with the terms of the appropriation act in housing those branches of the Department that are now paying rent. The erection of the administrative structure will require further appropriation.

Some interesting facts bearing upon the working force of the Department of Agriculture and the development which has taken place in this respect are presented in the annual report of the appointment clerk for the past year.

The Department was established July 1, 1862. Its immediate predecessor was the Agricultural Division of the Patent Office, the force of which included 9 persons the year that the transfer was made. In 1863, the second year of the Department, the number of employees had reached 29, and four years later it was about a hundred. This number was not exceeded until 1881, and in 1889, soon after the Department was raised to the first rank, the total number of employees was less than five hundred.

With the transfer of the Weather Bureau to the Department in 1891, the number was increased to 1,577 persons. Since that time the force has increased several hundred in number every year. During the administration of the present Secretary, from 1897 to 1903, the growth has been especially rapid, showing a net increase of 1,756 persons. In the past two years over 400 persons a year have been added to the force.

The present enrollment (July 1, 1903) is 4,200 persons. Of these, 1,410 are in the Weather Bureau, 1,386 in the Bureau of Animal Industry, 324 in the Bureau of Plant Industry, 297 in the Bureau of

Forestry, 137 in the Bureau of Statistics, 130 in the Bureau of Soils, 106 in the Office of Experiment Stations, 154 in the Division of Publications, and 58 in the Bureau of Chemistry, the remainder being distributed through the various divisions of the Department. The above number includes the inspectors, microscopists, and taggers engaged in the meat and other inspection work of the Bureau of Animal Industry, the forecast officials and observers in the regular service of the Weather Bureau, and a considerable number of special agents, student assistants, collaborators, etc., in various branches of the service; but does not include the voluntary observers and correspondents of the Weather Bureau and the Bureau of Statistics. The latter have an important part in the collection of data by these bureaus, as is indicated by the aggregate number, which reaches 67,337. The Weather Bureau has 3,341 voluntary observers and 13,996 voluntary crop correspondents. The voluntary service of the Bureau of Statistics includes 11,000 county correspondents and their assistants, 9,000 State statistical aids, and 30,000 township correspondents, from whom monthly reports are received, and these reports are supplemented from time to time by reports from farmers and planters, cotton ginners, millers, and others, bringing the total number of voluntary correspondents in its service up to approximately 256,000 persons.

In the classification of the regular force of the Department nearly two thousand fall under the head of "scientists, scientific investigators, and their assistants." While this classification does not show the number who are stricly occupied with investigation, it indicates in a general way the present magnitude of the scientific force of the Department engaged in investigation and in inspection, and undoubtedly places the Department in a class by itself among institutions of its kind in this or any other country.

CONVENTION OF ASSOCIATION OF AMERICAN AGRICULTURAL COLLEGES AND EXPERIMENT STATIONS.

The seventeenth annual convention of this association, held in Washington, November 17–19, 1903, was one of the largest meetings in point of attendance which has ever been held. Something over 200 delegates and visitors were registered, and the representation was very general from different sections of the country. The meetings were held in the Shoreham Hotel, where very satisfactory provision was made for the general sessions and the section meetings. A very pleasant social feature was a reception tendered the convention by Secretary and Miss Wilson on the evening of November 18 at their residence. This was largely attended by the members of the association and visitors, the scientific staff of the Department of Agriculture, and others. By special arrangement the delegates paid their respects to President Roosevelt at the White House on the afternoon of November 18.

As has been customary for several years past, the annual meeting of the Official Horticultural Inspectors was held during the days of the convention, in conjunction with the meetings of the section on entomology. A brief account of their meetings is given elsewhere in this number.

The convention as a whole was notable for its harmony and the expedition with which business was transacted, and was remarked by many of the delegates as a most satisfactory meeting.

GENERAL SESSIONS.

The address of the president of the association, James K. Patterson, of Kentucky, was given on the evening of the first day of the convention. It dealt with the general topic of the origin and work of the colleges and universities represented by the association, and the influence of these institutions upon the development of technical and industrial education. It was an eloquent and scholarly review of the conditions in English and American history which have led up to the newer education, the influences which have had to be met and overcome in its development, and the recognition which technical education is now receiving, due in no small degree to the influence of the land-

grant colleges of this country. A high tribute was paid to the great work of these institutions, which the speaker declared have given a new conception of manual training and set the pace for scientific study and experimentation in America. The application of their work he pronounced far in excess of the original conception, and their experience and the methods which they have worked out have served as an example to other countries. The speaker pictured the future of this country—agricultural, industrial, and social—and along with it the future development and position of the land-grant colleges, which he conceived to be destined to occupy an increasingly prominent and important part in promoting industrial development and in contributing to the advancement of both general and applied science.

Pursuant to a resolution adopted by the association last year, provision was made for memorial addresses on the late President W. L. Broun, of Alabama, and the late President W. M. Beardshear, of Iowa. An address on the public life and services of Doctor Broun was delivered by President P. H. Mell, of South Carolina. Doctor Gunsaulus, of Chicago, who was to have delivered the address on President Beardshear, was prevented from being present, but he was requested to furnish the manuscript of his address for publication.

One of the most important items of business was the consideration of the amendments to the constitution proposed at the Atlanta meeting. These amendments had been before the association for a year, and were adopted with practically no discussion. They provide for a reduction in the number of sections to two, one on college work and administration and the other on experiment station work, three members of the executive committee to be chosen by the first section and two by the latter. No action on public and administrative questions is to be final without the assent of the college section. There is provision for each section to create such divisions as it may find desirable, but no such divisions have yet been made, and the report of the committee on the organization of the new section for station work recommended that for the present no such divisions be made. The section on horticulture and botany, however, expressed a desire to continue its meetings in the future, and appointed a committee to confer with the executive committee with reference to this matter.

The reduction in the number of sections to two will necessarily bring about a material change in the programme of these section meetings. The committee on the organization of the new section for station kwor recommended that the section be open to the consideration of all phases of station activity, including matters of administration, and the discussion of methods and appliances of research, but should not include the presentation of results of work as such, or of general papers. The papers and discussions at a given convention are to be concentrated upon one general subject, as a rule, and it is expected that there will be a rotation of subjects from year to year, so

as to cover the various lines of station activity. A standing committee on programme was provided for by each of the new sections to which subjects for discussion may be suggested.

The executive committee in its report, read by H. C. White, noted the efforts of the committee to secure the consideration of the mining school bill, and the steps which have been taken toward making a campaign for an increase in the Federal appropriation for experiment stations. The success in securing an appropriation for a college and station exhibit at the St. Louis Exposition was referred to. The committee has ascertained that the agricultural colleges will not be discriminated against in distributing the benefits of the Cecil Rhodes bequest. The committee was directed by resolution to continue its effort to secure the passage of the mining school bill and an increase in the appropriation for the experiment stations. On recommendation of the committee it was voted that hereafter vacancies in standing committees caused by resignation or death may be filled by the respective committees.

The report of the treasurer, E. B. Voorhees, showed the total receipts during the year to be $1,688.55 and the total expenditures $1,425.29, leaving a balance in the treasury of $263.23. It was voted to continue the annual assessment at $15.

The report of the bibliographer, A. C. True, called attention to the more important bibliographies which have appeared during the year, a list of 110 bibliographies with explanatory notes constituting the main part of the report. Special mention was made of the International Catalogue of Scientific Literature, several parts of which have been noted in this journal. The incompleteness of this catalogue in regard to certain lines of work in agricultural science, notably the work of the experiment stations, was a matter of much regret.

The standing committee on indexing agricultural literature called attention in its report to the index cards for the publications of the Department of Agriculture which are being prepared by the Library, and also to the cards for the accessions to the Department Library. The latter are now being printed by the Library of Congress, and can be obtained at small cost, as may also the catalogue cards of the Library of Congress relating to agriculture. The card catalogue of the Department Library now contains over 110,000 cards, and the Library is thus in position to render more efficient aid than ever before to the agricultural colleges and experiment stations by furnishing them information in regard to the literature on particular topics, loaning books, etc. Attention was called in this report to the combined index, now in press, of the first twelve volumes of Experiment Station Record, and to the card index of agricultural literature issued by this Office. It was requested that this report be published at an early date for the assistance of librarians of the colleges and stations.

The report of the committee on methods of teaching agriculture, presented by A. C. True, was on the relation of the natural sciences to agriculture in a four-years' course, and presented a plan for a course of study including these natural sciences and noting in brief the principal subjects under each to be covered. The report pointed out that the older method of arranging the courses in agriculture tended to make specialists in such subjects as agricultural chemistry or vegetable pathology, rather than to make trained agriculturists. It was urged that there should be a sufficient period of general study before specialties are taken up, and that the paths of the specialist and the agriculturist should early diverge. The college course can not be expected to fit men for expert work in this Department, the experiment stations, and similar institutions, but for such work at least a master's degree and ere long the doctor's degree will likely be required. This paper brought out much discussion, illustrating the marked interest which has developed within the past few years in the matter of courses of study and in agricultural education of different grades. The work of this committee was highly commended and was pronounced one of the most important features of the association's work.

There was considerable discussion of the subject of the graduate school of agriculture, and the hope was expressed that it may be possible to arrange for a session of this school next summer. This matter was placed in the hands of the committee on graduate study at Washington, whose title was changed by dropping "at Washington," so as to make it the committee on graduate study. President Northrop withdrew from this committee, owing to his inability to satisfactorily look after its interests, and President C. W. Dabney was appointed chairman in his place, the vacancy on the committee being filled by the appointment of L. H. Bailey.

The report of the standing committee on military instruction in land-grant colleges was made by G. W. Atherton. The committee reported interviewing the officials of the War Department in charge of military instruction in the land-grant colleges, and receiving from them an unfavorable report relative to any change being made in General Orders 94, which increases the amount of military instruction in the colleges and reduces the detail of officers to two years. This order was characterized by the chairman and by other speakers as impossible of execution, and called forth a vigorous discussion which resulted in the adoption of a resolution requesting the committee on military instruction to continue its efforts to secure a modification of General Orders 94, and to formulate a practicable scheme for military instruction at the colleges.

The standing committee on agricultural engineering presented its first report through W. E. Stone, chairman. The report pointed out

the increase in the number of engineering problems in agriculture and their prominence, the enormous extent to which agricultural machinery, and especially that of a complicated character, is being used by American farmers, the problems of irrigation and of drainage, the terracing of hillsides, the construction of roads, and other matters, as illustrating the desirability of more systematic attention to instruction in these topics in connection with the college courses and of extended scientific investigation. The courses in engineering in the colleges, it was stated, have not kept pace with the progress of the times. The committee declared in favor of separate departments of rural engineering in the colleges, and the enlargement of the work of this Department to include agricultural engineering in addition to irrigation, and recommended that the executive committee of the association aid in securing the increased appropriation asked from Congress for the latter purpose. This report was adopted, and the association also adopted a resolution commending the work of the Department along the lines of irrigation and agricultural engineering. The report brought out considerable discussion and indicated that this matter is occupying the attention of a number of institutions at this time. A special request was made that the report of the committee be speedily published in circular form in order that it may be available.

The report of the committee on collective college and station exhibit at the St. Louis Exposition was presented by W. H. Jordan, chairman, who outlined the origin and history of this movement, and gave an abstract of the law making appropriation for installing and maintaining an exhibit of animals and materials belonging to or used by the land-grant colleges and experiment stations. Details concerning the exhibit, such as the position, classification, allotment of space, and allotment of funds, were entered into, and a list was given of the persons in charge of the different exhibits. Doctor Jordan urged the hearty cooperation of the colleges and stations in the preparation of this exhibit.

The report of the committee on cooperation between the stations and this Department, presented by E. A. Bryan, called attention to the statement of fundamental principles embodied in the two previous reports, expressed gratification at the appointment of a committee within the Department of Agriculture for perfecting the details of a system of cooperation, and reiterated its belief that a full and free consultation between the stations and the members of the Department forces in regard to the work undertaken in the several States is very desirable, and would do much to remove possible sources of friction.

In this connection mention may be made of a conference held just prior to the convention, on cooperation between the Department and the stations in experiments relating to irrigation and agricultural engineering. The conference was attended by representatives of the

stations interested and of this Office. After discussion of the mutual advantage of cooperation in these larger enterprises, and of the facilities of the Office for bringing together the results of work along similar lines for publication, a plan of cooperation was suggested. It was proposed that lists of subjects should be submitted upon which cooperation is deemed desirable, those subjects which are thus shown to be of the most general interest to be taken up first. In conducting the cooperation the stations would furnish the facilities and men, and the Office of Experiment Stations would furnish a part of the necessary funds and the general supervision and publish the results, full credit being given to each station for the work done by it. A resolution favoring this plan of cooperation and pledging the hearty support of the stations interested was adopted by the conference.

The standing committee on uniform fertilizer laws, of which H. J. Wheeler is chairman, called attention to the satisfactory progress which is being made in the direction of greater uniformity, the recommendations of the association having been of value in securing the recent passage or amendment of fertilizer laws in Alabama, Florida, Indiana, Missouri, North Dakota, Pennsylvania, and Tennessee. This report also included recommendations concerning the provisions of laws for feeding stuff inspection.

The report of the standing committee on pure-food legislation, made by W. A. Withers, noted considerable progress along the line of pure-food legislation during the year. New legislation was enacted in two States, and provisions made by Congress for the inspection and control by this Department of foods imported from foreign countries. This was pronounced an unusually important step in food legislation, and its execution has resulted in considerable progress in the preparation of standards of purity.

The report of the standing committee on animal and plant breeding was presented by the chairman, W. M. Hays. The progress made during the year was reported as most satisfactory. The announcement was made of a meeting to be held at St. Louis, December 29 and 30, for the purpose of forming an association of plant and animal breeders.

The committee on revision of methods of seed testing recommended certain changes in the previous report, published as Circular 34 of this Office. These changes relate to an improved germinating chamber and other apparatus, instructions for sampling, etc.

The farmers' institute work which the Department has taken up through this Office was outlined by A. C. True, who stated clearly the policy of the Department in regard to this work. There will be no attempt to interfere with the State management of farmers' institutes in any way, but rather to cooperate with the State officials and to aid them in building up the institutes in the several States. The Department will be a general agency for coordinating and strengthening this

work throughout the country. One of the main objects at present is to help to increase the efficiency of the institute lecturers, now numbering over 800, less than half of whom are connected with the work of the colleges or the stations. A corps of specially trained institute workers was recommended as eventually desirable, to relieve the college and station men of much of the burden of this work, as it is still the opinion of the Office that the prime object of college men is to teach and of station men to investigate. The speaker pointed out the greatness and importance of the farmers' institute enterprise as a means for the future development of agriculture, the building up of a proper system of agricultural education and research, and developing a generation of farmers who will be in position to appreciate and apply the results of the work of these institutions.

A resolution presented by C. E. Thorne commended the reviews furnished by the Experiment Station Record, and suggested an extension of these to include more full abstracts in the case of some of the foreign publications, which are accessible to only a portion of the station workers, and directed the executive committee of the association to urge upon the Secretary of Agriculture the securing of additional funds for this purpose.

The plans of the new building for the Department of Agriculture were exhibited and explained by B. T. Galloway.

A very cordial invitation was extended to the association to hold its next meeting at Portland, Oregon.

The following officers were elected for the ensuing year:

President, W. O. Thompson, of Ohio; vice-presidents, D. F. Houston of Texas, J. C. Hardy of Mississippi, J. H. Worst of North Dakota, H. J. Wheeler of Rhode Island, and B. C. Buffum of Wyoming; secretary and treasurer, E. B. Voorhees, of New Jersey; bibliographer, A. C. True, of Washington, D. C.; executive committee, H. C. White of Georgia, G. W. Atherton of Pennsylvania, J. L. Snyder of Michigan, W. H. Jordan of New York, and C. F. Curtiss of Iowa.

Section on college work and administration.—Chairman, W. E. Stone, of Indiana; secretary, G. E. Fellows, of Maine; committee on programme, W. E. Stone of Indiana, G. E. Fellows of Maine, and H. W. Tyler of Massachusetts.

Section on experiment station work.—Chairman, E. H. Jenkins, of Connecticut; secretary, M. A. Scovell, of Kentucky; committee on programme, J. H. Shepperd of North Dakota, B. W. Kilgore of North Carolina, and M. A. Scovell of Kentucky.

GENERAL SESSIONS.

No sessions were held by the section on mechanic arts. The programmes of the other sections were quite full and are briefly noted below.

SECTION ON AGRICULTURE AND CHEMISTRY.

The three sessions of this section were occupied chiefly with papers and discussions relating to soils, especially soil fertility. Throughout these discussions there were frequent references to the principles laid down in a recent bulletin of the Bureau of Soils,[a] and their conflict with views which have previously been held regarding soil fertility and its maintenance.

The chairman of the section, C. G. Hopkins, of Illinois, in his opening address on The Present Status of Soil Investigations, pointed out the conflicting conclusions reached by various investigators, particularly with reference to the value of chemical methods of studying the fertility of soils. He illustrated the valuable service that chemical analysis may render in this connection by citing the results of his own studies on various typical Illinois soils, and suggested that discordant views might be harmonized and the work promoted by keeping clearly in mind the fact that functions of soils are of two kinds: (1) to furnish favorable physical conditions for plant growth, and (2) to supply the necessary plant food; i. e., they are both physical and chemical, and one is as indispensable to the successful growth of crops as the other. The use and value of leguminous crops and fertilizers and manures in rotation for maintaining and increasing soil fertility were illustrated from results of field experiments.

Milton Whitney, of the Bureau of Soils, in a discussion of Methods for the Extension and Practical Application of Soil Surveys, summarized the work of his Bureau during the past year in surveying and mapping typical soils in different parts of the United States. The main portion of his address, however, was devoted to a discussion of the work of the Bureau on the chemistry of soils as related to crop production, and a preliminary statement was made regarding investigations in progress in continuation and extension of those which were made the basis of Bulletin 22 of the Bureau. These include a further study of the physical properties of soils with reference to the movement of the soil water, which has shown little or no difference in the movement of water in widely different soils; studies of the behavior of the soil water as the drought limit is approached, which differs in a marked degree from that of the water of saturated soils or water in mass; experiments on the growth of plants in soil extracts, which gave results similar to those obtained in experiments with the original soils, and studies of transpiration as related to the functional activity of plants grown in good and poor soils and in the extracts of the same.

Transpiration was less active in the poor soils and their extracts than in good soils, and was influenced by the kind of salts present, but not by the amount. The effect of certain salts in retarding root action and of others in accelerating it was suggested as a possible explanation of the apparent influence of the use of fertilizers. The effect of aeration in correcting the poor results obtained with poor soils or their extracts was noted, and was thought to confirm the position taken in Bulletin 22 that the use of fertilizers appears to have the same effect as good cultivation. "It appears now that if we have perfect aeration . . . fertile and poor soils grow plants of equal vigor and feeding capacity." The speaker prophesied the development of a method, to be used in the field, in studying the conditions of the soil as related to the growth and functional activity of the plant, and the possible determination of how far these conditions may be changed by aeration or physical treatment. "Certainly I think it is going to be possible for us to determine what fertilizers can be used to correct these difficulties under the conditions of our experiment, which is a long way ahead of anything that we have at the present time."

A paper by E. W. Hilgard, of California, on The Chemistry of Soils as Related to Crop Production was read in his absence. This paper was an analysis of Bulletin 22

[a] U. S. Dept. Agr., Bureau of Soils Bul. 22.

of the Bureau of Soils. Doctor Hilgard questioned the reliability of the water-extract method as a means of determining the fertility of soils, and strongly dissented from many of the conclusions and generalizations contained in the bulletin. The paper cited numerous illustrations of the value of chemical methods for determining the productiveness of soils, and laid especial stress on the importance of the relative proportion of soil constituents as distinguished from their total amounts.

Three papers were read on Methods of Conducting Investigations Relating to the Maintenance or Increase of Soil Fertility. In the first of these C. E. Thorne dwelt upon the relation of laboratory and field experiments, and laid stress upon the value of the latter when continued for long periods on the same plats. Compared with such work laboratory work was declared to be comparatively simple. The requirements of plat experiments were pointed out and the necessity of great care in execution was emphasized, illustrations being drawn from the experience at the Ohio Station. The speaker was unable to see how the results of the past 10 years at that station could have been forecasted in the laboratory by a chemical or physical examination of the soil or otherwise, or how any time could have been saved. In conclusion, he laid down the general proposition that deductions relating to soil fertility must be confirmed in the field; that field work should be as scientific in its methods as laboratory work; and that when this is the case, the results are as reliable as any scientific laboratory work.

The second paper on this subject, presented by E. B. Voorhees, took up the different methods practiced to maintain and increase the fertility of the soil, considered the relation of income and outgo of plant food to crop production, and compared the availability of nitrogen from different sources for leguminous and nonleguminous crops. The discussion of these topics was based on the results of experiments conducted at the New Jersey Station. The methods of investigations pursued in this connection were described in detail in the course of the paper.

H. W. Wiley, the third speaker, outlined the reasons for the depreciation of soil fertility, and discussed at some length the results obtained by the Bureau of Chemistry of this Department, in pot culture experiments with soils from different parts of the United States. The speaker presented a comparison of the amount of phosphoric acid and potash removed by oats grown in these pot experiments, and the mount of these elements which were found soluble in two-hundredth normal hydrochloric acid under definite conditions. Attention was also called to the nitrifying power of the different soils used.

In a paper on Differences between four Southern and four Northern Soils, and Improvements in Soil Management which these Differences Suggest, F. H. King, of the Bureau of Soils, gave an account of cooperative plat experiments with different amounts of manure and guano on corn and potatoes, on typical soils in North Carolina, Maryland, Pennsylvania, and Wisconsin. In connection with these experiments observations were made on temperature, evaporation, rate of nitrification, soluble salts, and other physical and chemical conditions. The southern soils studied were more compact, i. e., less granular, had more defective aeration and drainage, but carried less water, showed a slower rate of nitrification, contained less soluble salts, and gave smaller yields than the northern soils. The means suggested for improving the productive capacity of the southern soils included deeper plowing, the turning under of more organic matter, the raising of more live stock, and the growth of smaller varieties of corn.

R. H. Forbes, of Arizona, discussed the Methods for the Extension and Practical Application of Soil Surveys, pointing out the great value of soil surveys for selecting lands adapted to new crops and industries under pioneer conditions, and especially of alkali surveys and quick and easy methods of determining the location and amounts of alkali in soils.

L. G. Carpenter, of Colorado, presented a paper on Methods and Value of Securing Irrigation Supplemental to Rainfall for Humid and Semi-arid Districts, in which he

considered the subject from the standpoint of (1) insurance against failure, and (2) securing maximum yields, as applied to humid regions and those of deficient rainfall. The advantage of supplemental irrigation as a means of securing greater diversification of crops was pointed out, and the quantities of water applied as related to the kinds of crops produced and the system of farming pursued were discussed.

A paper on Experiments in Animal Breeding was read by F. B. Mumford, who pointed out the need of experiments where all the conditions can be controlled. He gave illustrations of the kind of problems that needed to be studied in animal breeding, among others questions of prepotency, an investigation of which should form the foundation of the study of principles of breeding. Mendel's law, although it has received much attention from plant breeders, has not been demonstrated as far as animals are concerned. The need of a standard of measurements was pointed out, and birth weight was suggested as perhaps coming nearer to representing the effect of breeding than any other known standard. Experiments on the birth weight of lambs were briefly mentioned, which showed that the size and breed of the male had no relation to the birth weight, but that the latter was intimately associated with the weight of the female. A heavy birth weight was found to be intimately associated with vigor, thrift, rapid growth after birth, and early maturity of the lambs. If this is found to hold true the result is thought to be a very important one. The studies are being continued.

A paper on the same subject sent by C. S. Plumb was read by title owing to the lateness of the hour.

SECTION ON HORTICULTURE AND BOTANY.

In the absence of the chairman, H. L. Bolley, the sessions were presided over by J. C. Arthur.

Several papers dealt with the teaching of botany and horticulture in the agricultural course. L. H. Pammel, in a paper on Botany in the Agricultural Course, referred to the botanical work provided for in the syllabus for agronomy of the committee on methods of teaching agriculture, and reviewed the courses of required botany in various agricultural colleges and other institutions. He recommended that special courses in botany should be provided, as preparatory to courses in theoretical botany and the practical application of botany to horticulture and other sciences.

F. A. Woods presented, for the committee on courses in botany, an outline of a course in elementary botany, together with some suggestions as to more advanced courses. This committee was continued, and was directed to formulate its courses in reference to cognate courses on economic lines. The appointment of a committee to act in conjunction with this committee and to report courses of study in horticulture was also authorized.

The Foundation of Agricultural Teaching was the subject of a paper by H. Metcalf, in which it was contended that a few subjects pursued for a long period give better results than a larger number of topics covered in the same time. The speaker believed that agricultural botany should be developed to occupy as important a position in an agricultural course as mathematics does in mechanical or civil engineering. Plant production being the object of agronomy, plant life should be the primary study and economic plants should be the ones studied before all others. It was believed that botany should be extended over the 4 years of the college course, even if the amount of time devoted to it each year was relatively small.

In a paper on Methods of Practical Instruction in Horticulture, H. L. Hutt described the instruction in horticulture at the Ontario Agricultural College, which includes fruit growing, gardening, floriculture, and landscape gardening. Instruction is by means of lectures, laboratory work, library work, observation excursions, and practical work in the orchard and garden. Each of these methods of instruction was

discussed at some length. In the more advanced work seminary methods of instruction were followed to a great extent and have proved very profitable.

F. V. Coville gave an account of the establishment of the Desert Botanical Laboratory, which has been equipped by the Carnegie Institution near Tucson, Arizona. The relation between the purely botanical subjects which are to be studied at this laboratory and agricultural and horticultural practice was pointed out, attention being called to studies on the effective use of irrigation waters and also their economical employment. The laboratory is in charge of Dr. W. A. Cannon, formerly of Columbia University.

Cooperation was the theme of a paper by F. L. Stevens. Experiments of this character, carried on with farmers or through the rural schools, were believed to be of great value for demonstration purposes and to reach a class which bulletins do not. Numerous illustrations drawn from the speaker's own experience were cited. In discussing this paper, J. C. Arthur referred to the treatment of seed at elevators. The proprietors of one large elevator treated 150 bu. of seed oats with formalin at a cost of about 40 cts., the results being so satisfactory that the seedsmen propose treating all of their seed grain in the future. H. L. Hutt testified to the value of cooperative experiments, stating that the Ontario Agricultural College has nearly 5,000 cooperative experiments in progress.

In a second paper F. L. Stevens gave an account of the Granville tobacco wilt, which was illustrated by lantern slides. This will form the basis of a bulletin of the North Carolina Station, now in press, and will be noted later. R. E. B. McKenney, of this Department, in discussing the paper believed the disease to be the same that occurs in Ohio and other districts widely removed from North Carolina. It was pronounced due to a Fusarium-like organism.

Crop Rotation as a Factor in Combating Plant Diseases was the subject of a paper by W. A. Orton, of this Department. Many plant diseases were stated to owe their spread and injury to improper soil conditions, which may be corrected by rotation, green manuring, etc. A lack of humus and potash waste was said to be incidental to cotton rust and shedding of bolls, and these diseases can be almost entirely eliminated by rotation, green manuring, growth of winter cover crops, and application of potash. Rotation appears to be one of the most efficient ways of combating the watermelon wilt, and the cotton-root rot, which has been referred to species of Ozonium, can be readily controlled by this means. The tomato Fusarium disease requires rotations with 5 or more years intervening between crops of tomatoes. Diseases which spread through the air, whether of fungus or bacterial origin, are less easily influenced by rotations, but the vigor of the plant can be increased by the restoration of soil fertility. In addition to rotation, resistant varieties are necessary for such diseases as cotton wilt, nematodes, etc. Rotations for the orchard and nursery were also discussed with reference to root rot, nematodes, etc.

M. A. Carleton exhibited forms of notebooks and records, which he has found very well adapted to field and laboratory work in his investigations with cereals. The system described was designed to secure accuracy, rapidity, uniformity, and permanency of records.

A report was made from the committee on plant-breeding nomenclature, favoring the use of the word "clon," which has lately been proposed by H. J. Webber for plants grown from cuttings, bulbs, etc., the progeny all being members of the same individual.

SECTION ON ENTOMOLOGY.

The sessions of this section were presided over by J. B. Smith in the absence of the chairman.

In a paper on Problems of Forest Entomology, A. D. Hopkins called attention to the need of special methods of eradication in fighting forest insects, since many of

the methods used on field and garden crops are not profitable. The most important point is that the methods should be inexpensive, and fortunately such methods have been found in the control of certain forest insects, especially insects injurious to tan bark. Trees infested with the pine-bark beetle should be cut between October and May. In the control of forest insects good results may be had from girdling trees to serve as trap trees.

The importance of laboratory and field work in economic entomology was emphasized by E. P. Felt, who argued in favor of accurate laboratory experiments, by means of which many details of life history and habits may be worked out more satisfactorily than under field conditions. All methods of investigation, however, should be combined, and it was urged that the data obtained from untrained observers may often prove quite reliable and valuable. The same speaker also described several record devices, notably cards for recording data relating to specimens, and arrangements for filing entomological correspondence.

C. M. Weed read a paper on Keeping Entomological Notes, describing the usages in vogue in New Hampshire, and exhibiting file boxes for holding bottles of alcoholic material, and also boxes for holding leaf galls and other coarser material.

J. B. Smith read a paper on The New Jersey Ideal in the Study and Report upon Injurious Insects. The speaker argued that farmers desire practical information, and do not care for technical details. The entomological bulletins should be educational, but should not contain material relating to synonymy or even descriptions of new species. The feeding habits of insects should be described, likewise the nature of injury caused by them and the reason for the application of the recommended treatment. Attention should also be called to the relation of the treatment to cultural methods and the life history of the insects. Laboratory results should be confirmed by field investigations. At the New Jersey Station no insectary is maintained; a few breeding cages are kept in the laboratory, but most observations are made in the field.

A. F. Burgess discussed the necessity of uniform methods of inspection of nursery stock. Attention was called to the fact that the San José scale is the direct cause of most inspection laws, and to the necessity of studying the source of infestation. Infested city lots and neglected orchards frequently furnish great difficulties in the control of the San José scale. Fumigation with hydrocyanic-acid gas was shown to be perfectly effective in destroying the scale, and not injurious to fruit trees when applied in the proper manner. Fumigation was held to be far more satisfactory than inspection, since it is impossible to detect all cases of infestation by San José scale, woolly aphis, or crown gall. The proportions of cyanid of potash, sulphuric acid, and water used in various States were presented in statistical form and the 1 : 1 : 3 formula was recommended.

SECTION ON COLLEGE WORK.

In this section two subjects were discussed: The Mission of the Land-Grant Colleges, and Short Courses. The first subject was introduced by W. O. Thompson, of Ohio, in a paper setting forth (1) the history of the movement bringing the land-grant colleges into existence, and (2) the writer's interpretation of the first and second Morrill Acts, based partly on the discussions in Congress bearing on those acts. Briefly stated, the writer's conclusions were that those favoring the establishment of the land-grant colleges were of the opinion that some other form of education than the classical may be liberal; that it was the intention of these men to give a liberal as well as a practical education, implying that industrial education is liberal; that precedence was to be given always to agriculture and mechanic arts, and that military instruction was intended to occupy a subordinate position. In his opinion the act of 1890 did not indicate a change of mind on the part of Congress regarding the

mission of the land-grant colleges, but rather an attempt to interpret more fully and in detail the act of 1862, regarding which there had been considerable misunderstanding.

A round-table discussion of short courses was participated in by nearly a dozen speakers. Nearly all were agreed that the short course should not be taken by young students who might profitably pursue agricultural high school or college courses and that no credits for degrees should be given for short-course work. H. H. Goodell stated that at the Massachusetts Agricultural College short-course students have taken agriculture, horticulture, bee culture, etc., in the regular college classes. This plan was criticised by several, President Northrop laying special emphasis on the desirability of keeping the short-course work outside of the circle of regular college work. He considered the short courses as "charitable or benevolent appendages" on the college, allowable only when they will not detract from the efficiency of the regular college work. R. W. Stimson considered short courses as pioneer work—more or less temporary expedients, for the purpose of extending the influence of the college and of drawing students to the long courses.

In the subsequent informal discussion the idea was advanced that young students should go to agricultural high schools or colleges, and older students should get their instruction in farmers' institutes and like organizations. In opposition to this plan, J. C. Hardy contended that there is a wide gap between the farmers' institute and the agricultural high school, and that technical instruction of all grades should be provided for, either in the agricultural colleges or in special schools organized for the purpose.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The determination of available phosphoric acid and potash in calcareous soils, H. H. Cousins and H. S. Hammond (*Analyst, 28 (1903), No. 329, pp. 238–240*).—The method of Dyer was found to give unsatisfactory results when used with the highly calcareous soils of Jamaica. By following the practice advocated by Hilgard of neutralizing the carbonates in the soil before subjecting it to the solvent action of the citric acid solution, results were obtained which agreed with the known productiveness of the soil.

The solvent action of the liberated carbon dioxid and of the neutral citrate formed have been urged as objections to this modification of the method, but comparative tests made by the authors on soils free from carbonates and on those to which carbonates were added showed that the solubility of the phosphoric acid remained absolutely constant whether carbonates were added and neutralized or not. "As regards potash, the figures indicate that in two cases the carbonic acid has exerted an additional solvent action. Our experience in Jamaica leads us to doubt whether citric acid is an adequate detective solvent for all forms of potash in a soil available for present consumption by plants."

On the determination of free phosphoric acid and the amount of this substance in superphosphates, A. D. Herzfelder (*Landw. Vers. Stat., 58 (1903), No. 5–6, pp. 471–479*).—The method of the association of German fertilizer manufacturers, viz, titration of the water extract with soda solution, using methyl orange as an indicator, is described, as well as the official Austrian method and that of Müntz, in both of which free phosphoric acid is determined gravimetrically in the alcohol extract. Comparative tests of the methods are reported and objections to all of them are pointed out.

The author proposes the following method: Extract 1 gm. of the finely ground substance in a Soxhlet apparatus with water-free ether for 10 hours. Evaporate the ether and take up in about 20 cc. of water, evaporating to dryness and taking up in water 3 times. Filter and wash with water slightly colored with methyl-orange as long as a red color is observed. Usually from 100 to 150 cc. of water is required. Titrate the filtrate with normal soda (?) solution, multiplying the number of cubic centimeters used by 7.1 to get the percentage of free phosphoric acid present.

A comparative study of French, English, German, and Hungarian superphosphates with reference to water-soluble and free phosphoric acid showed the last two to be much richer in free phosphoric acid than the French and English superphosphates.

The quantitative determination of phosphates in the stomach contents, G. H. A. Clowes (*Amer. Jour. Pharm., 75 (1903), pp. 325–330*).

A modification of Dumas' volumetric method of determining nitrogen, R. Bader and A. Stohmann (*Chem. Ztg., 27 (1903), No. 52, pp. 663, 664, fig. 1; abs. in Chem. Centbl., 1903, II, No. 12, p. 740*).—The principle of Lippman and Fleissner's

modification of Kopfer's method[a] is applied in Dumas' method, the method of conducting the combustion being described in detail.

The applicability of Dumas' method of determining nitrogen to gas mixtures, C. CHARITSCHKOFF (*Zhur. Russ. Fiz. Khim. Obshch., 35 (1903), pp. 411–416; abs. in Chem. Centbl., 1903, II, No. 5, p. 311*).

Concerning methods of estimating nitrogen and protein in feces, A. ZAITSCHEK (*Arch. Physiol. [Pflüger], 98 (1903), No. 11–12, pp. 595–613*).—Experiments which are reported led the author to conclude that feces in drying undergo a marked loss of nitrogen which is greater in the case of carnivora than of herbivora. Adding acid when the feces are dried does not entirely prevent this loss, and if accurate results are desired the nitrogen should be determined in a number of samples of fresh feces. To learn the digestibility of protein the albuminoid nitrogen in food and feces should be determined. The nitrogen lost in drying feces is dependent upon the amount of nonalbuminoid nitrogen present and is doubtless also influenced by the water content of the feces.

The oxidation of atmospheric nitrogen by means of electrical discharges, F. VON LEPEL (*Ber. Deut. Chem. Gesell., 36 (1903), No. 6, pp. 1251–1258*).—A brief account of studies of conditions favoring the process.

Table for calculating protein from nitrogen using the factor 6.25, O. GÖLTSCHKE (*Ztschr. Analyt. Chem., 42 (1903), No. 8, Sup., pp. 10*).—The protein values are given corresponding to amounts of nitrogen ranging from 0.01 to 16 per cent.

The determination of nitric acid in water, A. MÜLLER (*Ztschr. Angew. Chem., 16 (1903), No. 31, pp. 746, 747*).—The method of Schulze-Tiemann is considered preferable to that of Frerichs (E. S. R., 14, p. 940).

A new quantitative method of determining ammonia, A. BAYER (*Chem. Ztg., 27 (1903), No. 66, pp. 809, 810*).—The method is applicable to such solutions as sewage, liquid manure, tanning liquors, etc., and is as follows: To 100 cc. of the solution add 2 cc. of fuming hydrochloric acid and 2 drops of phenolphthalein and for each 50 mg. of NH_3 per liter 15 cc. of 10 per cent magnesium chlorid. Add 12 to 15 gm. of pulverized disodium phosphate and shake in a rotary apparatus until the phosphate is completely dissolved, then add sodium hydrate solution drop by drop until a faint permanent rose color is obtained. The gelatinous precipitate formed becomes crystalline after standing ¼ hour and the rose color disappears. Add soda solution until the color remains permanent, allow to stand ¼ hour, and filter without washing. Distill ammonia from the filter and contents by means of magnesium oxid.

Progress in the field of the chemistry of waters, including natural and artificial mineral waters, A. GOLDBERG (*Chem. Ztg., 27 (1903), No. 71, pp. 869–874*).—A review (with numerous references) of the literature published on this subject during 1902.

A new method for the determination of organic substances in waters, more particularly in those containing chlorids and bromids, C. LENORMAND (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 15, pp. 810–814*).—A colorimetric method is proposed in which the color obtained by adding permanganate to the water without further treatment is compared with that obtained by adding sodium bicarbonate along with the permanganate and boiling.

The influence of distilled water on the determination of the reducing power of potable and sewage water by means of permanganate solution, H. NOLL (*Ztschr. Angew. Chem., 16 (1903), No. 31, pp. 747, 748*).—Distilled water was found to introduce a decided error, which should be determined and corrected.

Solubility of gypsum in solutions of sodium chlorid, A. D'ANSELME (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), pp. 372–374; abs. in Jour. Chem. Soc. [London], 84*

[a] Monatsh. Chem., 7 (1896), p. 9.

(*1903*), *No. 489, II, p. 478*).—The solubilities obtained in solutions of different concentrations agree with those reported by Cameron (E. S. R., 13, p. 927).

On the protamins and the constitution of albuminoid substances, A. KOSSEL (*Bul. Soc. Chim. Paris, 3. ser., 29* (*1903*), *No. 14, pp. I–XVIII*).

A new method of determining sulphuric acid, F. RASCHIG (*Ztschr. Angew. Chem., 16* (*1903*), *No. 26, pp. 617–619*).—A discussion of some of the difficulties encountered in using the method proposed by Müller (E. S. R., 15, p. 121).

Titration of sulphuric acid with benzidine chlorhydrate, W. J. MÜLLER (*Ztschr. Angew. Chem., 16* (*1903*), *No. 27, pp. 653–655*).—A reply to the above article.

Determination of sulphuric acid by means of benzidine, F. RASCHIG (*Ztschr. Angew. Chem., 16* (*1903*), *No. 34, pp. 818–823*).—Further comments on Müller's method.

The estimation of sulphur in urine by means of sodium peroxid, G. MODRAKOWSKI (*Ztschr. Physiol. Chem., 38* (*1903*), *No. 5–6, pp. 562–566*).

Hoppe-Seyler's handbook of physiological and pathological-chemical analysis, THIERFELDER (*Hoppe-Seyler's Handbuch der physiologisch- und pathologisch-chemischen Analyse. Berlin: Hirschwald, 1903, 7. ed., pp. 618; rev. in Hyg. Rundschau, 13* (*1903*), *No. 5, pp. 227, 228*).—A revised edition of this valuable text-book. The attempt has been made to include the material which has accumulated since the previous edition.

The examination of meat, yeast, and other extracts for xanthin bodies. I. The xanthin bodies of meat extracts, K. MICKO (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6* (*1903*), *No. 17, pp. 781–791*).—Analytical methods are described.

The electrolytic estimation of minute quantities of arsenic, more especially in brewing materials, T. E. THORPE (*Jour. Chem. Soc.* [*London*], *83* (*1903*), *No. 489, pp. 974–986, figs 2*).

Determination of vanillin in vanilla, A. MOULIN (*Bul. Soc. Chim. Paris, 3. ser., 29* (*1903*), *No. 7, pp. 278–280*).—The decolorized ether extract is treated with a mixture of sulphuric and acetic acids and crystals of potassium nitrate are added. The formation of methyl picrate from the vanillin gives the solution a yellowish color, which is compared with a scale prepared with known amounts of vanillin.

The detection and estimation of mineral acid in acetic acid and vinegar, P. SCHIDROWITZ (*Analyst, 28* (*1903*), *No. 329, pp 233–237*).

A new method for the determination of halogen compounds in organic substances, H. DAUBIGNY and G. CHAVANNE (*Bul. Soc. Chim. Paris, 3. ser., 29* (*1903*), *No. 15, pp. 807–810*).

The use of normal sodium oxalate in quantitative analysis, S. P. L. SÖRENSEN (*Ztschr. Analyt. Chem., 42* (*1903*), *No. 6–7, pp. 333–359, fig. 1*).—The author concludes from the results of experiments which are reported that sodium oxalate when carefully prepared and dried at 230° C. can be used in the titration of acids without noticeable error, even in work requiring very accurate determinations.

The testing of sodium oxalate and its use in volumetric analysis, S. P. L. SÖRENSEN (*Ztschr. Analyt. Chem., 42* (*1903*), *No. 8, pp. 512–516*).—Methods for determining the presence of water, sodium carbonate, and inorganic and organic impurities in sodium oxalate are given, with brief directions for the use of this material in volumetric analysis.

The absorption of nontanning substances by hide powder and its influence on the estimation of tannin, H. R. PROCTER and F. A. BLOCKEY (*Jour. Soc. Chem. Ind., 22* (*1903*), *No. 8, pp. 482–484*).

Select methods of chemical analysis, A. CLASSEN and H. CLOEREN (*Ausgewählte Methoden der analytischen Chemie. Brunswick: Friedrich Vieweg & Son, 1903, vol. 2, pp. XVI+831, pls. 3, figs. 133*).—This is the second volume of this work, previously referred to (E. S. R., 13, p. 421). Special methods are given for oxygen, ozone, hydrogen, hydrogen peroxid, sulphur, chlorin, bromin, iodin, fluorin, nitrogen,

explosives (nitro-cellulose, nitro-glycerin, dynamite, explosive gelatin and gelatin dynamite, and smokeless powder), argon, helium, phosphorus, boron, silicon, carbon, carbon monoxid and dioxid, percarbonate and hydrocyanic acid, and for the elementary analysis of organic compounds.

Textbook of chemical technology, F. FISCHER (*Lehrbuch der chemischen Technologie. Leipzig: Otto Wigand, 1903, pp. VI+293, figs. 188*).—An abridgment of the author's larger *Handbuch der chemischen Technologie.*

Plant and agricultural chemistry for students and agriculturists, M. SOAVE (*Chimica vegetale e agraria ad uso degli studenti e degli agricoltori. Torino: Carlo Clausen, 1902, pp. XV+415, figs. 41*).

Introduction to the study of plant and agricultural chemistry, K. ASO and E. POZZIESCOT (*Introduction à l'étude de la chimie végétale et agricole. Paris: F. R. du Rudeval, 1903, pp. 200*).—A simple and original presentation of this subject based upon lectures on agricultural chemistry by O. Loew at the Imperial University of Tokyo.

An apparatus for the determination of nitrogen, R. MARQUIS (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 14, pp. 780–782, fig. 1*).—A pump and endiometer for use in the Dumas method are described.

A method of calibrating burettes, D. W. HORN and ELIZABETH M. VAN WAGENER (*Amer. Chem. Jour., 30 (1903), No. 2, pp. 96–105; abs. in Chem. Centbl., 1903, II, No. 12, p. 737*).

Picnometers, R. LEINBACH (*Jour. Prakt. Chem., n. ser., 66 (1902), No. 9–10, pp. 475–477, fig. 1; abs. in Bul. Soc. Chim. Paris, 3. ser., 30 (1903), No. 14, p. 928*).—Two forms are described.

A new condenser, BRACONNIER and G. CHATELAIN (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 14, pp. 779, 780, fig. 1*).—This condenser is so arranged that the cooling medium passes through as well as around the vapors to be condensed, thus presenting a larger condensing surface and adapting the apparatus to highly volatile substances.

A pressure regulator for fractional distillation under reduced pressure, G. BERTRAND (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 14, pp. 778, 779, fig. 1*).

A new absorption apparatus and safety tube, H. VIGREUX (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 15, pp. 841–843, figs. 3*).

A gas furnace for laboratories, K. FRIEDRICH (*Ztschr. Angew. Chem., 16 (1903), No. 36, pp. 857–861, figs. 2*).

On the history of the thermometer, F. BURCKHARDT (*Verhandl. Naturf. Gesell. Basel, 16 (1903), pp. 1–69, fig. 1*).

International catalogue of scientific literature. D—Chemistry, II (*Internat. Cat. Sci. Lit., 2 (1903), pt. 2, pp. XIV+671*).—This completes the volume, the first part of which was previously noted (E. S. R., 14, p. 632).

BOTANY.

The synthesis of albuminoids by plants, E. LAURENT and E. MARCHAL (*Bul. Acad. Roy. Belg., Cl. Sci., 1903, No. 1, pp. 55–114*).—A historical review is given of the sources of nitrogen for plants, the investigations of many authors being critically summarized. After reviewing the literature the authors describe at considerable length their experiments on the synthesis of albuminoids by various flowering plants. The methods of determining the different forms of nitrogen are described and comparisons are drawn between the action of flowering plants and some of the lower orders.

The authors conclude that in the case of the lower orders of plants, such as *Clostridium pasteurianum*, various bacteria, Rhizobium, etc., these organisms are able to assimilate free atmospheric nitrogen, either when living autonomously or in sym-

biosis with leguminous or other plants. Ammoniacal nitrogen is readily assimilated by the lower orders of plants without the intervention of sunlight, but in the higher plants the assimilation, while taking place in darkness, is much more active in the light. Nitric nitrogen is assimilated by the lower organisms in darkness, but among green plants with few exceptions the assimilation of nitrates is most rapid when the plants are exposed to the light and particularly in the more refrangible rays of the spectrum. Whenever free nitrogen, ammonia, or nitric nitrogen are assimilated in darkness there is a considerable consumption on the part of the plant of carbohydrates, which furnish the necessary energy for the reduction and synthesis of the albuminoids.

The lower plants in general are able to synthesize albuminoids in the dark, but in higher plants, as a rule, this takes place only in the light. Among the higher plants amid bodies in limited quantity are produced in portions of the plants which are free from chlorophyll, as in the instance of germinating seeds in darkness. There does not seem to be any transformation of nitric acid or ammonia in a full-grown flowering plant except that taking place in the sunlight.

The influence of light and darkness upon growth and development, D. T. MacDougal (*Mem. New York Bot. Gard.*, *2* (*1903*), *pp. XIII + 319, figs. 176; abs. in Bot. Centbl.*, *92* (*1903*), *No. 14, pp. 296, 297*).—After summarizing the previous investigations on the effect of light and darkness on the growth of plants, the author gives the results of his own experiments with over 100 species, representing many orders of plants. The etiolated condition of the leaves of different plants, the effect of darkness on flowers and inflorescences, and the effect on spores and sporangia of ferns are described. In discussing the theories of etiolation and the effects of light and darkness, the author says that etiolation is not an adaptation to darkness, and that the forms which plants assume in the dark are not governed by an effort to reach the light.

The various phenomena of etiolation are, in the first instance, due to the mere absence of light, and subsequent modifications appear which may be regarded as beneficial to the plant, but at times may prove disadvantageous. The comparison of normal and etiolated plants shows that growth and differentiation are not only independent phenomena, but are easily separable. Light acts as a stimulating influence in inducing morphological differentiation, but it is not necessarily direct in its action, since the stimulative influence may be received by one portion of the plant and transmitted to another. The impulse may often be communicated to organs which are not actually formed at the time of the stimulation.

The amount of growth or increase in volume that may be accomplished by the extension of the imperfectly developed tissues in the absence of illumination is subject to great variation. In many instances the total length, diameter, and volume of the etiolated shoot may be less than that of a normal one, while in other instances it may be decidedly greater. The author states that there is no evidence afforded by the behavior of plants in darkness to warrant the conclusion that light directly affects the rate of growth. A bibliography of more than 200 references accompanies the work.

The influence of a lack of oxygen on plants, M. Dude (*Flora*, *92* (*1903*), *p. 205; abs. in Bot. Centbl.*, *93* (*1903*), *No. 27, p. 18*).—The effect of a lack of oxygen on various seeds and spores was investigated. It was found that keeping seed in an atmosphere free from oxygen resulted in their ultimate death.

Quite a number of species of seed were kept in an oxygen-free chamber for a considerable time and samples were tested from day to day for their vitality. Rye lost its germinative ability after 50 days' exposure, peas after 43 days, sunflowers 40 days, vetches 35 days, and white mustard 15 days. In every case germination was retarded. Where the seed and spores were kept free from oxygen for only 5 days their germination was considerably retarded and the subsequent growth was entirely abnormal.

11776—No. 4—03——3

When growing plants were investigated the young parts were affected sooner and more severely than the more mature portions of the plant. The effect of varying quantities of oxygen was not tested.

The effect of sulphurous acid on plants, A. Wieler (*Ber. Deut. Bot. Gesell., 20* (*1902*), *p. 556; abs. in Bot. Centbl., 92* (*1903*), *No. 10, p. 205*).—Sulphurous acid is shown to have a more or less detrimental effect upon the assimilative activity of all plant tissues. In the experiments of the author *Ficus elastica* and *Abutilon* sp. lost all power of assimilation when subjected to atmospheres containing a considerable quantity of the gas. The beech tree was found sensitive to 1 part in 314,000, and the fir to 1 part in 500,000. Grapes were less injured by small quantities of sulphurous fumes, and oaks were still more resistant.

The author shows that the stomata are left open when exposed to the gas and the carbon dioxid assimilating mesophyll is liable to injury. A somewhat prolonged exposure to the gas causes the green tissues to become yellow and the chlorophyll loses its ability to normally regenerate the destroyed chloroplasts. Another effect of the sulphurous-acid gas is to drive the water from the leaf cells into the intercellular spaces, as can be readily seen by the examination of such susceptible leaves as those of the beech.

The presence of hydrocyanic acid in the buds of Prunus, E. Verschaffelt (*Arch. Neerland. Sci. Exact. et Nat., 2. ser., 7* (*1902*), *pp. 497–509; abs. in Bot. Centbl., 92* (*1903*), *No. 9, pp. 183, 184*).—A report is given of studies made on the variation of hydrocyanic acid during the opening of buds of species of Prunus. The proportion of hydrocyanic acid in the buds and young shoots shows that the absolute quantity increases very materially during the opening of the buds, while the relative quantity in the different parts may remain the same.

The cause of the variation is not positively determined, but it was found that the hydrocyanic acid in the internodes was not less below closed buds than open ones. In the case of *Prunus laurocerasus* the evergreen leaves placed in darkness retained their hydrocyanic-acid content much longer than the recently developed leaves. These begin to turn yellow and rapidly lose their prussic acid. There does not appear to be any less hydrocyanic acid in the leaves after the budding of branches which carry them. It seems probable that the buds and the young shoots contain glucosids of the amygdalin type.

The presence of solanin in tobacco seed, J. Starke (*Rec. Inst. Bot. Univ. Bruxelles, 5* (*1902*), *pp. 295–298; abs. in Bot. Centbl., 92* (*1903*), *No. 9, pp. 182, 183*).—The author investigated the claim of Albo that tobacco seeds contain an alkaloid similar to, if not identical with, solanin. The method employed was checked by testing potato shoots for solanin, after which 12 gm. of tobacco seed and later 124 gm. of the seed of *Nicotiana macrophylla* were tested in the same manner without finding a trace of solanin or any analagous substance.

The rôle of diffusion and osmotic pressure in plants, B. E. Livingston (*Decen. Pubs. Univ. Chicago, 2. ser., 8* (*1903*), *pp. 162; abs. in Bot. Centbl., 93* (*1903*), *No. 27, p. 19*).—In the first part of this work the author summarizes the physical side of diffusion and osmotic pressure, while in the second portion he considers the physiological problems involved. A summary is given on the effect of turgidity on plants, and chapters are given on the absorption and transmission of water and materials held in solution. In regard to the latter the author concludes that by far the most important factor in their distribution through the plant body is simple diffusion.

Concerning the influence of osmotic pressure, the author concludes that while weak solutions may accelerate vital activities, concentrated ones retard them. The effect of high concentration seems to be due to the extraction of water from the living cells of plants. Whether this is the direct cause of response to these concentrated solutions is not known.

The electro-motive force in plants, A. B. Plowman (*Amer. Jour. Sci., 4. ser., 15* (*1903*), *pp. 94–104; abs. in Bot. Centbl., 93* (*1903*), *No. 29, p. 61*).—In a preliminary

paper giving the results of experiments on white lupine, *Codiæum regalis*, and *Poinsettia* sp. the author concludes that the functional activities of the plant cause differences of electrical potential in its various parts, and the intensity of these differences depend, in part at least, on the physiological condition of the plant.

Recent investigations in plant hybridization, C. CORRENS (*Bot. Ztg., 2. Abt., 61 (1903), No. 8, pp. 114–126; abs. in Bot. Centbl., 92 (1903), No. 21, pp. 418–488*).—The author gives a critical review of the more important contributions to the subject of plant breeding which were published during the autumn of 1901 and the spring of 1902.

Observations on the temperature of the subterranean organs of plants, H. H. DIXON (*Trans. Roy. Irish Acad., 32 (1903), pt. 3, Sec. B, pp. 145–170, pls. 3*).—According to the author, while the temperature of the above-ground part of the plant has been a subject of considerable investigation, but little attention has been given to the underground portions. He reports experiments in which the temperature of hyacinth bulbs, tubers of anemone and peony, roots of *Ficus carica* and *Vitis vinifera*, etc., were examined.

He found that subterranean organs, like the aerial parts of plants, may have during active growth a higher temperature than their surroundings. After the period of active growth has passed this elevation of temperature is no longer noticeable. There does not appear to be any true diurnal periodic rise in the temperature of subterranean organs such as has been reported by many investigators for aerial organs, and whatever rise does take place is due to the increased respiratory activity of the plant. In the less massive subterranean organs, such as fibrous roots, the variation in temperature is not sufficient to make itself appreciable above the fluctuations of the surrounding medium.

The author discusses the errors affecting the thermoelectric method of determining plant temperatures and gives some suggestions for reducing them to a minimum.

A comparison of the vegetation of the Landes and that of Fontainebleau, G. BONNIER (*Bul. Soc. Bot. France, 50 (1903), No. 2, pp. 174–176*).—A comparison is made between the character of plants of the same species grown in the Landes district of France and in the vicinity of Fontainebleau. The soil of the Landes is very sandy, underlaid at no great depth with a moist subsoil, while at Fontainebleau the sandy soil is of great depth. The plants of the 2 regions show marked differences in their general aspect, in their structure, and in their physiological functions. One striking difference was the entire absence of nectar and consequent insect visitation of plants at Fontainebleau that produced abundant nectar in the Landes.

Ferns, C. E. WATERS (*New York: Henry Holt & Co., 1903, pp. XII+362, figs. 228*).—A manual for the northeastern States, with analytical keys based on the stalks and on the fructification. The book is popular but thoroughly scientific, and describes and illustrates all the ferns known to occur in the range of Gray's Manual of Botany. Keys are furnished for the identification of all the species, and aided by the excellent illustrations it is possible for even an amateur to recognize any species met with. Many of the illustrations are from photographs made especially for this work and are not excelled by any similar publication. A chapter is devoted to the subject of fern photography, which with slight modification would doubtless be adapted to use in photographing other groups of plants. This work will be found to be one of the leading popular books on the ferns of the region included.

METEOROLOGY—CLIMATOLOGY.

Methods of meteorological investigation, W. N. SHAW (*Science, n. ser., 18 (1903), No. 459, pp. 487–497*).—This is an address before the subsection of astronomy and meteorology of the British Association for the Advancement of Science at its Southport meeting. It is a plea for closer cooperation between the universities and state weather services in order to build up a more thorough and effective sytem of

meteorological investigation. The unsatisfactory condition of present knowledge relating to the movement of the atmosphere and its relation to weather conditions is pointed out, and attention is called to the importance of simultaneous barometer readings in different parts of the world with corresponding weather observations in order that a synchronous weather chart for the world may be constructed. The importance of correlating the results of studies of the upper atmosphere with conditions prevailing at the surface is also pointed out. In general the author concludes that "the real requirement of the time is not fewer observations, but more men and women to interpret them."

Tables of daily precipitation at special river and rainfall stations of the United States Weather Bureau for the years 1893, 1894, 1895 (*U. S. Dept. Agr., Weather Bureau Doc. 228, pp. 256*).—The arrangement of the tables is alphabetical and the record is complete to the letter P. Notice of this compilation has been delayed in expectation of its completion.

Meteorological observations, J. E. OSTRANDER and F. F. HENSHAW (*Massachusetts Sta. Met. Buls. 175, 176, 177, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during July, August, and September, 1903. The data are briefly discussed in general notes on the weather of each month.

Annual precipitation in Oklahoma, C. M. STRONG (*Oklahoma Sta. Rpt. 1903, p. 65*).—A tabular summary of the precipitation records for 25 places in the Territory, including data for 1902 and previous years (extending in some cases to 1889) and general averages.

Meteorological observations, C. B. RIDGAWAY (*Wyoming Sta. Rpt. 1903, pp. 49, 50*).—A summary of observations at Laramie, Wyo., on temperature, relative humidity, dew-point, atmospheric pressure, precipitation, evaporation, and direction and velocity of the wind during the year 1902.

British rainfall, 1902, H. S. WALLIS and H. R. MILL (*London, 1903, pp. LXXVI + 250, illus.*).—Observations at 3,500 stations are summarized.

"Red rain" and the dust storm of February 22, T. E. THORPE (*Nature* [*London*], *68* (*1903*), *No. 1758, pp. 222, 223*).—Analyses of the dust are reported and discussed. (For previous note see E. S. R., 14, p. 1054.)

Meteorological annual for 1903, A. LANCASTER (*Annuaire météorologique pour 1903. Brussels: Observatoire météorologique de Belgique, 1903, pp. 660*).—This annual contains, among other papers, articles on A Study of the Force of the Wind in Belgium, by A. Lancaster; The History of Meteorology in Belgium, by J. Vincent; A Study of the Movement of Cirrus Clouds in Cyclones and Anticyclones, by E. Van der Linden, and Bibliographic Notes on Clouds (Classification and Nomenclature), by J. Vincent.

Meteorology of the spring of 1903 (*Bul. Dir. Agr. et Com.* [*Tunis*], *8* (*1903*), *No. 28, pp. 400–405*).—Observations at a number of places in Tunis on rainfall, temperature, humidity, cloudiness, wind movement, etc., are summarized for the months of March to May, 1903.

A study of the climate of Tunis, G. GINESTOUS (*Bul. Dir. Agr. et Com.* [*Tunis*], *8* (*1903*), *No. 28, pp. 347–394, pls. 3, figs. 18*).—The climatic features of different sections of Tunis are discussed and the available meteorological observations are summarized in tables and diagrams.

Indian rainfall, J. ELIOT (*Indian Met. Memoirs, 14* (*1902*), *pp. 709*).—This is a reprint of Blandford's tables of rainfall published in 1886, with the inclusion of similar data for the 14 years, 1887–1900.

Variations in barometric pressure and the forecasting of weather, J. PÉROCHE (*Rev. Sci. Paris, 4. ser., 20* (*1903*), *No. 4, pp. 108–110*).

WATER—SOILS.

The artesian waters of South Dakota, J. H. SHEPARD (*South Dakota Sta. Bul. 81, pp. 43–62*).—This is substantially a condensed reprint of matter first published in Bulletins 41 and 49 (E. S. R., 7, p. 287; 8, p. 965) of the station.

Significance of silicic acid in waters of mountain streams, W. P. HEADDEN (*Amer. Jour. Sci., 4. ser., 16 (1903), No. 92, pp. 169–184*).—Chemical studies of the waters of the Cache la Poudre River and some neighboring streams are reported which show a very high percentage of silicic acid (15 to 46 per cent of the solid matter) in the waters. This is believed to be "due to the action of water and carbon dioxid, and, perhaps, also of the acid products arising from the decomposition of vegetable matter on the feldspars of the granite of the region."

On the application of fluorescein in underground hydrology, E. A. MARTEL (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 3, pp. 225–227*).—A summary of results of observations by the author and others on the efficiency of fluorescein as a means of studying the movement of underground waters.

Soil moisture investigations for the seasons of 1901 and 1902, J. J. VERNON and J. D. TINSLEY (*New Mexico Sta. Bul. 46, pp. 46*).—The investigations here reported are a continuation of those previously reported (E. S. R., 13, p. 430). The later experiments, however, were transferred to land which was thought to be more uniform than that used in the experiments of 1899 and 1900. The soil of the plats used is in the main made up of river deposit with more or less wash from the foothills. "The first and second feet are mainly clay loam, passing into loam in some places and into clay in others. . . . The third foot varies from loam to clay loam, and in some places there are thin strata of clay. The fourth foot is generally a reddish sand, and under this lies a fairly clean sand down to the water table at about 14 ft." The soil "is variable enough to prevent the results on the different plats from being strictly comparable."

The ground was plowed to a depth of about 6 in. in November, 1900. Borders were thrown up around the plats and the first irrigation was given December 18, 1900, the second February 7, 1901. In March following 2 plats were subsoiled to a depth of about 20 in. The seed bed was prepared by disking the soil 3 or 4 in. deep and leveling with a smoothing board. Corn was planted April 10 and on May 8 all the plats were irrigated. For the crop of 1902 the ground was prepared in about the same way as in the previous year. It was plowed in December, 1901, and 2 plats were subsoiled. All except 3 plats were given a heavy irrigation on March 12. On April 3 the soil was stirred to a depth of 2 or 3 in. with harrows and corn was planted. All plats were again irrigated on April 23. Certain plats were not irrigated after the spring application of water in order to determine the amount of moisture in the soil when corn shows decided effects of drought; some plats were irrigated when the corn seemed to need it; some were irrigated only twice—when the corn was a few inches high and at time of tasseling; some were irrigated in the ordinary Mexican way—at time of planting, before tasseling, and when the grain was forming; and finally, certain plats were irrigated every 10 to 14 days. Observations on the growth of the crop and the moisture content of the soil at frequent intervals were made as in previous experiments. The conclusions reached are as follows:

"While the 'Mexican method' of 3 irrigations will produce a fair crop of corn, it is probable that in ordinary seasons from 1 to 3 additional irrigations may be given with advantage.

"In general, the moisture content of the soil and yield of corn increase with the number of irrigations; but on the individual plats there is little if any connection between moisture content and yield.

"The custom in this valley of partially substituting irrigation for cultivation is not without some foundation. The moisture content of the soil and the yield of corn are not materially increased by frequent surface cultivations on these soils.

"Subsoiling in these tests has not proved to be of marked advantage.

"On this soil, clay loam, corn wilts when the amount of moisture falls much below 20 per cent.

"The benefit derived from winter irrigation will depend mainly on the texture of both surface and subsoil. In these tests its benefit was confined mainly to insuring good germination."

In an attempt to determine the effect of frequent cultivation on the soil moisture, it was found to be "practically impossible with ordinary implements to produce a dust mulch on the clay loam and clay soils" experimented with, which are characteristic of the Mesilla Valley.

Electrodes of the moisture apparatus placed at different depths (3 to 18 in.) in the soil within 3 ft. of irrigated plats "showed no appreciable rise in the moisture content of the soil during the season." The conclusion is therefore drawn that "in the clay loam soils of the Mesilla Valley lateral percolation is very slight."

On the mechanical analysis of soils, T. Schloesing (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 26, pp. 1608–1613; 137 (1903), Nos. 6, pp. 369–374, fig. 1; 7, pp. 399–402*).—The author shows as a result of a continuation of previous investigations (E. S. R., 14, p. 18) that it is possible to separate the fine sand of cultivated soil (*terre végétale*) into a number of grades of decreasing degrees of fineness by noting the time required for deposition from water of a given depth and the weight of the deposits formed during successive intervals of time.

A method of mechanical analysis of soils based upon this principle, with the apparatus required, is described. The sample of soil previously treated on the filter with weak nitric acid to remove lime, and afterwards with weak ammonia and freed from coarse particles by decantation, is shaken up in water in a cylinder 33 cm. long. This cylinder is provided with devices for automatically maintaining a constant level of water, and for draining off the deposits formed through the bottom into receptacles drawn under the outlet of the cylinder by clockwork arrangement. The operation requires about 21 hours and is practically automatic. It is not claimed that exact results are obtained by the method, although as the average of the results with various soils 7 grades of sand were separated, varying in diameter of particles within the following limits: (1) 70–90 mm., (2) 65–80 mm., (3) 50–70 mm., (4) 30–50 mm., (5) 20–35 mm., (6) 15–20 mm., (7) 5–15 mm. Particles smaller than 5 mm. in diameter remain in suspension indefinitely.

A contribution to the study of the assimilation of the minerals of the soil by plants, J. Crochetelle (*Ann. Sci. Agron., 2. ser., 1902–3, II, No. 1, pp. 33–44*).—This article reports studies of the basicity of different soils (calcareous and noncalcareous) by means of citric acid, as used in Dyer's method for available plant food in soils, and of the assimilation of phosphoric acid by chlorotic plants. The determination of the lime content of soils by means of dilute citric acid was found to be very unreliable in the case of granitic soils, but very useful in case of soils producing chlorotic plants. Data are reported which indicate that plant chlorosis is due to interference with phosphoric acid assimilation by an excess of lime in the soil neutralizing the root secretions of the plants.

Practical methods for maintaining the fertility of the soil, W. Saunders (*Connecticut State Bd. Agr. Rpt. 1902, pp. 203–228*).—An argument in favor of better care and utilization of farm manures.

Soils—their requirements and improvements, H. J. Wheeler (*New Jersey State Bd. Agr. Rpt. 1902, pp. 127–158, pls. 5*).—A general discussion of this subject based mainly upon the investigations of the experiment stations, especially that of Rhode Island.

Unproductive black soils, H. A. HUSTON (*Indiana Sta. Bul. 95, pp. 31, pls. 4, figs. 5*).—This is practically a reprint of Bulletin 57 of this station (E. S. R., 8, p. 34), with the addition of mechanical and chemical analyses of 3 samples of unproductive black sandy soil and 1 sample of unproductive muck. The chemical analyses indicate a deficiency of phosphoric acid and potash, especially the latter, in the black sandy soils. The unproductive muck soil, however, contained larger percentages of these than adjacent productive soil. The conclusions regarding the temporary improvement of unproductive black lands by use of straw or kainit and permanent improvement by means of efficient drainage are the same as in the previous bulletin. In the present bulletin, however, more specific recommendations are made regarding the use of kainit and other potash salts as fertilizers for corn on black lands containing considerable sand but not having a high-water level. A trial of phosphoric acid in addition to potash salts is also suggested.

Soil conditions in the Philippines, C. W. DORSEY (*Philippine Bureau Agr. Bul. 3, pp. 57, pls. 10, fig. 1, map 1*).—This bulletin discusses general soil conditions in the abacá or Manila hemp districts; in Union Province, Luzon, and in the Philippine forests, and gives an account of a more detailed survey of the Batangas area, Luzon. The agricultural adaptations of the various soils are given special attention. It is stated "that certain districts possess soils adapted to the cultivation of Manila hemp, sugar cane, rice, tobacco, cocoanuts, coffee, and cacao, . . . but there are also many fine tracts of land where these industries can be greatly extended and improved, and new crops, such as cotton and tea, a host of fine fruits, and minor produce crops can be profitably introduced."

The preservation of the soil from damage caused by sluits, E. B. BRADFIELD (*Agr. Jour. Cape Good Hope, 23 (1903), No. 2, pp. 190–195*).—This article discusses briefly the damage caused by and methods of prevention of soil washing.

Reclamation of drift sands in Cape Colony, C. D. H. BRAINE (*Agr. Jour. Cape Good Hope, 23 (1903), No. 2, pp. 161–178, pls. 4*).—A description of the extent and character of the drift sands of Cape Colony, with some account of the government attempts to reclaim these areas, and analyses of Eerste River drift sand at different depths and periods. The method of reclamation followed has involved the spreading of town refuse on the sand and the planting of sand-binding trees and grasses. The average cost of 5 years' reclamation work at Eerste River was $48.74 per acre. The trees found most useful for planting on the sands were *Acacia saligna* and *A. cyclopis*. Various species of Eucalyptus have also been planted with more or less promise of success.

"The Fabricia (*Leptospernum lævigatum*) propagates readily, and is most effective in arresting sands in warm climates. Other useful trees are the *Tamarix gallica*, *Widdringtonia cupressoides*, and the *Cupressus macrocarpa*. . . . Of the grasses used in the Cape Colony, by far the most successful is the *Ehrharta gigantea* or pypgrass, the vigor of its growth far exceeding that of any other. Perhaps the most useful is the indigenous *Triticum junceum*, which is being used on the exposed littoral dune at Port Elizabeth, as it thrives well near the sea. The *Elymus arenarius* does not grow freely on the driest parts of the sands, and has, on the whole, shown poor germination, although in some cases healthy and strong. Extensive experiments have been made with marram grass (*Psamma arenaria*), also known as *Ammophila arundinacea* and *Arundo arenaria*, but the results have been very disappointing. . . . Other useful grasses are the *Cynodon dactylon* and *Sporobolus matrella*, which were self-introduced at Eerste River and grew vigorously. The Panicum and Stenotaphrum are also indigenous grasses that do well on sandy soils."

Agricultural geology, J. E. MARR (*London: Methuen & Co., 1903, pp. XI + 318, figs. 104, map 1*).—The author states in his preface that "this book has been written, after study of the schedule framed for the guidance of candidates for the International Diploma of Agriculture, to be used by students who are reading for examinations in

agriculture, though it may be found useful to others." It is divided into 4 sections: (1) Study of the composition and structure of rocks; (2) the operations of geological agents, including weathering, agents of transport, etc.; (3) geological surveying; and (4) study of the strata of the British Isles in the order in which they were formed.

FERTILIZERS.

Fertilizer experiments, C. A. MOOERS (*Tennessee Sta. Bul. Vol. XVI, No. 1, pp. 20, figs. 5*).—This bulletin gives the results of experiments on fortieth or fiftieth-acre plats, to determine the fertilizer requirements of certain typical Tennessee soils and to test the best methods of applying fertilizers. The crops experimented with were sweet potatoes, white potatoes, grass and clover, and cowpeas. "Both field experiments and laboratory work on the soils of this State are of more than ordinary value, on account of the uniform composition of each type. Those of most importance in East Tennessee repeat themselves in narrow strips, having a general direction from northeast to southwest. The typical soils of the other sections of the State are not so complicated and will require less investigation."

Both chemical analysis and field experiments show the need of phosphoric acid on all of the soils experimented with. Next to the fundamentally important phosphoric acid, nitrogen is most needed, and the least needed element is potash. In the experiments with sweet potatoes, the principal object was to determine the most profitable amount of fertilizer and the best proportions of the fertilizing ingredients, especially the best amount of cotton-seed meal to use in connection with the standard amount (300 lbs. per acre) of acid phosphate. The soil used for the experiments was a sandy loam characteristic of the iron limestone formation. Greatly increased yields were obtained from the use of a mixture of 350 lbs. of cotton-seed meal with 300 lbs. of acid phosphate. The addition of potash produced little effect. The most profitable returns, however, were obtained during 2 seasons by applying 1,520 lbs. per acre of a mixture consisting of 720 lbs. of cotton-seed meal, 600 lbs. of acid phosphate, and 200 lbs. of muriate of potash. "Judging from other results, however, the amount of potash could have been reduced to advantage."

The experiments with white potatoes were made on a shale soil very deficient in plant food and on a very poor white gravelly hill soil. On the basis of the results obtained, the following fertilizer mixture is recommended: 360 lbs. of cotton-seed meal, 300 lbs. of acid phosphate, and 50 lbs. of muriate of potash, used at rates of from 500 to 1,000 lbs. per acre.

The experiments with orchard grass and clover were made on what had formerly been very poor and unproductive soil, but which had been improved for the grass by turning under a crop of cowpeas and rye which had been moderately fertilized and manured.

"The yields of grass and clover were greatly increased by applications of acid phosphate and nitrate of soda. Acid phosphate used alone affected the clover more than the grass, while the mixture of acid phosphate and nitrate of soda resulted in a predominating growth of grass. Acid phosphate, 300 lbs. to the acre, used alone, greatly increased the yield of clover, and was by far the most profitable fertilizer."

The experiments with cowpeas were made on a soil known to be very deficient in phosphoric acid, the special object being to compare the relative fertilizing value of raw phosphates with acid phosphate. Acid phosphate alone gave the most profitable returns. On very poor land good results followed the use of potash in addition to the phosphate. In both pot and field experiments fine-ground raw rock phosphate did not produce any marked increase of yield on a soil known to be poor in phosphoric acid. "In pot experiments the phosphoric acid from fine-ground raw bone was found to be about one-half as efficient for both cowpeas and turnips as the phosphoric acid from acid phosphate."

In the experiments on methods of applying fertilizers it was found that "better results followed the use of 250 lbs. of a complete fertilizer for corn when applied in the row than when applied broadcast and harrowed into the soil. Slightly better yields came from the broadcast application of 500 to 1,000 lbs. to the acre than from the same amounts applied in the row, but the results should not be considered conclusive. Cotton-seed meal was found to retard seriously the germination of seed with which it was applied in direct contact, and it should not therefore be drilled with wheat. When applied in the row for crops planted in rows it should be mixed with the soil before the seed is dropped. Cotton-seed meal applied broadcast in the fall for wheat gave favorable returns as compared with nitrate of soda furnishing the same amount of nitrogen."

Notes on the management of barnyard manure, H. BUHLERT (*Fühling's Landw. Ztg., 52 (1903), Nos. 17, pp. 625–630; 18, pp. 647–654*).—A review of investigations on this subject.

Derivation of animal ammoniates—dried blood, tankage, hoof meal, bone, and other products, E. M. PAGET (*Amer. Fert., 19 (1903), No. 3, pp. 5–23, figs. 12*).—The method of manufacture of these products used in packing houses is described. Articles previously noted (E. S. R., 14, p. 953) are incorporated in this article.

A new source of nitrogen for agriculture, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 6 (1903), No. 32, pp. 173–176*).—This is a summary and discussion of the experiments of Wagner and Gerlach (E. S. R., 15, p. 25) on the fertilizing value of the so-called lime nitrogen (calcium cyanamid).

Rendering atmospheric nitrogen available for agriculture and industry, A. FRANK (*Ztschr. Angew. Chem., 16 (1903), No. 23, pp. 536–539*).—This is the full text of a paper read before the International Congress of Applied Chemistry at Berlin, in 1903, a brief extract of which has already been noted (E. S. R., 15, p. 131).[a] In it the author gives statistics of consumption of nitrogen compounds to show the importance and desirability of some practical means of utilizing atmospheric nitrogen for industrial purposes. He reviews the history of attempts to fix the free nitrogen of the air in the form of nitrates, cyanids, and ammonia from Priestley's experiments in 1785 in oxidizing the atmospheric nitrogen by means of the electric spark to the recently proposed methods of preparing cyanamid by passing atmospheric nitrogen freed from a large part of the oxygen normally associated with it in the air over fused carbids of the alkali earths or by fusing a mixture of calcium carbonate and coal in presence of the nitrogen gas in an electric furnace.

In this connection he refers to the work of himself and Caro beginning in 1895 on the preparation of the carbids of the alkali earths, originally with a view solely to the manufacture of cyanids, experiments being made first with barium carbid and later with calcium carbid. It was found in these experiments that the fixation of the nitrogen by barium or calcium carbid did not result in the formation of barium or calcium cyanid, as was expected, but in barium or calcium cyanamid ($BaCN_2$ or $CaCN_2$) which yielded cyanids on fusion with alkali salts. By heating the cyanamid with water under high pressure calcium carbonate and ammonia were formed as follows: $CaCN_2 + 3H_2O = CaCO_3 + 2NH_3$. The better grade of cyanamid prepared by the above process contain from 14 to 22 per cent of nitrogen. By dissolving the cyanamid in water and crystallizing in the cold, a dicyanamid $(CN_2H_2)_2$ containing 66 per cent of nitrogen was obtained. This is a white salt resembling ammonium chlorid.

The fertilizing value of the cyanamid (the so-called lime nitrogen) is discussed, and the experiments of Gerlach and Wagner (E. S. R., 15, p. 25) are referred to as establishing the high value of the product for this purpose.

[a] In the previous notes on this subject the cyanamid has been incorrectly referred to as a by-product of acetylene-gas manufacture.

Preliminary report of the Cyanid Company of Berlin on its work in the preparation of cyanids and on the utilization of the nitrogen of the air for fertilizing purposes (*Ztschr. Angew. Chem., 16 (1903), No. 22, pp. 520–522*).—The article explains the principles and the development of the company's processes of preparing cyanamids and cyanids, first from barium carbid as proposed by Frank and Caro, and later from calcium carbid as proposed by Pfleger; and also by direct treatment of a mixture of calcium carbonate, coal, and atmospheric nitrogen in an electric furnace.

The fertilizing value of the cyanamid is briefly noted, and other commercial applications of the process, e. g., in preparing cyanids, etc., are explained.

The preparation of alkali cyanids from calcium cyanamid, G. Erlwein (*Ztschr. Angew. Chem., 16 (1903), No. 23, pp. 533–536; Chem. Ztg., 27 (1903), No. 47, p. 567*).—This is a paper read before the International Congress of Applied Chemistry at Berlin, 1903, which reviews the history of the development of this process with special reference to its commercial applications.

The utilization of atmospheric nitrogen, F. Rothe (*Ztschr. Angew. Chem., 16 (1903), No. 27, pp. 658, 659*).—The author claims in this article to have worked out independently of Frank and Caro the processes involved in the fixing of free nitrogen of the air by means of carbids of the alkaline earths or mixtures of carbonates of the alkaline earths and carbon.

Progress in the potash industry, M. Hagen (*Chem. Ztg., 27 (1903), No. 60, pp. 747–749*).—A brief review.

Frosts and potash fertilizers, L. Dumas (*Jour. Agr. Prat., n. ser., 6 (1903), No. 33, p. 226*).—A brief note on a recent article by Couturier (E. S. R., 15, p. 236), in which it is suggested that the effect of potassic fertilizers in increasing the resistance of plants to frost is probably due to the greater vigor of plants so treated, and that doubtless resistance to frost is accompanied by an equal power of resistance to fungus diseases.

Fertilizers, R. E. Rose and E. E. McLin (*Mo. Bul. Florida Dept. Agr., 13 (1903), No. 85, pp. 17–39*).—The results of inspection under State law of a large number of samples of fertilizers are reported, with notes on valuation, average composition of fertilizing materials, etc.

Fertilizer inspection, C. D. Woods and J. M. Bartlett (*Maine Sta. Bul. 94, pp. 93–103*).—This bulletin gives the results of analyses of samples of commercial fertilizers collected by a representative of the station. It also includes notes on valuation.

Analysis of commercial fertilizers sold in Maryland, H. B. McDonnell et al. (*Maryland Agr. Col. Quart., 1903, No. 21, pp. 54*).—The results of analyses of 489 samples of fertilizers examined from March to June, 1903, are reported.

Analyses of commercial fertilizers and manurial substances, C. A. Goessmann (*Massachusetts Sta. Bul. 90, pp. 30*).—Analyses are reported of 225 samples of fertilizers collected in the course of regular fertilizer inspection during 1902, and of 77 samples of fertilizing materials sent to the station for examination, including wood ashes, lime ashes, coal and wood ashes, tankage, ground bone, cotton-seed meal, nitrate of soda, lime compounds, phosphatic slag, bat guano, horse manure, sheep manure and wool waste, sugar beet refuse, cassava waste, compound fertilizers, and soils.

Fertilizer analyses, F. W. Robison (*Michigan Sta. Bul. 210, pp. 125–145*).—The results of the inspection of fertilizers during the spring of 1903 are reported with the test of the Michigan fertilizer law, and a brief general discussion on the nature and use of fertilizers.

Analyses of commercial fertilizers (*South Carolina Sta. Bul. 82, pp. 10*).—This bulletin reports analyses and valuations of 163 samples of fertilizers examined during the season of 1902–3.

Commercial fertilizers and commercial poisonous insecticides, H. H. Harrington (*Texas Sta. Bul. 67, pp. 21–34*).—"This bulletin contains a discussion

of some of the fundamental principles underlying the use of fertilizers and insecticides, together with their chemical composition, and a list of dealers and agents who handle commercial fertilizers in this State." Analyses of 67 samples of fertilizers and 9 samples of insecticides examined in accordance with State law, and 7 samples of miscellaneous fertilizing materials, including tobacco waste, goat and sheep manure, barnyard manure, and spent boneblack from a sugar refinery, are reported.

Fertilizers, 1903, T. Macfarlane (*Lab. Inland Rev. Dept. Ottawa, Canada, 1903, Bul. 86, pp. 41*).—Analyses are reported of 128 samples of fertilizing materials sent to the department of internal revenue by manufacturers, importers, or vendors, in accordance with the provisions of the fertilizer act of 1890, as representing the goods to be offered for sale in Canada during the season of 1903–4. The tabulated analyses are accompanied by notes on the extent of the fertilizer trade in Canada, on the "citric soluble" phosphoric acid of fertilizers (that is, the phosphoric acid soluble in 1 per cent citric acid), and on the use of fertilizers and manures in general, the latter including determinations of moisture, ash, and nitrogen in 24 samples of peat moss.

Commercial fertilizers in Portugal, O. Klein (*Ztschr. Angew. Chem., 16 (1903), No. 34, pp. 829–831*).—Statistics of the trade are given. It is stated that from 75,000 to 80,000 tons of fertilizers are annually used in Portugal.

Is the assimilation of free nitrogen due to bacteria or is this a chemical process? II, A. A. Bonnema (*Chem. Ztg., 27 (1903), No. 67, pp. 825, 826*).—In continuation of previous investigations (E. S. R., 14, p. 850) the author reports observations on the iron content of the root tubercles of leguminous plants, which he believes show that iron hydroxid is present in considerable amounts and is essential to the process of assimilation of free nitrogen by the root tubercle organisms.

FIELD CROPS.

Report of the Upper Peninsula Substation for the years 1901 and 1902, L. M. Geismar and C. D. Smith (*Michigan Sta. Spec. Bul. 20, pp. 1–26*).—After describing the station grounds and discussing the weather conditions which prevailed during 1901 and 1902, the authors report the results of culture tests with a large number of cereal, forage, and horticultural crops.

Of 4 varieties of winter wheat Dawson led, with a yield of 41 bu. per acre, followed by International No. 6, with 33.23 bu. In the tests with Spring wheat for the 2 years, Wild Goose yielded from 6 to 10½ bu., Velvet Chaff over 19, Saskatchewan Fife 12, and Minnesota No. 163 and Stanley each 17⅓ bu. per acre. Nicaragua gave a very small yield and Canadian Blue Democrat proved to be a weak variety.

Plat tests were made with 10 varieties of barley in 1901 and 6 varieties in 1902. The first season all varieties lodged badly. Swan, which seemed to have the stiffest and longest straw, ripened earliest. The second year Manchuria led, with a yield of 41.66 bu. per acre, followed by Oderbrucker, Canada Six-Rowed, French Chevalier, and Canadian Thorp, with yields of 30.83, 25.5, 25.5, and 24.5 bu. per acre, respectively.

The season of 1901 was not very favorable for oats. Black Beauty and Daubeny gave the best results in strength of straw and weight and yield of grain. These 2 varieties yielded over 42 bu. per acre, while Silver Mine ranking next in yield produced only 33.33 bu. In 1901, 5 varieties, Columbus, Black Beauty, Lincoln, American, Banner, and Dupauper, produced 63.75, 53.75, 52.50, 48.75, and 37.50 bu. per acre, respectively.

Among the large number of varieties of corn grown in 1901, Gilman and Wernich Sweet Pearl Dent proved superior. Neither in 1901 nor in 1902 did any variety mature perfectly. Minnesota King came nearest to reaching maturity, followed by

Yellow Dent. Seed ripened at the station proved equal in vitality to seed obtained from other sources. Only 1 variety of sweet corn, Oakview Early Market, planted May 23, reached the edible stage.

Notes on the growth of a large number of forage crops are given. Good results were obtained with a number of varieties of alfalfa, including sand lucern. Crimson Clover in 1902 yielded 2,533 lbs. of hay per acre. The yields of field peas for the season ranged from 29 to 41 bu. per acre. The Black-Eyed Marrowfat pea gave a yield of 41 bu. of peas and 4,100 lbs. of straw per acre. Winter vetch produced 4,373 lbs. of hay per acre, while spring vetch gave a little less than 3,000 lbs. A yield of 920 lbs. of ripe seed per acre, with 5,400 lbs. of straw, was obtained from spring vetch in 1902.

Spring vetch and wheat grown together produced 5,200 lbs., and vetch alone only 3,400 lbs. of hay per acre. The mixed crop cured in a much shorter time than the vetch alone. Frost injured the growth of soy beans, and completely destroyed cowpeas. Lentils yielded at the rate of 160 lbs. of seed and 3,760 lbs. of straw per acre. In 1902 brome grass gave a yield of 3,285 lbs. of hay per acre in July, and by the middle of September had again headed at a height of 16 in. The growth and yields of rye, clover, timothy, orchard grass, redtop, spurry, sorghum, millet, rape, hemp, and flax are briefly noted.

The results of variety tests with potatoes in 1901 are reported and a number of varieties described. Pingree and Sir Walter Raleigh ripened earliest, being followed by Bovee, Six Weeks, Pride of Michigan, Hearst, and Irish Cobbler. Sir Walter Raleigh, Rose of Erin, Northlight, and Wonder of the World, in the order given, were most resistant to blight. Delaware led with a total yield of 333.33 bu. per acre, followed by Sir Walter Raleigh with 312.84, and Rose of Erin with 293.33 bu. In 1902 Sir Walter Raleigh ranked first, with a yield of 226.33 bu., and Rose of Erin second, with a yield of 222.22, while Delaware this season gave only 151.11 bu.

The results of fall and spring planting of potatoes, together with the effects of spraying with Bordeaux mixture against blight, are reported. The fall planting was done October 30, and the different varieties under test matured from September 15 to 28. The yields obtained from fall planting compared very favorably with spring planting. Spraying in every case largely increased the yield. The work with vegetables and fruits is noted elsewhere.

Cooperative work with the U. S. Department of Agriculture, E. NELSON (*Wyoming Sta. Rpt. 1903, pp. 57–66*).—This work consists of grass and forage plant investigations. A number of grass plats were started in 1901, and the record of the second year's growth is here reported. *Festuca pratensis*, *F. rubra*, *Agropyron occidentale*, *A. dasystachyum subvillosum*, and *Bromus pumpellianus* remained green during September, while the other species reached full maturity in August. *Bromus pumpellianus* surpassed both *B. inermis* and *B. marginatus* in thriftiness and amount of leaf growth. *Melilotus officinalis* made a dense growth, but was entirely killed by frost on September 11. *Poterium sanguisorba* grew from 13 to 20 in. high and matured seed. It withstood the frost well and remained green until late in the fall.

Experiments in methods of seeding were made with *Atriplex argentea*, *A. nuttallii*, and *A. truncata*. Seeding ½ in. deep gave the best results. No difference was observed between late fall and spring seeding. Seeds of the 3 species were stratified in moist sand in a cool cellar for 60 days and planted in comparison with dry seed. A few plants were obtained from the stratified seed of *A. argentea* and *A. truncata*, while none of the dry seeds grew. Germination tests of seed of 7 species showed very low percentages of germination for the species with seeds inclosed in very thick and hardened bracts. Of the seed of *A. philonitra* and *A. truncata*, with bracts not so thick and indurated, 27 and 39 per cent, respectively, germinated, and of 25 husked seeds of *A. nuttalii*, 24 grew. Seeds of *A. argentea* run through a hand-grinding mill for the purpose of crushing the husk produced plants much earlier than untreated seeds, and the growth at the end of the season was also considerably larger.

Report on cultural tests in 1901–2, A. DAMSEAUX (*Bul. Agr. [Brussels], 19 (1903), No. 1, pp. 1–12*).—Among a number of varieties of wheat Desprez Yellow square head, Kirsche Improved square head, Teverson, and White Flemish proved most resistant to an extremely wet season. In a fertilizer test with rye the plat receiving 2 kg. of superphosphate gave a larger yield than the plats receiving 4 or 6 kg. Ligowo and Yellow Flemish oats were the most productive varieties.

The attacks of rust on oats were less severe where the crop had been fertilized with Thomas slag. The best quality of sugar beets was produced by Schlitte Hornung Kleinwanzlebener, and Strube. Kirsche Improved Yellow mangel among 6 common varieties produced the largest yield and the largest quantity of dry matter per hectare. The roots of this variety ranked first in the percentage of nitrogenous substance. The quantity of leaves and crowns produced were smallest among the varieties tested.

A plat of chicory fertilized with sulphate of ammonia gave a much better yield of dry matter than a plat fertilized with nitrate of soda. Topping tobacco apparently increased the yield by 400 kg. per hectare and the nicotine content by 1.2 per cent. Abutilon this season failed to ripen seed and produced only 680 kg. of fiber per hectare as compared with 1,400 kg. the year before.

A new variety of lupine having a red blossom produced 39,400 kg. of green forage per hectare and seemed well adapted to moderately stiff calcareous soils. Soil inoculation tests with lupines and vetch proved effective in pot cultures, but gave contradictory results in the field.

The content of dry matter, sugar, and nitrogen compounds in fodder beets at different stages of growth, J. A. LE CLERC (*Inaug. Diss., Univ. Halle, 1903, pp. 56*).—The work with field beets by different investigators is briefly reviewed, the analytical methods employed by the author are described, and the results of analyses made at regular intervals from June 6 to November 11 are tabulated and discussed. It was found that the percentage of water in the beet bore a close relation to the rainfall, rising with the increase in precipitation and falling with the decrease. The highest percentage of sugar in the dry matter was reached September 9, during the period of greatest light intensity. This period also showed the highest temperature and the longest duration of sunshine.

Beets grown at intervals of 30 cm. in rows 45 cm. apart were found to contain on September 22 and October 20 1.43 and 2.27 per cent more water and 13.95 and 11.56 per cent less sugar in the dry matter, respectively, than beets grown in the same way, but with the exception that 2 plants were allowed to grow in a hill instead of one. The beets thinned to 1 plant in a place yielded 7,714 kg. of dry matter and 3,345 kg. of sugar, while the thicker-grown beets produced 10,240 kg. of dry matter and 5,579 kg. of sugar per hectare.

Analyses made November 11 showed that the upper third contained more water and less sugar than the rest of the beet, while the lower third was richer in sugar and poorer in water than the upper portion. The middle third was about an average between the two. This result is considered an argument for the culture of beets developing mostly beneath the surface of the soil.

During the period of rapid growth the leaves contained about 93 per cent of water, but analyses made October 30 showed that their water content had fallen to 90 per cent. Sugar was not detected in the leaves by means of the polariscope.

The crown of the beet is estimated to comprise from 15 to 25 per cent of the entire plant and about 75 per cent of the portion growing above ground. The water content of the crowns remained about constant between the dates of October 18 and October 30. This portion contained about 17 per cent of the total sugar content of the beet. In completely-developed beets the author regards the crowns as containing one-sixth of the dry matter and the sugar, 18 per cent of the total nitrogen, and 24 per cent of the nitric acid.

At the beginning of the investigation the proportion of nitrogen and dry matter was 1:28 and at the end 1:70. On July 28 the proportion of nitrogen to sugar was 1:19 and on October 30 1:40. The dry matter and the sugar increased much more rapidly than the nitrogen. The thinned beets had a higher nitrogen content than the unthinned and smaller beets. It is believed that owing to a greater assimilating surface the larger plants absorbed more nitrogen salts, especially nitrates. In the thinned and unthinned beets 35 and 48 per cent, respectively, of the nitrogen was in the form of nitrates. The nitrogen content was largest in the crown and diminished toward the point, being in this respect the reverse of the sugar content.

The author discusses the albuminoid, nitric, and amid nitrogen content of fodder beets. All of the nitrogenous compounds except the amido acids increased relatively much faster in the roots during ripening than in the tops. The roots contained approximately 0.7 of the dry matter, 0.8 of the sugar, more than half of the total nitrogen and albuminoids, and 0.7 of the amids. The feeding value of the roots and tops is considered.

Improvements in cereals, W. SAUNDERS (*Connecticut State Bd. Agr. Rpt. 1902, pp. 119–129, pl. 1*).—This article contains a brief review of the work in this line by a number of plant breeders, and has special reference to the improvement of wheat, barley, and oats by the Canadian Experimental Farms. General directions for carrying on the work are given.

A partial record of the crossing with wheat at these farms shows that from 1,650 flowers carefully worked, only 220 kernels were obtained. Crosses of Hard Red Calcutta and Gehun, early Indian varieties, and Ladoga, an early maturing Russian sort, with Red Fife and White Fife, were made to combine the earliness of the Indian varieties with the vigor, productiveness, and high quality of the Fife wheats. The cross-bred varieties thus obtained ripen 3 to 4 days earlier than the Fife varieties and are vigorous and productive. Of the different new sorts, Preston, a cross of the Red Fife with Ladoga, has taken the lead in productiveness, showing an average yield for 6 years of 33 bu. and 53 lbs. per acre, or an increase of 1 bu. and 28 lbs. over Red Fife. Laurel, a cross of Red Fife with Gehun, has produced even higher yields, but has been under observation only 3 years.

The best results for earliness were obtained from a cross with Onega, a variety from the most northern wheat district of Russia, and Gehun, which comes from a high elevation in the Himalayan Mountains. Two of the resulting crosses, Early Riga and Harold, ripen a week earlier than Red Fife, but the grain is small and the yield only medium. In the author's experience any marked gain in earliness has usually involved a reduction in the weight of the crop.

In a recent experiment Red Fife was fertilized with pollen from the large-grained *Triticum polonicum* for the purpose of producing a variety with a larger kernel than the ordinary grain. The progeny thus far obtained has shown remarkable variation.

Distinct hybrids of 2-rowed and 6-rowed barleys produced at the Experimental Farms are described in a general way and the work with oats and peas is mentioned.

The structure of the corn kernel and the composition of its different parts, C. G. HOPKINS, L. H. SMITH, and E. M. EAST (*Illinois Sta. Bul. 87, pp. 77–112, figs. 4*).—This bulletin contains additional data relating to the improvement in the chemical composition of the corn kernel, as treated in previous bulletins (E. S. R., 11, p. 633; 14, p. 855). The chemical and physical composition of the different parts of the corn kernel was further studied and the additional results, together with some of the data previously obtained, are here given in tabular form and discussed.

The authors consider the corn kernel to consist of the following 6 physical parts: Tip cap, hull, horny gluten, horny starch, white starch, and germ. The tip cap is described as covering the tip or base and comprising about 1.5 per cent of the grain, and the hull as the very thin outer coat, comprising about 6 per cent of the kernel and containing a lower percentage of protein than any other part of it. The horny

gluten lies immediately under the hull, comprises from 8 to 14 per cent of the grain, and is more abundant in the kernels with a high protein content. This part contains from 20 to 25 per cent of protein, and is the richest in this substance of all the parts of the kernel.

The horny starch, the chief substance in the sides and back of the kernel, comprises about 45 per cent of ordinary corn, but the percentage is much higher in corn with a high protein content and lower in corn with a low protein content. This part of the kernel is rich in starch, and contains about 10 per cent of protein. Owing to the large proportion of the kernel which it constitutes, it contains a greater total amount of protein than any other part. The white starch, occupying the center of the crown end of the kernel and usually partially surrounding the germ, comprises about 25 per cent of the kernel, being less in high-protein corn and greater in low-protein corn. It contains only from 5 to 8 per cent of protein. The germ comprises about 11 per cent of the kernel and varies according to the oil content, constituting a larger proportion in high-oil corn and a smaller proportion in low-oil corn. In oil the germ ranges from 35 to 40 per cent, and furnishes from 80 to 85 per cent of the total oil content of the kernel. Corn high in protein is described as containing a large proportion of horny gluten and horny starch, and a correspondingly smaller proportion of white starch. In corn of a high protein content the horny parts comprise over 60 per cent of the kernel and contain about 80 per cent of the total protein present.

In 1900 comparison was made between 2 strains of corn bred for 4 years for high oil and low oil content, respectively. The plants representing the 2 strains were grown this season under identical conditions. The results show only an average difference of 1.97 per cent in the oil content and of 0.18 per cent in the protein content. These figures show that there is less than 5 per cent of a perfect correlation between the oil and protein. From these and previous results it is concluded that as the percentage of protein increases in corn, the starch decreases and the oil content remains practically unchanged, and that the selection of high-protein seed corn should be governed by a large proportion of horny parts, and of high-oil seed corn by a large proportion of germ.

The chemical composition of 4 strains of pedigreed corn compared for high and low protein and high and low oil was determined from samples of 10 ears each taken from the crop of 1902 and representing the seventh generation. The protein content of the low-protein ears varied from 6.36 to 7.9 per cent, with an average of 6.71 per cent, while the protein content of the high-protein ears varied from 13.98 to 15.01, with an average of 14.44 per cent. The average oil content of the low-protein ears was 4.21 per cent and of the high-protein ears 4.93 per cent.

A slight correlation was noticed to exist between the average percentages of protein and germ, but there were some marked exceptions. In one case an ear with 6.37 per cent of protein contained 9.53 per cent of germ, while in another instance an ear with 14.74 per cent of protein contained 9.51 per cent of germ. One of the lowest protein ears with a protein content of 6.48 per cent contained 10.79 per cent of germ, while the highest protein ear, with 15.01 per cent of protein, contained only 9.82 per cent of germ. The results of analyses of the low-oil and high-oil ears show an average for the low-oil corn of 2.52 per cent of oil and 9.98 per cent of protein, and for the high-oil ears of 7 per cent of oil and 11.31 per cent of protein. In these figures the slight correlation between oil and protein again becomes apparent, the high-oil corn containing nearly 3 times as much oil as the low-oil corn, but being less than one-seventh richer in protein. A very marked correlation between oil and germ is shown in the results obtained in studying the oil and germ in low-oil and high-oil corn. The 10 low-oil ears contained an average of 2.52 per cent of oil and 7.74 per cent of germ, and the 10 high-oil ears an average of 7 per cent of oil and 13.84 per cent of germ.

The effect of breeding in changing the composition of the different physical parts of the kernel is shown by the fact that the germs from the low-oil corn contained about 25 per cent of oil and those from the high-oil corn nearly 42 per cent, while the endosperms from the low-protein ears contained less than 6 per cent of protein and those from the high-protein ears nearly 14 per cent. Results further show that breeding for high or low protein produced no marked effect upon the ash content or the oil content of either the germs or the endosperms, and that it only slightly influenced the protein content of the germs. As calculated on the basis of 100 lbs. of corn, there was a maximum difference of only 0.75 lb. of protein in the germs from 100 lbs. of low-protein and high-protein corn, and a difference of 7.06 lbs. of protein in the endosperms.

The composition of parts of the corn kernel separated by hominy mills is compared with the composition of these same parts separated by hand.

Field experiments with maize, G. L. Sutton (*Agr. Gaz. New South Wales, 14 (1903), No. 7, pp. 656–664, figs. 19*).—Descriptions of 25 varieties of corn tested at the Hawkesbury Experimental Farm in 1902 and 1903 are given. The details enumerated have reference mainly to the ear. A number of the varieties were imported from the United States.

Why popcorn pops, M. I. Wilbert (*Amer. Jour. Pharm., 75 (1903), No. 2, pp. 77–79*).—Observation and experiment led the author to the conclusion that the popping of popcorn is caused by the expansion of moisture in the starch cells. It was found that old and dry corn did not pop readily. Such corn "will at best only split open from a number of cells near the center of the corn kernel. If the application of heat be made slowly, it is possible to dry the kernels of corn, parch, and even char them without rupturing the outer coat in any way."

It was also noted that "at the base of the kernels, or at the point of attachment to the cob, the cells are less compact and are seldom, if ever, ruptured by the generated steam. It is from this point too that the kernels of corn appear to dry most rapidly." The bearing of this point on the theory that popping is caused by an explosion of steam is found in the fact that "popcorn invariably bursts first at the densest portion of the kernel, and never at or near its base or point of attachment."

When old and dry corn was soaked for 12 hours and then dried for an equal time it did not pop well. If kernels were allowed to dry on the surface for 24 hours longer "the resulting kernels of popped corn were not only very large, light and flaky, but had absolutely no suggestion of toughness."

As regards the loss of weight in popping, the author noted that 100 grains of whole or unpopped corn weighed 13 gm., the same quantity partially popped 11 gm., fully popped 9.2 gm., and dried and parched 7.5 gm.

The author states that studies should be made of the changes in cell structure caused by popping, as well as determinations of the amount of material rendered soluble by the heating of the starch.

Cotton in the United States, Y. Henry (*Le coton aux États-Unis. Paris: Augustin Challamel, 1903, pp. 61, fig. 1, maps 2*).—A brief review of cotton culture in the United States, including descriptions of a number of varieties grouped according to the period of their maturity.

Experimental investigations on hemp, M. Molliard (*Bul. Soc. Bot. France, 50 (1903), No. 2, pp. 204–213*).—The influence of the size, number, and weight of the akenes on crop production of hemp is shown, as well as the effect of soil, humidity, light, etc., on the growth and seed production. The effect of the weight of seed on the sexuality of the plants was investigated, and while the weight of the seed seemed to have an influence on determining the sex of the plants, the results obtained were not sufficiently marked to warrant generalization in this respect.

Pasture and forage plants for South Dakota, E. C. Chilcott (*South Dakota Sta. Bul. 81, pp. 1–26*).—This bulletin discusses in a popular manner the culture and

uses of corn, saccharine and nonsaccharine sorghums, rape, oats and peas, sand vetches, spurry, millet, winter rye, and root crops in South Dakota. In connection with this discussion some of the results obtained at the station with these crops during the last 10 years are briefly reviewed. Directions are given for the extermination of weeds in pastures by sheep, and a scheme of cropping is suggested which it is believed would furnish green forage continuously throughout the season.

Of all the grasses grown for pasture at the station, *Bromus inermis* is reported as having given the best results. In 1896 experiments were made with corn and sorghums grown for silage and for seed. The yields, together with the quantity of seed sown per acre of corn, Kafir corn, Jerusalem corn, amber cane, and yellow millo maize are tabulated. Amber cane stood first, with a yield of 6,850 lbs. of green forage per acre, and Jerusalem corn ranked last, with a yield of 3,075 lbs., while corn gave about an average between the two.

The results in the test for seed production were largely in favor of corn as compared with Kafir corn and Jerusalem corn. Early Essex and Victoria rape were found equally good. A mixture of 2 bu. of vetch and 1 bu. of oats sown at the rate of 120 lbs. per acre produced 18,440 lbs. of green forage per acre. Vetch grown alone yielded about 5 tons of green forage, which amounted to 2,532 lbs. of hay per acre. Spurry, 7 weeks after sowing, yielded 18,680 lbs. of green forage, or 2,920 lbs. of dry feed per acre. Three varieties of winter rye sown in the fall came through a severe winter in almost perfect condition.

Some native and exotic grasses at Bathurst Farm, R. W. PEACOCK (*Agr. Gaz. New South Wales, 14 (1903), No. 7, pp. 579–583, figs. 11*).—The adaptability of different grasses to Australian conditions as observed at the farm is discussed and the value of each species is briefly noted.

Nitrate of soda and muriate of potash as top-dressing for grass land, C. D. WOODS (*Maine Sta. Bul. 94, pp. 107, 108*).—A brief account is given of an experiment in applying these substances in solution by means of an automatic spray pump, such as is used for spraying potatoes. The season was unfavorable and the potash seems to have been of no benefit, but the nitrate of soda was probably profitable.

Hydrocyanic acid in fodder plants, J. C. BRÜNNICH (*Jour. Chem. Soc.* [*London*], *83 (1903), No. 488, pp. 788–796*).—The author made a study of the conditions under which hydrocyanic acid is formed in sorghum and other plants. It was found that the amount of hydrocyanic acid gradually diminishes as the crop matures, but it was impossible to state at what age the crop becomes absolutely safe for use. As a rule, however, it may be assumed that sorghum is safe for fodder as soon as the seeds are fully developed. Drying sorghum does not remove the hydrocyanic acid. The amount of poison appears to be increased by the use of heavy nitrogenous fertilizers. A certain amount of the poisonous glucosid was found in corn in various stages until the formation of the cobs, but never in dangerous quantities. The author recommends that all forage plants related to sorghum should be used with discretion in the green or dried state and should not be fed in an immature stage or to animals which have fasted for a long time.

A monograph on rice, C. D. GIROLA (*Monografía del arroz. Buenos Ayres: Min. Agr., 1899, pp. 65, figs. 5*).—After giving brief general notes on the rice plant the author discusses the climatic conditions suitable to the culture of the plant, describes different species and varieties under cultivation, and gives directions for the culture and harvesting of the crop with special reference to Argentine Republic. The composition of a number of varieties is shown in tables. The culture of rice in different countries is briefly noted.

Variety tests with rye, E. SIERIG (*Deut. Landw. Presse, 30 (1903), No. 72, p. 621*).—Eight varieties were under test; the yields are given and the growth of the different varieties is compared. An application of 100 kg. nitrate of soda per hectare seemed to be the maximum utilized by Hanna, Petkus, Pirna, and Selchow, while

Schlansted, Hadmersleben, Klosterroggen, Prof. Heinrich, and Probstei varieties were apparently capable of using more than double that quantity.

It was observed that the weight per hectoliter, as well as the weight per 1,000 grains, decreased quite regularly with the increase of the quantity of nitrate of soda applied. The best results were obtained from Petkus rye, which gave a financial return of 71.65 marks more per hectare than the variety ranking last.

Progress of the beet-sugar industry in the United States in 1902, C. F. Saylor (*U. S. Dept. Agr. Rpt. 74, pp. 1–140, pls. 5*).—This report is similar to those for previous years (E. S. R., 14, p. 350). It, here considered, reviews the prospects of the beet-sugar industry, enumerates its collateral and indirect benefits, points out the results of experience with reference to the culture of beets and the building of factories for the manufacture of beet sugar, and discusses the improvement in factories and farm conditions. The value and uses of sugar-beet pulp are considered at some length. The Brussels conference and countervailing duties are discussed, and the history of the industry in the United States is outlined. The condition of sugar-beet culture and of beet-sugar manufacture is noted by States and summarized as follows:

Number of factories, with their capacity for working beets and producing sugar for 1903, by States.

State.	Number of factories.	Daily capacity in beets.	Annual capacity for production of sugar.
		Tons.	*Tons.*
Michigan	21	13,100	115,542
California	8	10,200	89,964
Colorado	9	6,250	55,125
Utah	7	3,350	29,547
Nebraska	3	1,200	10,584
New York	2	1,200	10,584
Wisconsin	1	500	4,410
Minnesota	1	350	3,087
Ohio	1	350	3,087
Oregon	1	350	3,087
Washington	1	350	3,087
Total	55	37,200	328,104

Three of the factories in Utah are slicing stations only. Statistics of the production of sugar beets and the manufacture of beet sugar, collected from the factories, and other statistical data with reference to consumption, imports, exports, etc., are presented. Selected farm results in different States, showing the possibilities of sugar-beet culture for the respective localities, are also reported.

In 1902, 1,895,812 tons of beets were worked, costing on an average $5.03 per ton and producing a total of 436,811,685 lbs. of sugar.

Single-germ beet balls and other suggestions for improving sugar-beet culture, T. G. Palmer (*U. S. Dept. Agr. Rpt. 74, pp. 141–152*).—This article discusses the financial returns in sugar-beet culture, the use of machines for planting beet balls and for pulling and topping beets, the cultivation of the crop, the effects of sugar-beet culture on the land and the succeeding crop, and the lowering of the cost of producing sugar. Special consideration is given the subject of multiple-germ and single-germ beet balls. The author points out that the use of single-germ beet balls would very materially reduce if not practically eliminate the labor of thinning beets.

Sugar-beet seed: Its importance and production, J. E. W. Tracy (*U. S. Dept. Agr. Rpt. 74, pp. 153–156*).—The quantities of sugar-beet seed used and produced in the United States are estimated and the history of domestic seed production, together with the condition of the industry at the present time, is briefly reviewed.

Experiments in the culture of the sugar beet in Nebraska, T. L. Lyon and A. T. Wiancko (*Nebraska Sta. Bul. 81, pp. 13, fig. 1*).—The cooperative experiments

here described were made in 1902 and are in part a continuation of previous work (E. S. R., 14, p. 34). About 200 acres of deep, friable loam soil, uniform in physical character and fertility, were devoted to the experiments.

The results of a test of 28 varieties from imported and home-grown seed apparently showed that the quality of the seed is more important than the variety. The home-grown seed compared very favorably with the imported seed, which gave rather irregular results. Contrary to previous results barnyard manure applied this season at the rate of 22 tons per acre seemed to have no effect on the yield and quality of the crop. All beets grown where salt was used as a fertilizer were relatively good in quality and showed no difference in susceptibility to disease as compared with beets from other plats in this experiment.

The results from early-planted beets were decidedly better than from late-planted beets. This season, which was much wetter and cooler than normal, rather deep cultivation gave the best results. In previous years cultivation about 3 in. deep was most profitable. Deep hand-hoeing when the plants were 4 to 5 in. high gave a considerable increase in yield. Beets grown on weedy fields showed a low sugar content. In the series of cultivation tests the plat on which cultivation was continued late into the season after the leaves were full grown produced the largest tonnage per acre The beets on 1 plat in these tests were stripped of half of their leaves on July 8 when they had reached their full size. It was found that while the beets on the other plats were affected with leaf spot to the extent of about 50 per cent, the plat from which half the leaves had been stripped showed only about 30 per cent. Breaking off the leaves did not injuriously affect the yield and quality of the crop.

Alkali lands and sugar-beet culture, III, H. C. Myers (*Jour. Soc. Chem. Ind., 22 (1903), No. 13, pp. 782–785, figs. 7*).—A study of alkali soils in Utah and Colorado, with special reference to sugar-beet culture, is presented. An examination of Utah soils producing beets of low purity showed that the surface foot of soil contained very little alkali and that the low purity was due to the injurious salts brought up from below the surface foot by improper irrigation. In another instance it was found that the average purity of beets on soil containing 1,880 lbs. of alkali per acre in the surface foot was 81.3, and that when the alkali content was reduced to 376 lbs. the purity rose to 84.9. The alkali content of the second foot of soil as determined in this work seemed to vary between 3,120 and 5,600 lbs. per acre. The percentage of carbonates, nitrates, sulphates, and chlorids found in the surface foot, and the composition of white alkali are shown in tables.

In studying the bottom lands near Greeley, Colo., the quantity of alkali removed from the soil by a beet crop was determined to be 322.5 lbs per acre, of which 134.3 lbs. were removed in the tops. Investigations on the upland soils in this same vicinity are also reported. Analyses of virgin desert upland soils and of soils under cultivation for 30 years and similarly situated are compared. The cultivated soil had produced wheat, potatoes, and alfalfa in rotation without fertilization. The analysis of this soil was made after the first crop of sugar beets had been harvested. In both soils the nitrates, phosphates, and humus were low, while potash averaged well in the virgin soil and showed a marked increase after 30 years of cultivation. The percentage of humus was also highest in the cultivated soil. The sugar beets produced on this soil were high in sugar content and purity. The treatment of a crop of sugar beets injured by hail and its recovery are recorded in this connection.

The following plants collected by the author on virgin alkali soil in Utah are recorded as indicators of alkali: *Artemisia tridentata, Distichlis spicata, Atriplex confertifolia, Suæda torreyana, Atriplex canescens, Lycium andersonii, Gutierrezia euthamiæ, Amaranthus albus, Bigelovia graveolens.*

The sugar industry of the United Provinces of Agra and Oudh, S. M. Hadi (*Allahabad: Govt. Printer, 1902, pp. 112, pls. 10, figs. 58*). This book treats of the species and varieties of sugar cane grown in these Provinces and of the methods employed in the cultivation of the crop and the manufacture of sugar.

The manufacture of cane sirup, H. H. HARRINGTON (*Texas Sta. Bul. 68, pp. 20, figs. 12*).—After briefly noting the manufacture of glucose sirup this bulletin discusses the culture of sugar cane for sirup making and describes the manufacture of the product. A plan of a sirup mill is shown. The chemical composition of cane, sorghum, maple, and glucose sirups is given in a table.

The cultivation and treatment of the Kumara (sweet potato) by the primitive Maoris, WALSH (*Trans. and Proc. New Zealand Inst., 35 (1902), pp. 12–24*).—The methods of cultivating the sweet potato (*Ipomœa chrysorrhiza*) grown by the New Zealand natives before the introduction of European foods are described, as well as methods of harvesting, storing, and cooking.

Tobacco, O. J. A. COLLET (*Le tabac. Paris: Augustin Challamel; Brussels: Falk, 1903, pp. 282, pls. 30, figs. 34*).—A detailed description of the tobacco industry on the eastern coast of Sumatra, with special reference to Deli.

Fertilizer experiments with tobacco in Japan, M. LEHMANN (*Landw. Vers. Stat., 58 (1903), No. 5–6, pp. 439–470; abs. in Deut. Landw. Presse, 30 (1903), No. 74, p. 643*).—Fertilizer experiments conducted during 1900 and 1901 are described and the results and conclusions reported. The tobacco plants under investigation were grown in wooden frames and pots. The work will be repeated to determine whether the results thus far obtained will be confirmed by the results of future tests.

The tobacco plants seemed to be more in need of nitrogen than of either potash or phosphoric acid. The nitrogen was required in equal degree by all parts of the plant, while potash was apparently mainly utilized by the leaves and roots and phosphoric acid by the stems. After nitrogen, potash was most needed and its effect was especially marked immediately after transplanting. The best results with the different nitrogenous fertilizers applied were obtained with nitrate of soda, but satisfactory returns were also obtained where sulphate of ammonia and dried blood were used. The tobac o fertilized with dried blood showed an especially good glow. Of the various potash fertilizers, "martellin" seemed to be decidedly the best, followed by wood ashes, nitrate of soda, and carbonate of potash in the order named.

Liming the soil appeared advantageous to the plants during early development, but later on its influence seemed to cease and the difference between plants in limed and unlimed soil gradually disappeared. It is, however, recommended that the lime supply of the soil be not allowed to become exhausted, because a strong development in the early stages of growth gives to the plant greater resistance to injurious agents.

Soy-bean cake was apparently more economical as a tobacco fertilizer than rape cake, and this is considered of importance to Japanese agriculture, because soy-bean cake is much the cheaper. The glow of tobacco fertilized with soy-bean cake was very good. "Martellin" and carbonate of potash also seemed to have a good effect on the glow, while the chlorids and sulphates apparently reduced or totally destroyed it. Very heavy applications of fertilizers are considered injurious on account of the resulting high-water content of the leaves and stronger development of the roots and stems at the expense of the leaves. From 0.5 to 2 per cent of perchlorate in nitrate of soda did not seem to act injuriously. The results indicate that the perchlorate in this proportion had a favorable effect on the development of the leaves and especially of the roots.

Description of wheat varieties, C. S. SCOFIELD (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 47, pp. 19, pls. 7*).—This bulletin presents a form on which are given in regular order a list of adjectives considered of the most importance in describing a variety of wheat, together with an explanation of all the listed terms. The adjectives proposed for use in variety descriptions are grouped under the following heads: Young stool; half-grown plant; mature plant; head (field notes); head (laboratory notes); awns; spikelet; grain; milling qualities; general characteristics.

The stooling of wheat, F. ANTONIS (*Ann. Sta. Agron. Oise [France], [illegible], No. [illegible], pp. 11–13*).—A discussion of the subject which chronicles an instance of a stool of wheat yielding 4,875 grains from one grain of seed.

HORTICULTURE.

Report of the assistant in horticulture, E. Nelson (*Wyoming Sta. Rpt. 1903, pp. 54–57*).—A brief outline is given of the horticultural work of the station during the season of 1902. Canaigre seed planted at the station germinated and made a fair growth during the season. Plants grown from roots remained green until very late in the fall, but those allowed to remain in the soil over winter were killed. A native form of flowering currant, producing yellow berries of fair size and valued for culinary purposes, has been secured and planted with a view to its domestication and improvement. Burpee Quarter Century tomato is reported as giving good yields.

New vegetables, G. Wythes (*Gard. Chron., 3. ser., 34 (1903), No. 876, pp. 250–253, figs. 6*).—New varieties of cabbage, vegetable marrow, artichoke, and beans are illustrated and described. A pear-shaped custard marrow was obtained by crossing the bush with the old custard variety. The plants have a trailing habit and fruit freely.

The variety Early Gem cabbage is a very small early variety, having a single row of outer leaves. It was obtained by crossing Ellam with Sutton Little Gem. The variety of cabbage called St. Martin was originated with the object in view of securing a perfectly hardy cabbage for use from November to April. It was obtained by crossing the Rosette Colewort with the Christmas Drumhead cabbage. The plant is dwarf and the heads roundish and of medium size. The new long white artichoke described was obtained by means of rigid selection for several seasons.

The dwarf bean Progress was obtained by crossing Mohawk or Six Weeks with Canadian Wonder. These beans yield produce from June to October when properly handled. They are not considered vigorous enough to withstand red spider and drought. The dwarf bean Early Favorite was obtained by crossing Mohawk and Veitch Ne Plus Ultra. It is considered especially valuable for forcing and also for cultivation in the open ground. It is especially early and a good cropper. Another variety obtained from a batch of seedlings which has been given a name is Wythes Early Dwarf, secured as a result of crossing Syon House with Mohawk.

Vegetables and fruits at the Upper Peninsula Substation, L. M. Geismar and C. D. Smith (*Michigan Sta. Spec. Bul. 20, pp. 25–52*).—An account is given of the growth during the seasons 1901 and 1902 of a number of varieties of turnips, carrots, parsnips, kohl-rabi, Brussels sprouts, cabbage, cauliflower, radishes, lettuce, onions, squashes, cucumbers, bush beans, sweet corn, tomatoes, peas, spinach, garden beets, celeriac, celery, pumpkins, mangels, herbs, sunflowers, musk and watermelons, orchard fruits, strawberries, gooseberries, currants, blackberries, raspberries, and cherries. Descriptive notes of a number of the more promising varieties are usually given for each crop.

It has been found that carrots, parsnips, and salsify can be safely left in the ground over winter at the station and harvested the following spring in perfect condition. Experiments in warding off frosts by the use of extensive fires made with logs and stumps resulted in keeping the temperature 2° above the surrounding uninfluenced portions of the orchard. The insect *Basilarchia arthemis* was found injuring the buds of apples.

Vegetables, V. H. Davis (*Jour. Columbus Hort. Soc., 18 (1903), No. 3, pp. 95–97*).—Notes are given on the growth in the Ohio University gardens of strawberries and a number of vegetables. From 1 acre produce was sold as follows: Cabbage $68.75, peas $61.30, onions $50.22, radishes $13, spinach $3.80, corn $20; total, $215.07. Asparagus which had been treated with sodium nitrate the preceding summer showed a marked increase in strength of growth as a result of the application. Magnus is preferred as a market tomato, and Stone for canning. The author believes that it will pay to train early tomatoes if for no other reason than to facilitate gathering.

Vegetables for profit, T. W. Sanders (*London: W. H. & L. Collingridge, 1903, pts. 1, pp. 93, figs. 22; 2, pp. 101, figs. 30; 3, pp. 96, figs. 25; 4, pp. 116, figs. 33*). This is a

series of small handbooks designed to meet the requirements of market gardeners in England. Part 1 is devoted to green crops—broccoli, Brussels sprouts, cabbage, cauliflower, herbs, etc.; part 2 to root crops—potatoes, onions, beets, parsnips, carrots, turnips, and other roots and tubers; part 3 to asparagus, beans, peas, rhubarb, sea kale, marrows, etc.; and part 4 to mushrooms, cucumbers, salads, tomatoes, etc. Each book contains detailed information on planting, cultivation, and harvesting the various crops which it purports to treat of, and, in addition, describes the insect pests and fungus diseases affecting them, giving suggestions as to methods for their control. Recipes are frequently included as to methods of cooking the different vegetables.

Vegetables and fruits of Madagascar (*Légumes et fruits à Madagascar. Paris: Augustin Challamel, 1903, pp. 40, pls. 4, fig. 1*).—An account is given of a large number of tropical and subtropical fruits grown on the east side of Madagascar, with an account of the installation of a vegetable garden and orchard at the Government experiment station.

Storage of some common vegetables (*Iowa Agr., 3 (1903), No. 6, pp. 176–178*).—Directions are given for the winter storage of potatoes, root crops, cabbages, onions, squashes, and celery.

Cabbage: Varieties, fertilizers, B. C. PITTUCK and S. A. MCHENRY (*Texas Sta. Bul. 69, pp. 23–48*).—This bulletin presents in text and tabular form the results of tests of a number of varieties of cabbage at the Beeville Substation for the years 1898–1902. The yields obtained at Beeville and in cooperation with farmers in 5 different localities with 5 different fertilizer formulas are also included. No definite conclusions have been drawn from this work.

The method of building reservoirs at the station and of applying water to cabbages is given in some detail. Water is first applied by opening furrows close to the drill. When the plants get older a large flat sweep is used to level the middles and spread the water. From 20,000 to 40,000 gal. of water is applied per acre before transplanting, and about 35,000 gal. at each irrigation thereafter. The cost of irrigation varies from 2 to 8 cts. per 1,000 gal. of water applied. The crop is cultivated from 6 to 9 times during the season and hoed at least once. The harlequin cabbage bug is controlled by means of the blow torch. In shipping cabbages in carload lots good ventilation has been secured by erecting a triangular shaft 2½ ft. wide and 3½ ft. high, and running the entire length of the car. This shaft is latticed by use of 1 by 3 in. stuff, using about 6 to the side. The cost of growing an acre of cabbages to maturity is estimated at $12.85 per acre.

Dandelions, W. M. MUNSON (*Maine Sta. Bul. 95, pp. 109–113, figs. 7*).—The author calls attention to the injurious effects to lawns caused by cutting off dandelions a little below the crown early in spring. Dandelions thus mutilated send up from 2 to 6 new crowns and soon completely infest a lawn. Some illustrations are given showing seedlings of the common dandelion and of the plants developed from root cuttings and from cutting off old roots.

Brief notes are also added on the cultivation of dandelions for market. For this purpose it is recommended that seed be sown early in spring in drills 12 to 15 in. apart and covered ¼ to ½ in. deep. Cultivation is the same as for carrots. Plants should be partially blanched by placing a covering of boards or boughs over the rows. French Garden and the Improved Thick Leaved are considered the most important varieties.

Ginseng, W. M. MUNSON (*Maine Sta. Bul. 95, pp. 117–120, figs. 4*).—Popular information is given on the nature and culture of ginseng. The author does not encourage the culture of ginseng in Maine.

Experience with ripening tomatoes after frost (*Rural New Yorker, 62 (1903), No. 2799, p. 658, fig. 1*).—After a frost which killed tomato leaves, but did not injure the fruit, about 600 bu. of green tomatoes were gathered and placed some in a cold frame and some in a storage room of a canning factory. They ripened up well. But few rotted. Most of them were solid when ripe and made a fair canned product.

The influence of electricity on vegetation, F. PAULIN (*Ann. Sta. Agron. Oise* [*France*], *1903, No. 35, pp. 35–40*).—In the work conducted electricity was conveyed to the plants by means of urpight rods placed in the ground with a network of wire connecting them below, and placed deep enough in the ground not to interfere with cultivation. Under the influence of the electricity thus generated the yield of potatoes was increased 50 per cent. Cauliflowers matured a month earlier than plants not under the influence of electricity. The yield of beans and peas was nearly doubled. Figs matured perfectly out of doors, as did also grapes for wine.

In another experiment 50 tomato seeds subjected to the influence of electricity produced 45 plants, while 50 other seeds not thus treated gave but 35 plants. With another variety 49 seeds subjected to electricity produced 45 plants, while 49 untreated seeds produced only 33 plants. It is stated in this connection that no difference was noticed in the after-growth of tomato plants whether the seed had been subjected to electricity or not. It is also stated that the seed not subjected to electricity was sown dry, while the other seed had been moistened.

Preliminary report on the root and stem development of leaf cuttings, and its importance in plant reproduction, H. LINDEMUTH (*Gartenflora, 52* (*1903*), *No. 18, pp. 479–485*).—The author discusses the propagation of plants from leaf cuttings, and gives a table showing the length of time required for the rooting of some 28 species of plants propagated by leaf cuttings. A list is also given of 13 species which could not be propagated by leaf cuttings. The author states that with the citrus leaf cuttings have often rooted, but in his experience never produced stems.

Orchard cover crops in Delaware, C. P. CLOSE (*Delaware Sta. Bul. 61, pp. 32, figs. 9*).—This bulletin contains an account of the seeding, growth, and comparative value of a large number of different plants and combinations of plants as orchard cover crops on different soils in Delaware. The work was begun in 1901 and the results secured during 2 seasons are reported upon. The weight of the top growth and the root growth to a depth of 12 in. of the different crops grown at the station was determined. The tops and roots were analyzed and the total amounts of nitrogen, potash, and phosphoric acid in each are recorded. The moisture content of the soil in which the cover crops grew, as compared with cultivated soil alongside, was also investigated. All these matters are reported in considerable detail, the behavior of each crop or combination of crops in each of the different localities for each of the 2 years being noted under separate headings.

An idea of the growth and fertilizing value of several of the more prominent crops is shown in the table below. These crops were seeded July 22 at the station on a clay-loam soil and were harvested from November 7 to 22 following:

Weight and composition of orchard cover crops in Delaware.

Crop.	Weight of green tops.	Weight of tops and air-dried roots.	Nitrogen in—		Potash in—		Phosphoric acid in—	
			Tops.	Tops and roots.	Tops.	Tops and roots.	Tops.	Tops and roots.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
Cowhorn turnip	11,297	31,819	64.4	109.5	80.3	142.6	14.3	26.0
Rape	26,620	27,484	116.2	161.3	148.2	161.3	41.8	46.9
Crimson clover	18,800	19,213	128.2	134.4	84.0	88.2	59.2	61.2
Red clover	6,909	8,121	69.8	103.0	46.5	56.4	18.9	29.0
Alfalfa	5,430	7,410	54.8	95.2	32.2	41.7	13.1	21.6
Hairy vetch	13,150	13,750	108.0	121.2	78.4	85.5	22.5	27.2
Cowpeas	5,933	6,327	65.2	69.5	47.4	49.8	16.6	18.9
Soy beans	10,952	11,708	130.9	140.2	46.2	48.0	37.8	40.2

The root growth to depths of 8 and 12 in., respectively, of some of the more important crops was determined. The weight of the roots of crimson clover in the first 8 in. of soil was 381 lbs., of red clover 1,185 lbs., of alfalfa 1,972 lbs., of hairy vetch 584 lbs., of cowpeas 301 lbs., and of soy beans 717 lbs. In the next 4 in. of soil

there was found 32 lbs. of roots of crimson clover, 27 lbs. of red clover, 8 lbs. of alfalfa, 16 lbs. of hairy vetch, 93 lbs. of cowpeas, and 39 lbs. of soy beans. These figures show that with all these plants by far the greatest amount of roots is found in the first 8 in. of soil.

Some of the crops which have proved most satisfactory at the station are hairy vetch, rye, crimson clover, alfalfa, and red and mammoth clovers. Other crops that were used were cowhorn turnips, dwarf Essex rape, Egyptian clover (Berseem), cowpeas, soy beans, velvet beans, Australian saltbush, and Canada field peas. These were used alone and in various combinations. One of the best combinations consisted of hairy vetch 40 lbs. and rye 30 lbs. per acre. The amount of seed to use per acre for different crops in combinations is given by the author as follows: "Rye 1 to 1½ bu.; cowhorn turnips 1 to 2 lbs.; dwarf Essex rape 8 to 10 lbs.; red, mammoth, or crimson clover 15 to 20 lbs.; cowpeas 90 lbs.; soy beans 90 lbs.; hairy vetch 40 to 50 lbs.; alfalfa 30 lbs.; hairy vetch 40 lbs. and rye 30 lbs.; hairy vetch 20 lbs. and cowpeas or soy beans 45 lbs.; hairy vetch 20 lbs. and turnips 12 oz.; hairy vetch 20 lbs., crimson clover 8 lbs., and turnips 8 oz.; hairy vetch 20 lbs. and red, mammoth, or crimson clover 8 lbs.; turnips 8 oz., rye 20 lbs., and red, mammoth, or crimson clover 4 lbs.; turnips 12 oz. and crimson clover 8 lbs.; turnips 12 oz. and soy beans or cow peas 40 lbs.; dwarf Essex rape 4 lbs. and rye 1 bu.; rape 4 lbs., soy beans or cow peas 40 lbs., and rye 20 lbs.; alfalfa 15 lbs. and red, mammoth, or crimson clover 7½ lbs.

"Many other combinations may be used successfully. The object should be to use such a mixture of crops that a part, at least, shall live over winter. A few of the combinations above contain all fall crops, and for that reason are not so desirable as though they contained a part of those that live through the winter and grow in the spring."

The soil moisture determinations made indicate that cultivated soils, during periods of dry weather, contain considerably larger quantities of moisture than soils seeded to cover crops, the variations ranging from 1 to 11 per cent in favor of the cultivated areas in these experiments.

The fertilization of apple blossoms, H. S. PEART (*Canad. Hort., 26 (1903), No. 9, pp. 361–363*).—The author covered a certain number of apple blossoms on trees representing 29 different varieties with paper bags. Only 8 of the varieties produced any fruit at all under the bags, and only 1 or 2 fruits developed from the covered blossoms on any one tree. The varieties thus showing a certain amount of self-fertility were Alexander, Baldwin, Chenango, Early Harvest, Greening, Holland, Twenty Ounce, and Ontario. Only 8 of the remaining 21 varieties which bore no fruit when self-fertilized under the paper bags are named in the account. These are: Blenheim, Ben Davis, Canada Red, King, Mann, Fameuse, Spy, and Ribston.

A discussion is given of the desirability of intermixing varieties in the orchard which shall bloom at about the same period. It is stated that the Spy is in full bloom at the same time as Ben Davis and Princess Louise.

The grading and packing of apples, M. A. McNEILL (*Canad. Hort., 26 (1903), No. 9, pp. 364–366*).—A general discussion of this subject, dealing particularly with the requirement of the Fruit Marks Act of the Dominion of Canada of 1901, which designates the marks which must be used throughout the Dominion of Canada for different grades of apples. Under this act apples of best quality are marked No. 1, or XXX; second quality No. 2, or XX, and third quality No. 3, or X. The last two grades of apples are not defined, but apples that are graded as No. 1 must be well-grown specimens of one variety, sound, of nearly uniform size, of good color for the variety, of normal shape, and not less than 90 per cent free from scab, worm holes, bruises, and other defects, and properly packed.

Investigations on the structure of the grape berry, A. BONNET (*Ann. École Nat. Agr. Montpellier, n. ser., 3 (1903), No. 1, pp. 58–102, pls. 3, figs. 18*).—This gives an

account of the anatomical structure of the grape berry at different stages of maturity, and is illustrated by a large number of drawings. Detailed accounts are given of the structure of a large number of Vinifera varieties and of the structure of the skin of a number of American species. Great differences were found in the thickness of the skin of Vinifera and American species. For instance the species *Vitis coriacea* had a thickness of 9.9 μ, *V. berlandieri* 8.5, *V. æstivalis* 8.3, *V. cinerea* 8, *V. rubra* 7.8, *V. labrusca* 7.6, *V. monticola* 6.7, *V. riparia* 6.5, *V. arizonica* 5.7, *V. rupestris* 4.6, and *Vinifera* 3.8.

A discussion is given of the relation between the structure of the skin and the resistance to cryptogamic diseases.

The book of the peach, H. W. Ward (*London: The Walter Scott Pub. Co., Ltd., 1903, pp. 113, pl. 1, figs. 28*).—This is a practical handbook on the cultivation in Great Britain of peaches under glass and out of doors against walls. The work takes up the details of building and managing peach houses, trellising peach trees against walls, pruning and training, packing and marketing, and the control of the injurious insects and diseases affecting peaches.

Orchard studies. VII, Notes on varieties of Domestica plums, W. B. Alwood and H. L. Price (*Virginia Sta. Bul. 134, pp. 40–46, figs. 3*).—Descriptive notes are given on 13 varieties of plums. The following varieties are recommended: *Medium early*—Bradshaw and Washington; *Mid-season*—Yellow Egg; *Medium late*—Gueii and Naples; *Late*—Agen, Grand Duke, Shropshire, and Reine Claude.

Crossbred fruits, W. Saunders, (*Connecticut State Bd. Agr. Rpt. 1902, pp. 129–133*).—An account is given of the improvement of certain fruits by crossbreeding and selection in Canada and elsewhere during recent years. The origin of the Canada and Othello grapes, Ontario apple, and American Wonder pea are noted. The author originated the gooseberries Pearl and Red Jacket, and the grapes Kensington and Emerald. Efforts to cross the blackberry and raspberry have met with but little success. Seed has sometimes been obtained, but it usually failed to germinate, and even when it did germinate the plants were weakly and worthless. A number of apples have been secured by crossing with the Siberian crab, *Pyrus baccata*, which have been found useful in the colder regions of the Northwest.

A failure with root-pruned trees (*Rural New Yorker, 62 (1903), No. 2799, p. 661*).—The writer states that he closely followed the system of close-root pruning in New Jersey in setting out 1,000 peach trees. A drought occurred during the summer and 800 trees died, while the remainder made a very poor growth.

Questions on grafting, L. Daniel (*Rev. Vit., 20 (1903), No. 510, pp. 355–357*).—The author notes an experiment in which Raparia Gloire was grafted with a bud of Siebel 2003, taken from stock which had also been grafted on Riparia the preceding year. The fruit of Siebel 2003 is black, the berries large, and it is a second early sort. As result of this graft a small white grape was obtained whose season of ripening was earlier than that of Madeline, which is considered the earliest grape in that section.

These results are considered to clearly indicate a reciprocal action between stock and scion and to refute, therefore, the conclusion of L. Ravaz, who read a paper at the recent Agricultural Congress in Rome to the effect that the reciprocal action of grapes between scion and stock is null.

On the effects of the graft, L. Ravaz (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 41, pp. 438–442*).—A controversial article in which the value of the evidence cited by L. Daniel on the reciprocal action of scion and stock in grape grafting, noted above, is minimized.

Preservation of fruits by cold storage, L. Loiseau (*De la conservation des fruits par les procédés basés sur l'emploi du froid. Paris: Librairie et Imprimerie Horticoles, 1903, pp. 31, figs. 2*).—An account is given of some experiments in preserving peaches and other fruits in a small refrigerating apparatus. The temperature was kept at

about 0 to 1° C. In one experiment at the end of a month the 600 peaches used were all in good condition. At the end of 35 to 40 days 10 per cent of them had deteriorated, and at the end of 2 months about 75 per cent had deteriorated. Peaches that had been wrapped in tissue paper or wadding did not keep better than those without any wrapping whatever. One of the striking features of the experiment was that peaches submitted to cold storage kept longer after removal than those picked fresh from the trees. Peaches picked from the trees could not be exposed for sale more than 3 days at the maximum without deteriorating, while the refrigerated peaches preserved a good appearance for 6 to 7 days after removal.

Some of the peaches placed in cold storage were harvested 5 to 6 days before maturity. The conclusion drawn from this work is to the effect that for the best results it is absolutely essential that the fruit should be allowed to develop on the tree until it has attained its maximum quality before placing in cold storage. If gathered too green it loses fragrance and quality in cold storage.

Mention is made of an experiment in shipping peaches to New York. Peaches were successfully sent from Havre, France, to New York City without loss of quality.

Cold storage on the farm, J. C. Blair (*Amer. Agr., 72 (1903), Nos. 14, pp. 268–270, figs. 4; 15, pp. 288, 290, figs. 2*).—Details of construction are given for a cold-storage house suitable for farm conditions and costing about $650. Many of the details are brought out in diagrams and plans.

The preservation of fruits, with description of fruit evaporators (*Conservacion de las frutas con descripcion de las evaporizadoras de frutas, etc. Buenos Ayres: Alejandro Reinhold, 1903, pp. 34, figs. 21*).—This pamphlet is devoted largely to descriptions of American and German machinery used in the preparation and evaporating of orchard fruits.

Preservatives in fruit shipping (*Queensland Agr. Jour., 13 (1903), No. 1, p. 31*).—An account of California methods of preserving citrous fruits in shipping. It is stated that there is usually a loss of from 5 to 15 per cent from rot in shipping oranges and lemons and that this can be prevented by fumigating the cars with formaldehyd. The method observed in preserving cars of fruit is to pour 6 oz. of formalin into a pint of water and place the vessel containing the fluid upon a small oil stove so that the water will simmer, after which the car is tightly closed.

Sterilized fruit must, R. Otto (*Proskauer Obstbau-Ztg., 8 (1903), No. 8, pp. 118, 119*).—The author presents the analysis of sterilized and unsterilized fruit must after it had been stored in a cellar for 4½ months. The sterilized must had been heated to 65° C. for a half hour. The chief difference in the analyses was in the sugar content. The total sugar in unsterilized must was 10.63 per cent and in the sterilized 10.71 per cent. The invert sugar of the unsterilized must was 6.52 per cent and the cane sugar 3.90 per cent, while the invert sugar of the sterilized must was 8.35 per cent and the cane sugar 2.24 per cent. It is thus seen that the sterilized must underwent a considerable decrease in cane sugar during storage and an increase in invert sugar.

Orchard studies, IX, X, XI, XII, W. B. Alwood (*Virginia Sta. Buls. 136, pp. 71–96; 137, pp. 99–135, figs. 14; 138, pp. 139–172, figs. 12; 139, pp. 176–184*).—Part IX treats of An investigation into the character of cider apples in Europe and comparisons with American fruit; Part X, A consideration of the commercial handling of cider fruit—grinding and expressing the must; Part XI, A consideration of the principles and technique involved in the fermentation and final finishing of ciders; and Part XII, The chemical composition of ciders. The material contained in these bulletins has already appeared in Bulletin 71 of the Bureau of Chemistry of this Department (E. S. R., 14, p. 1026).

Modern cider manufacture, or the art of making good cider, G. Jacquemin and H. Alliot (*La cidrerie moderne, ou l'art de faire le bon cidre. Malzéville-Nancy: Edg. Thomas, 1902, pp. VII+712, figs. 140, dgm. 1*).—This work is an exhaustive

treatise on the culture of apples and pears and the manufacture of cider and perry from them. Statistics are given on the production of cider, and notes on the history of cider making. About one-third of the book is taken up with a discussion of the propagation and culture of apples and pears and of the insects and diseases affecting them.

The remainder of the work, which deals with cider and perry, contains chapters on washing fruit, extraction of the juices, fermentation and the use of pure yeast cultures, sulphuring, clarification, and bottling of the manufactured products, the utilization of species of sorbus apples in cider making, pasteurization of cider, the diseases and defects of ciders, and the methods of handling such products. Chapters are also given on the manufacture of distilled spirits from cider, the production of vinegar, the preservation of apples and pears by drying, and the utilization of the pomace of these fruits.

Strawberry culture, P. Evans and F. W. Faurot (*Missouri State Fruit Exp. Sta. Bul. 7, pp. 14, pls. 9*).—This is a popular bulletin containing directions for the planting, selection, and cultivation of strawberries. The opinions of a number of growers representing 16 counties in the Ozark region on the best varieties for home and commercial use are tabulated. Sixty-nine per cent of the number replying recommend planting the medium and late varieties, and 31 per cent recommend early varieties.

Crawford's July report on strawberries, M. Crawford et al. (*Jour. Columbus Hort. Soc., 18 (1903), No. 3, pp. 103–109*).—Notes are given on a test of 55 varieties of strawberries.

Paraguay tea (Yerba mate), F. W. Neger and L. Vanino (*Der Paraguay-Thee (Yerba mate). Stuttgart: Fr. Grub, 1903, pp. 56, figs. 21*).—A botanical account is given of the various species of Ilex and other plants from which the tea yerba mate is produced in Paraguay. A chemical account is given of Paraguay teas and of the preparation and culture of mate and of its value from a commercial standpoint. A bibliography of the subject, including papers written by 29 different authors, is included.

Tea, W. B. Marshall (*Amer. Jour. Pharm., 75 (1903), No. 2, pp. 79–94*).—A descriptive article summarizing information on the botany and culture of tea, its preparation for the market, and related topics.

The propagation of tropical fruit trees and other plants, G. W. Oliver (*U. S. Dept. Agr., Bureau of Plant Industry Bul. 46, pp. 26, pls. 8*).—Detailed directions are given for the propagation of mangoes, loquats, figs, tea, and Manila hemp. It is stated that the mango grows to perfection over a large tract of land in southern Florida. Tests of various methods of propagating this plant at the Department indicate that the most satisfactory unions have been secured when bud wood taken from branches from 1 to 6 years old has been used. As stocks, 2 to 3 year old seedlings and moderate-sized trees are best. Stems at least an inch in thickness are desirable.

Budding was most successful when a rectangular piece of bark, having a bud in the center, was fitted into a section of the stock corresponding in shape and just a little smaller. After fitting the bud patch in the bark a small quantity of grafting wax should be smeared around the edges and then tied firmly in place with thick strands of raffia. The inserted buds should then be shaded from the sun. Another method is described, in which one end of the bud patch is pointed.

Directions are given for raising seedling stocks, transplanting young seedlings, and importing mango scions. A batch of mango scions was successfully forwarded to the Department from Ceylon by covering the ends of the scions with collodion, dipping the bud sticks in clay mud, and then packing in a small amount of moist coir and shipping in cylindrical tin tubes.

The common shield method of budding has been found most successful with the loquat. With the fig a very successful method of propagation has been to prepare the stock as in shield budding and then insert a small twig having 1 terminal and 2

lateral buds. The scions should be selected, when possible, from branches not ove $\frac{1}{2}$ in. in diameter.

The experiments in propagating tea at Summerville, S. C., have shown that vari ties do not come true to seed, and hence some method of vegetative propagation desirable. It is stated that the quickest and least troublesome method of propagatio is by cuttings of the newly-ripened shoots. These cuttings should be taken fro moderate-sized branches of the current season's growth of wood and cut into length of from 4 to 5 in. At least 2 leaves should be left on each cutting. Methods veneer grafting and herbaceous grafting of tea are also described.

Seedlings of Manila hemp were successfully shipped to the Department from th Philippines by gathering the seed as soon as ripe, mixing with finely powdere charcoal, and shipping in small cylindrical tin tubes. Upon arrival at the Depar ment the seeds were sown in garden flats filled to within an inch of the surface wit clean, large-grained river sand, into which the seeds were firmly pressed and the covered with $\frac{1}{2}$ in. of sand. A sheet of glass was then placed over the box and th sand kept at a night temperature of about 75°, and a day temperature of 80° F. required about 14 days for the seed to germinate.

The publication is accompanied by several plates which illustrate the differen methods of propagation described in the text.

The Smyrna fig at home and abroad, G. C. ROEDING (*Fresno, Cal.: Autho 1903, pp. 87, pl. 1, figs. 45*).—Part I of this work discusses comprehensively the cu ture of the Smyrna fig in its native home, giving details as to methods of harvesting drying, packing, labor conditions, etc., and the extent of the industry abroad. Pa II gives the history of the development of the Smyrna-fig industry in California, wit an account of the introduction of the wild, or Capri fig, and of the fig wasp (*Blast phaga grossorum*).

The cocoanut with reference to its products and cultivation in the Phili pines, W. S. LYON (*Philippine Bureau Agr. Bul. 8, pp. 34, pls. 2, figs. 3*).—This is popular bulletin dealing with the history, botany, uses, cultivation, harvesting, an enemies of the cocoanut in the Philippines. It is believed that under proper cond tions the cocoanut is one of the most profitable crops that can be grown in th Philippines.

The manuring of cacao, A. COUTURIER (*Jour. Agr. Trop., 3 (1903), No. 27, p 259–262*).—Analyses are given showing the composition of good cacao soils, and su gestions made for the rational fertilizing of cacao.

Elements of prairie horticulture, N. E. HANSEN (*South Dakota Sta. Bul. 8 pp. 67–110*).—This account contains suggestions based on work at the station for th culture of orchard and small fruits, vegetables, wind-breaks, and ornamental shru and flowers. The State is divided into 12 districts, and varieties of fruits which it thought will succeed best in each district are indicated.

No apple less hardy than the Duchess should be planted in the northern half the State. To prevent root killing in winter a mulch of stable manure spread sever feet out beyond the branches of the trees is recommended. If the fall is dry heav soaking of the soil with water before the mulch is put on is believed to be of grea service.

Varieties of the hardy northern native plums are the only sorts that can be succes fully grown, and the only reliable stock is *Prunus americana*. In other words, th only plums recommended for South Dakota planters are the native wild ones. Sug gestions are given on growing plums from seed. The author finds it advisable graft 2-year-old trees before the buds start in the spring, by inserting the graft in side cut 2 or 3 inches below the soil surface, using a wedge-shaped scion. The eart is replaced and no grafting wax used except to cover over the top of the scion to pr vent drying out.

The culture of cherries is precarious. The Early Richmond has been successfully grown in a few southern counties, otherwise the general experience with this fruit is unfavorable. It is believed a waste of time to attempt to grow quinces, apricots, peaches, or pears in the State. Russian apricots are hardy, but the blossoms are killed by late frosts. Some sorts of Russian pears are also perfectly hardy, but are killed by blight. Raspberries, blackberries and dewberries have failed to make satisfactory growth at the station. Currants and gooseberries, however, are easily raised and have proved perfectly hardy without winter protection. Red Dutch, Victoria, and White Grape are the best varieties of currants, and Houghton the best gooseberry. Strawberries can be successfully grown. No grapes other than the native wild sorts have thus far been successfully grown.

Extensive experiments in the breeding of native northwestern fruits at the station are under way. It is believed that the native Juneberry, sand cherry, buffalo berry, gooseberry, cherries, plums, grapes, currants, strawberries, raspberries, etc., can be bred up equal in size and quality to the cultivated varieties. Over 100,000 fruit seedlings of these different sorts are now being tested on the station grounds. Special attention is being given to the improvement of the native sand cherry (*Prunus besseyi*). Some 75 varieties have already been selected as being worthy of propagation.

Crosses of 225 varieties of strawberries have been made with the wild strawberry. In this connection the author notes that the ever-bearing strawberries imported from France winterkilled, but that the hybrids of this sort with Dakota wild strawberries proved hardy. Settlers in South Dakota are urged to plant and cultivate the native fruits before investing heavily in the tender varieties common in nurseries. Many suggestions are given on methods of work in improving the wild fruits.

Wind-breaks are considered very essential, and the native plants, such as ash, elm, boxelder, and hackberry, are commended for this purpose. Imported trees, such as white willow, Russian golden willow, and for large thorny shelter belts, the Russian wild olive, are also noted as valuable. Planters are cautioned against securing trees from States farther south, since these are nearly certain to winterkill when planted in South Dakota.

Special care is necessary in setting out evergreens on the lawn. Trees not more than a foot in height are recommended. Larger evergreens may be successfully transplanted in late winter with a frozen ball of earth attached to the roots. In general spring planting for all trees is recommended. Evergreens most likely to succeed are the Black Hills or Ponderosa pine, the red cedar of northern regions, and the Jack pine from northwestern Minnesota. Where several rows of evergreens are set the rows should be at least 16 to 20 ft. apart. The poplars, especially cottonwood and Certinensis, are considered particularly desirable pioneer trees for use until better sorts can be established. Suggestions are given on the care of street and lawn trees, and in planting on hardpan.

Of several varieties of tomatoes tested Earliest of All, Early Ruby, Early Bird, and Early Leader are considered desirable sorts. Peppers and eggplants can be successfully grown when the plants are started under glass. Directions are given for making a cold frame and for planting a number of different sorts of vegetables.

Trees and shrubs for English gardens, E. T. Cook (*London: George Newnes, Ltd., 1902, pp. 471, pls. 129*).—In this work the author brings out specially the beauty in trees and shrubs and their usefulness in landscape gardening. Directions are given for the propagation and pruning of the various ornamental trees and shrubs commonly grown in Great Britain, and of planting and caring for them.

The etherization of plants, T. Jannock (*Gard. Chron., 3. ser., 34 (1903), No. 875, p. 240*).—The author reports that he etherized lilacs August 24. By September 18 the etherized plants were in full bloom and foliage. Lilac blooms from etherized plants were finer and lasted longer than those from retarded plants.

The best hardy perennials for cut flowers, F. W. Meyer (*Liverpool: Blake & Mackenzie, 1901, pp. 104, col. pls. 48*).—Descriptions illustrated by colored plates together with cultural directions are given for a large number of the more popular hardy perennials used for cut flowers in Great Britain.

Commercial violet culture: A treatise on the growing and marketing of violets for profit, B. T. Galloway (*New York: A. T. De La Mare Ptg. and Pub. Co., Ltd., 1903, 2. ed. rev., pp. 239, figs. 67*).—The first edition of this treatise, previously noted (E. S. R., 11, p. 852), has been slightly revised to conform to the changes in the methods of growing violets for the market that have occurred during the past 4 years.

Sweet violets and pansies (*New York: Chas. Scribner's Sons, 1903, pp. 100, pls. 13, figs. 5*).—Practical information is contained in this book on the culture of pansies, sweet violets, and wild violets. It has been written by several authorities and edited by E. T. Cook.

Soil-carrying machine, C. H. Roney (*Amer. Florist, 21 (1903), No. 801, pp. 392, 393, figs. 5*).—A description is given of a machine used in carrying soil into greenhouses. The machine is believed to be a decided advantage over wheelbarrows or any other contrivance used by florists for this purpose.

Directory of florists, nurserymen, and seedsmen of the United States and Canada (*Chicago: Amer. Florist Co., 1903, pp. 414*).—In this directory the addresses are given of the florists, nurserymen, seedsmen, gardeners, horticulturists, landscape architects, parks, cemeteries, botanical gardens, societies, and horticultural supply concerns of the United States and Canada. The matter is arranged both by States and post-offices, and all names alphabetically. Considerable statistical matter has been incorporated from the United States Census of 1900.

FORESTRY.

Principles of American forestry, S. B. Green (*New York: John Wiley & Sons, 1903, pp. XIV+334, figs. 73*).—This is a book on elementary forestry which has been prepared especially for students and other beginners of the subject, as well as for the general reader who wishes to secure a general idea of forestry in North America. Much of the matter included was originally published by the author under the title Forestry in Minnesota (E. S. R., 14, p. 361), the material being largely rewritten for the present volume so as to be more general in character and better adapted to the whole country.

Our northern shrubs, Harriet L. Keeler (*New York: Charles Scribner's Sons, 1903, pp. XXX+521, figs. 240*).—This is a handbook of the shrubs indigenous and introduced in the region extending from the Atlantic Ocean to the Mississippi Valley, and from Canada to South Carolina, Georgia, and westward. The arrangement of the shrubs is by families, each representative being scientifically and popularly described; and keys are furnished whereby almost every shrub found in the region embraced may be identified and its habits learned.

The book is designed not only for the amateur who desires a more complete description of our shrubs than that usually given in text-books, but gives valuable information for the utilization of shrubs in the establishment and decoration of parks, roadways, school yards, railway stations, and home grounds.

With the trees, Maud Going (*New York: Baker & Taylor Co., 1903, pp. X+[illegible], figs. 40*).—A popular book designed to awaken an interest in trees and their surroundings. The author defines and describes the different plant organs and describes their functions, after which different tree associations are discussed. In addition to popularizing scientific truths regarding trees, the author has introduced considerable folklore and legendary fancies regarding them, the whole being woven together in a very attractive manner.

Forestry for the farm, J. Gifford (*Connecticut State Bd. Agr. Rpt. 1902, pp. 85–95, pls. 5*).—It is claimed that on nearly every farm there are some areas which by reason of soil conditions are better fitted for growing a wood lot than for general farming. If properly cared for these places may be made profitable by planting with suitable species of forest trees. In choosing species for planting adaptability to soil and climate, rapidity of growth, ease of propagation, freedom from disease, and utility must be considered. Directions are given for collecting forest-tree seed, their propagation in the nursery, and methods of planting. The value of the forest nursery is pointed out and suggestions given for propagating forest seedlings, as well as for planting the seed where the trees are to stand.

The economic value of forests, E. Bruncken (*Forestry and Irrig., 9 (1903), No. 7, pp. 353, 354*).—Attention is called to the fact that American and English writers on economics have paid but little attention to the economic consideration of forests and forest products. This is attributed to a lack of information on the peculiar position of the forest as an economic factor. The forest yields its crop at intervals of 50 to 150 years and consequently is often disregarded. The author thinks this subject an important field for investigation by intelligent economists and foresters.

Should the forests be preserved? (*San Francisco: California Water and Forest Assoc., 1903, pp. 48, figs. 10*).—This is a pamphlet which has been prepared by the Water and Forest Association as an answer to objections that have been raised regarding the establishment of new forest reserves and the enlargement of the old reserves in California. It is stated that the preservation of the forests is essential to the permanence of agriculture, and the fruit-growing and lumbering interests of the State, and that the establishment of reservations will tend to conserve these interests as far as possible.

Restoration of forests, O. H. Baker (*Tradesman, 50 (1903), No. 2, p. 81*).—On account of the rapid destruction of the forests in the United States, the author calls attention to the qualities of various Australian species which are believed to be adapted to cultivation on the denuded lands, especially on hilly and rocky ground unfit for general farming. The trees described are mostly species of Eucalyptus, many of which have been successfully grown in California and in other regions with a similar climate.

Making the wood lot more profitable, W. Mulford (*Connecticut State Bd. Agr. Rpt. 1902, pp. 71–84, pls. 5*).—In a popular lecture the author points out some of the sources of loss and results of mismanagement, and endeavors to show how this may be avoided and the farm wood lot made a source of permanent income.

A working plan for forest lands in Hampton and Beaufort Counties, South Carolina, T. H. Sherrard (*U. S. Dept. Agr., Bureau of Forestry Bul. 43, pp. 54, pls. 13, dgms. 11*).—The working plan here presented is a result of investigations made by the Bureau of Forestry on a tract of land owned by the Okeetee Gun Club in Beaufort and Hampton Counties, S. C., about 30 miles northeast of Savannah.

This tract comprises an area of about 60,000 acres and embraces low, flat sand plains bordered by broad swamps along the streams and brooks. Most of the timber has been culled and in some places agriculture has been practiced, but some of the areas have been abandoned and are now growing up to young forests. The original forest comprised dry sand lands and swamp forests, the latter remaining practically intact. Upon drier situations the forest was originally almost a pure forest of longleaf pine, while in places was a mixture of loblolly, Cuban, and pond pines. The swamps support a varied growth, the most characteristic trees of which are cypress and gums. The different forest types are described at considerable length and estimates given of the present stand of a number of measured areas.

The object of the working plan is to reforest the area and manage it as a forest without interfering in any way with the tract as a game preserve. Suggestions are

given for carrying out these plans, and statements regarding the future yield, market, occupation, etc., and directions for the lumbering of the tract are also given.

The diminished flow of the Rock River in Wisconsin and Illinois, and its relation to the surrounding forests, G. F. SCHWARZ (*U. S. Dept. Agr., Bureau of Forestry Bul. 44, pp. 27, pls. 6*).—The purpose of the investigation here reported was to ascertain the principal factors upon which the flow of the Rock River depends, and to discover, if possible, practical means for increasing the flow or equalizing the volume of the river. In the region drained by this river the forests have been greatly reduced in area and the condition of those still remaining is far from satisfactory. Since 1885 there appears to have been a decrease in the rainfall, and this has aided materially in diminishing the volume of the river flow. The improvement of the conditions depends on the storing of water, accomplished by the construction of artificial reservoirs, or by equalizing its flow through the agency of forest growth.

The present condition of the wood lots in the region is such that the wooded area might be extended with decided profit to the farm. This could be done without expert assistance or any considerable outlay of capital or other expenditure aside from protection of wooded areas from fires and the care and management of the present areas, together with the planting of additional ones. Detailed descriptions are given, showing some of the deficiencies of the wood lots and how they may be improved.

Injuries to shade trees from electricity, G. E. STONE (*Massachusetts Sta. Bul. 91, pp. 21, figs. 12*).—On account of the increased interest regarding shade trees and roadside improvement and the adverse conditions which trees grown in these situations have to contend with, the author has investigated a number of the problems and in the present bulletin shows the effect of electrical injury to shade trees.

A considerable amount of damage is found to be due to wires in causing abrasions, destruction of limbs, burning, etc., which necessitates much injudicious pruning. The greatest amount of damage is the local burnings caused by the electrical current, and the higher the electro-motive force the more injury is likely to occur to the trees. There appears to be little or no leakage from wires during dry weather, but in wet weather when a film of water is formed on the bark there is considerable transfer of electric current. No authentic cases, so far as the author could ascertain, have been observed where the alternating current, such as is used for electric lighting, has killed trees, although cases are recorded where the direct current used in operating street railways has destroyed large shade trees. This has been accomplished by reversing the polarity, causing the positive current to traverse the rail and the return current the feed wire, which usually carries the positive current.

In general, trees possess such high resistance to electric current as to serve as a protection against their destruction. Different portions of the trees were tested and it was found that the least resistance occurs in the cambium layer and those tissues adjacent to it. Electric currents of a certain intensity when applied to plants act as a stimulus, the alternating current acting more as a stimulus than the direct current. There seems to be some evidence that even though the current is not of sufficient strength to cause burning, it may overstimulate the plant, causing a retardation of its activities, which subsequently results in its death.

Investigations carried on in connection with these experiments show that the earth discharges during thunderstorms are more common than are generally supposed, and are known to disfigure and cause the death of many trees.

The honey locust in western Kansas, R. S. KELLOGG (*Forestry and Irrig., 8 (1902), No. 8, pp. 387-390, figs. 3*).—A description is given of the honey locust (*Gleditschia triacanthos*), which grows naturally in the valleys of eastern Kansas and has proved to be one of the hardiest trees for planting on the uplands of the western part of the State, where the annual rainfall is 20 in. or less. It has demonstrated its ability to withstand adverse conditions of soil and climate, being exceeded in this

respect only by the red cedar. The principal uses to which the honey locust plantation can be put are hedges, shelter belts, and ornamental plantations, the wood being of comparatively little value. The honey locust is easily propagated, and for extensive plantings sowing the seed in rows early in the spring and transplanting to permanent situations is recommended.

The culture and uses of the species of Eucalyptus (*West Indian Bul., 4 (1903), No. 2, pp. 145–175*).—This article contains an extended compilation from the Bureau of Forestry Bulletin 35 (E. S. R., 14, p. 575), together with notes on the distribution and growth of a number of species of Eucalyptus in Jamaica, Trinidad, St. Vincent, Barbados, Dominica, and other parts of the British West Indies, and a list of the species which are believed to be suitable for tropical conditions in that region.

The redwood (*Forestry and Irrig., 9 (1903), No. 6, pp. 300–305, figs. 5*).—In this article a description is given of one of California's most valuable timber trees, the data being largely compiled from Bureau of Forestry Bulletin 38 (E. S. R., 14, p. 971).

The Unalaska spruce plantation, B. ADAMS (*Forestry and Irrig., 9 (1903), No. 8, pp. 382–385, figs. 4*).—An account is given of an attempt made to establish a spruce plantation near Unalaska. The trees were planted nearly a century ago and have made only a very small amount of growth, and that only in sheltered portions of the island. From the results of this limited plantation the author believes that this part of Alaska is not adapted to timber growing.

Bamboos in the United States, L. HARRISON (*Forestry and Irrig., 9 (1903), No. 8, pp. 400–404, figs. 5*).—An account is given of some of the cultural possibilities of bamboos, most of the information being drawn from Bureau of Plant Industry Bulletin 43 (E. S. R., 15, p. 249).

Wood preservation, P. DUMESNY (*Conservation des bois. Paris: Bernard Tignol, 1902, pp. 35, figs. 3*).—The author briefly describes some of the methods that are in use for preserving timber against decay, rendering wood fireproof, etc. Considerable attention is given to the effect of electricity in seasoning timber and as an aid to the infiltration of timber with chemicals.

Foreign trade of the United States in forest products, 1902, F. H. HITCHCOCK (*U. S. Dept. Agr., Division of Foreign Markets Bul. 33, pp. 72*).—During the fiscal year 1902 there was imported into the United States $59,000,000 worth of forest products and $49,000,000 worth was exported. A summary is given of the imports and exports, the principal imports being gums of various kinds, lumber, cabinet woods, dyewoods, wood pulp, and cork. The exports consist very largely of lumber and timber, the combined shipment amounting to $36,000,000. In addition considerable quantities of naval stores, wood pulp, tan bark, and charcoal are exported.

SEEDS—WEEDS.

The effect of light on seed germination, E. HEINRICHER (*Bot. Centbl., Beihefte, 13 (1902), p. 164; abs. in Bot. Centbl., 92 (1903), No. 10, p. 204*).—The investigations of the author show that light exerts a strong influence on the germination of seeds. In some cases, as in Mesembrianthemum, Portulaca, and *Stapelia variegata*, the seed germinates equally as well in light or darkness. In some other cases the seed will sprout only in the dark, and seed of *Pitcairnia maidifolia* and *Drosera capensis* will germinate only in the light, those of the latter losing their germinative ability if kept in darkness. The seed of many cacti are hastened in their germination by the action of light. The effect of light upon the germination of seed of all the members of a plant family can only be determined by repeated trials, since nearly related species behave differently.

Observations on the duration of the vitality of seed, J. POISSON (*Bul. Soc. Bot. France, 50 (1903), No. 5–6, pp. 337–354*).—A review is given of considerable literature relating to the prolonged vitality of various species of seeds, and the author

briefly describes his own experiments, summarizing the results. The author claims that the prolonged vitality of many seeds depends upon the temperature in which they are stored, the dryness of the atmosphere, and the action of oxygen and of light. He claims that light exerts a positive effect on seeds aside from that of influencing them through a rise in temperature.

Report of the Seed Control Station of Christiania, 1902, O. Qvam (*Ber. Stat. Kem. Kontrolstat. og Frökontrolanst. Kristiania, 1902, pp. 35–54*).—A report is given of the seed control investigations conducted during the year 1902. During this period 1,287 samples of seed were tested, of which 573 were cereals, 279 grass seed, 346 leguminous forage plants, and the remainder seed of garden plants, forest trees, etc. The form of contract and guaranty are given, together with data regarding the fees for seed testing. The maximum, minimum, and average germinations of all the species of seed tested are shown in tabular form.

Some weeds of Iowa, L. H. Pammel (*Iowa Sta. Bul. 70, popular ed., pp. 295–372, figs. 63*).—This is a condensed and popularized edition of a more extended bulletin to be published relating to the weeds of Iowa, and is to take the place of previous publications of the station relating to weed problems. After describing the duration of weeds and giving general observations upon their eradication, the author describes at considerable length various weed pests, grouping them under the headings of weeds of corn fields, grain fields, clover fields, timothy meadows, pastures, garden crops, and poisonous weeds.

Hawkweeds, W. M. Munson (*Maine Sta. Bul. 95, pp. 114–116*).—The author comments upon the wide distribution of the orange hawkweed (*Hieracium aurantiacum*) throughout the State, stating that it has become one of the worst weeds destroying all grass in its vicinity and being of itself of no value for hay. Numerous attempts have been made to destroy this weed by the application of salt, kerosene, or other chemicals but the experience at the station shows that the only certain remedy for its eradication is clean culture with some hoed crop.

Notes are also given on the king-devil weed (*H. prealtum*), which is sometimes associated with the orange hawkweed and has proved in some regions more troublesome even that pest. It may be distinguished from the orange hawkweed by producing stems 2 or more feet high and several from the same root. For its eradication the same plan recommended for the orange hawkweed should be adopted, and the treatment should begin early in the year and continue throughout the growing season.

The chemical extermination of weeds, J. O. Morgan (*Agr. Education, 6 (1903), No. 1, pp. 10–12*).—The results of a number of experiments with different chemicals for the destruction of weeds are given. Weed plats of one-fourth rod each were selected and received applications of solutions of copper sulphate, corrosive sublimate, potassium sulphid, common salt, and sodium arsenate. The weeds embraced a large number of species of different genera of plants and as would have been expected the effect on the different forms varied widely.

The potassium sulphid appeared to have no effect whatever in checking the weed growth, and the copper and corrosive sublimate solutions were without very much effect in deterring them. The best results were obtained where sodium arsenate was used, and where considerable areas are to be treated it is suggested that spraying with this solution would give the best and cheapest results.

Noxious weed inspection, T. N. Willing (*Rpt. Dept. Agr. Northwest Territories, 1902, pp. 30–33*).—A review is given of the condition reported by the weed inspectors in the Northwest Territories, and the author calls attention to the fact that competent inspectors can not be retained and do good work at the present rate of compensation. The advantage of weed inspection is pointed out and some progress is being made in securing the compliance with the laws relating to weed destruction. Attention is called to the danger of the distribution of noxious weeds through the sowing of flaxseed, and to extensive farming is attributed the distribution of many of the worst weeds in the country.

Elevator inspection, which is included as part of the duties of the inspector of noxious weeds, is briefly reported upon. In the main it was found that the elevators throughout the Northwest Territories are careful in cleaning and distributing their seed. Some instances were found in which large amounts of noxious weed seed were present in the screenings from wheat and oats.

DISEASES OF PLANTS.

Immunity to plant diseases secured by the absorption of fungicides, E. MARCHAL (*Ing. Agr. Gembloux, 13 (1903), No. 12, pp. 524–527*).—On account of the apparent success which certain investigators had reported on securing the immunity of potatoes to the downy mildew, the author investigated the possibility of securing immunity to lettuce and various cereals against some of their more destructive parasites.

In the lettuce experiments young seedlings were removed to culture media containing from 6 to 8 parts of copper sulphate in 10,000, and after growing in this for some time were inoculated with spores of *Bremia lactucæ*. The plants seemed to show considerable resistance and the immunity seemed to be in proportion to the strength of the solution. Where grown in solutions containing 1 part in 10,000 or less of the fungicide no predisposition to immunity was shown.

The experiments with cereals were for the protection against rusts and mildew. In these experiments no immunity was secured. The author believes that immunity against such fungi as the downy mildews may to some extent be secured by the absorption of fungicides by the growing plant.

Parasitic fungi, G. P. CLINTON (*Connecticut State Bd. Agr. Rpt. 1902, pp. 253–265*).—In an address the author popularly describes parasitic fungi and their methods of attacking numerous economic plants. Suggestions are given for the control of parasitic fungi, selection, pruning, and treatment for fungicides being described. In conclusion, the author briefly describes bacteria, rusts, smuts, downy mildew, and powdery mildew as causes of plant diseases.

Pathological plant anatomy, E. KÜSTER (*Pathologische Pflanzenanatomie. Jena: Gustav Fischer, 1903, pp. VII+312, figs. 121*).—This is an outline study of the anatomy of pathological plant tissues in which the author treats of the modified structures produced by various factors that induce departures from normal. It is an outgrowth of a previous publication by the author on the anatomy of plant galls.

A study of some diseases of cereals in Mexico, S. BONANSEA (*Mem. y Rev. Soc. Cient. "Antonio Alzate," 18 (1903), No. 3, pp. 125–136*).—A list is given of the various cryptogamic parasites of cultivated cereals in Mexico. This includes various smuts, rusts, etc., and suggestions are given for their prevention so far as any means are known.

A cotton disease at Montserrat, H. H. BALLOU (*Agr. News [Barbados], 2 (1903), No. 38, p. 309*).—A brief description is given of a disease of cotton caused by a leaf-gall mite, *Phytoptus* sp. This pest has destroyed a considerable amount of cotton and so far as the author has been able to determine it has not previously been reported upon this plant. He states that all ratoon cotton should be destroyed and active measures taken for the destruction of the mite, as it threatens to become one of the most serious pests of the cotton plant.

Experiments in the prevention of oat smut, T. JOHNSON (*Econ. Proc. Roy. Dublin Soc., 1 (1902), pp. 119–131; abs. in Bot. Centbl., 92 (1903), No. 20, p. 465*).—A report is given of tests of formalin, hot water, sodium sulphid, and potassium sulphid for the prevention of oat smut in Ireland. Based upon the results obtained, the author recommends soaking the seed before sowing in solutions of potassium sulphid or sodium sulphid for simplicity of procedure and efficiency of treatment.

Investigations on the black shank of potatoes, O. APPEL (*Arb. K. Gesundheitsamte, Biol. Abt., 3 (1903), No. 4, pp. 364–432, pl. 1, figs. 15*).—The author gives a description of a bacterial disease of potatoes due to a hitherto undescribed species, *Bacillus phytophthorus*. This organism causes what is known as black shank of the stems and the rotting of the tubers. The attack on the stems is most apparent near the ground. The stems are blackened and become rotten; hence the name black shank or stem rot. Later the tubers are affected, being rendered useless by the rot.

The organism, which is fully described, is said to be quite distinct from *B. solanacearum*, widely known in this country. Numerous infection experiments in the laboratory and field have been made which show the infectious nature of the disease. Inquiries were instituted on the distribution of this disease, and from the replies received it was found to be quite generally distributed throughout Germany. Marked differences in the susceptibility of varieties of potatoes are noted, and experiments are reported which were carried on to test the ability of the organism to live on other host plants than potatoes. The bacteria were found capable of infecting horse beans, lupines, carrots, certain varieties of turnips, cucumbers, etc.

Soaking the seed tubers in Bordeaux mixture was found to reduce the amount of disease considerably but not entirely. As practical suggestions for combating this disease the author suggests a rotation of crops in which neither potatoes nor any of the above-mentioned crops should occupy the ground for a number of years, the planting of whole potatoes, disinfecting them with fungicides, and the avoiding of strong nitrogen fertilizers, especially Chili saltpeter and ammonium sulphate.

The infection of sugar beets by Rhizoctonia violacea, F. BUBAK (*Ztschr. Zuckerind. Böhmen, 1903, No. 8, pp. 5; abs. in Bot. Centbl., 93 (1903), No. 34, p. 193*).—During 1901 and 1902, sugar beets in Central Bohemia were attacked by the root-rot fungus *Rhizoctonia violacea*. In one locality, at least 15 per cent of the beets was destroyed by the disease. It was not definitely determined whether the infection was through the soil or introduced through spores upon the seed when planted. The author recommends for the prevention of the disease treating the soil with quick lime, better attention to drainage, and a rotation of crops so that beets will not be cultivated more than once in 4 years.

The rind disease of sugar cane in the West Indies, A. HOWARD (*Internat. Sugar Jour., 5 (1903), No. 53, pp. 215–225, pl. 1*).—The results of several years' study of the diseases of sugar cane are given, particular attention being devoted to the so-called rind disease. This disease in the West Indies is said to be identical with the red smut disease of Java, and is caused by the fungus *Colletotrichum falcatum*. This fungus is able to infect ripening canes at wounds and old leaf bases, and can attack the young canes in any of the rapidly growing tissues. The Melanconium found on diseased sugar canes in the West Indies is a saprophyte and is not to be considered as a cause of the rind disease, but readily attacks plants which have been weakened by the Colletotrichum. Experiments have shown that the destructiveness of this disease may be reduced by burning the diseased canes at time of harvest, stripping the growing canes, planting from the best cuttings, and controlling the cane-boring insects.

The Sereh disease in the West Indies, F. A. F. C. WENT (*Indische Mercuur, 25 (1903), Herinneringsnummer, p. 19; abs. in Bot. Centbl., 93 (1903), No. 29, p. 66*).—The author reports the presence of the Sereh disease in the cane fields of the West Indies and northern South America. From the leaf sheath of stalks has been taken the Verticillium form of *Hypocrea sacchari*, which seems to substantiate the author's hypothetical relationship between the Sereh disease and this fungus.

A bacterial disease of tobacco, G. DELACROIX (*Jour. Agr. Prat., n. ser., 6 (1903), No. 38, pp. 385, 386*).—A preliminary account is given of the bacterial disease of tobacco which has been observed in a number of regions in central France. The first appearance of the disease was noted in July when the plants had attained a

height of from 0.2 to 0.3 meter. At this time the stems and the principal veins of the leaves were observed to be more or less covered with oblong spots in which the tissue was discolored and depressed. As the disease progressed the stems and veins became covered with spots, the central portion of which became dry and white. The diseased stems lost their rigidity and the leaves became wilted.

The names canker, anthracnose, smut, etc., have been given this disease, which, according to the investigations of the author, is caused by attacks of a species of bacteria to which the name *Bacillus æruginosus* has been given. The disease is to be studied further and the cause and possible means of prevention will be fully described later.

On the occurrence of the wilt disease of sesame, A. von Jaczewski (*Ann. Mycol., 1 (1903), No. 1, pp. 31, 32; abs. in Bot. Centbl., 92 (1903), No. 23, p. 543*).—The author reports the presence of the fungus *Neocosmospora vasinfecta* on the cultivated sesame. An examination of diseased plants showed the stems infested with a mycelium, which was readily isolated and studied. From the characters observed, the author is led to believe that it is due to the above-named fungus. If the fungus should prove identical with that causing the wilt of cotton, cowpeas, melons, etc., another host plant is added to the list of species subject to its attack.

Tomato wilt, A. Despeissis (*Jour. Dept. Agr. West Australia, 7 (1903), No. 2, p. 103*).—A brief description is given of the bacterial blight of tomatoes, which has been recently ascribed to attacks of *Bacillus solanincola.* For the prevention of this disease it is recommended that spraying with Paris green in order to destroy the leaf-eating insects should be thoroughly practiced, and attention given to all other related plants which may be attacked by this same organism.

A disease of peas due to Fusarium vasinfectum, C. van Hall (*Ber. Deut. Bot. Gesell., 21 (1903), No. 1, pp. 2–6; abs. in Bot. Centbl., 92 (1903), No. 16, pp. 363, 364*).—A disease of peas due to attacks of a fungus, *Fusarium vasinfectum*, has been under observation in Holland for a number of years. The affected plants turn yellow and soon die, and an investigation shows that the roots are the seat of the fungus attack. The organism causing the disease has been isolated and studied on a number of media. It is believed to be closely related to the fungus which causes the wilt of melons, cotton, cowpeas, etc., and the author has described it as *F. vasinfectum pisi* n. var. Inoculation experiments have been successfully performed showing that this fungus is the cause of the disease. As it usually makes its appearance about June 24, the disease is locally known as St. John's disease of peas.

Two decays of stored apples, H. J. Eustace (*New York State Sta. Bul. 235, pp. 123–131, pls. 4*).—A description is given of an apple rot which was observed to follow the apple scab and a core decay of Baldwin apples. Subsequent to the publication of the station bulletin on the pink rot of apples (E. S. R., 14, p. 1088) specimens of diseased Rhode Island Greening apples were observed, which presented decayed areas somewhat similar in general appearance as that described as pink rot. A more critical examination, however, showed that the fungus causing the disease was entirely different.

In comparing the pink rot of apples and the decay caused by this new fungus, it was found that in the pink rot there is usually a conspicuous white or pinkish growth of the fungus in the center of the infected spot, while the new fungus does not show at all conspicuously on the surface of the decayed spot until forced to do so by artificial conditions. The pink rot of the fruit is a very shallow growing fungus, penetrating the tissues not more than one-eighth of an inch, while the new disease extends much deeper and in its later stages reaches to the core. The tissues decayed by the pink-rot fungus are very characteristic and decidedly bitter, while the tissue decayed by the other fungus is only slightly so. The fungus causing this new rot was determined as a species of Hypochnus, a description of which is given.

The amount of damage caused by this fungus to stored apples is probably not very large, but specimens of affected fruit have been observed from a number of localities. So far it has been found on Baldwins and Rhode Island Greenings only. Inoculation experiments have shown, however, that the organism would grow equally as well on other varieties as upon these two. The results of the inoculation experiments show that the fungus is a wound parasite, as the mycelium was unable to penetrate the unbroken epidermis of the fruit. The cracked epidermis, due to the apple scab, rendered the conditions advantageous for an attack of this fungus; and this new disease emphasizes the importance of protecting apples from scab by thorough and persistent spraying with Bordeaux mixture. Finding decayed apples in several cold storage houses indicated that low temperature alone can not be relied upon to hold this trouble in check, although it probably does retard its development to some extent.

The core decay of Baldwin apples described shows no outward manifestation, but upon being cut in two a part of the tissue surrounding the core was found to be decayed. This decayed tissue was brown, dry, and tasteless, and was entirely surrounded by healthy tissue of normal quality. Examination failed to show the presence of any fungus or other organism as the cause of the trouble. Other conditions, such as immaturity, effect of different fertilizers, different soils, overbearing, etc., have been examined, but so far the disease can not be attributed to any definite cause.

Two new apple rots, F. H. Hall and H. J. Eustace (*New York State Sta. Bul. 235, popular ed., pp. 4*).—A popular edition of the above-noted bulletin.

Spraying the plum orchard, W. B. Alwood and H. L. Price (*Virginia Sta. Bul. 134, pp. 31–40, figs. 5*).—The plum trees at the station are said to be subject to attacks of leaf diseases caused by *Cylindrosporium padi* and the brown rot (*Sclerotinia fructigena*), and experiments have been conducted for the prevention of these diseases. The details of the experiments are given. The treatment consisted ordinarily of a winter treatment of copper-sulphate solution followed by applications of a 4–5–50 solution of Bordeaux mixture. If thoroughly applied these methods are efficient in checking the disease.

For the control of the brown rot it is necessary to begin spraying quite early in the season, and for the leaf diseases late applications should be given if a healthy condition of the tree is to be maintained to the end of the growing period. For the prevention of the rot it is also desirable to collect and destroy all of the diseased fruit.

On the occurrence and treatment of fire blight in the pear orchard, W. B. Alwood (*Virginia Sta. Bul. 135, pp. 51–66, figs. 5*).—A report is given on investigations for the prevention of fire blight, due to *Micrococcus amylovorus*, in which spraying, pruning, fertilizing, etc., were tried. So far it has been found impossible to hold the disease in check by the cutting out of diseased tissues and spraying the plants, although it is still thought that this preliminary treatment should not be neglected. There seems to be some evidence that fertilizers will enable the trees to resist disease to a marked degree, but these tests must be continued before a definite opinion can be formed regarding their value. Different varieties seem to be affected unequally, and the author gives a list of varieties which in his experience are less subject to the disease than others.

A remedy for cranberry scald, C. L. Shear (*Amer. Agr., 72 (1903), No. 10, p. 309*).—According to the author's investigations, which have been carried on for the past 2 years, the cranberry scald infection takes place through the aerial portions of the plant, rather than by way of the roots, as has been formerly supposed. After having established this fact, the author experimented with fungicides for the control of the disease, testing potassium sulphid, ammoniacal solution of copper carbonate, and Bordeaux mixture.

The results obtained seem to indicate that a thorough application of properly prepared Bordeaux mixture will prove a practical remedy for the cranberry scald, and

it is probable that 4 or 5 applications should be made during the season, the last not earlier than August 15. As the foliage of the cranberry is very smooth and glossy, it has been found desirable to add to the ordinary formula for Bordeaux mixture 5 lbs. resin, 1 lb. potash, 1 pt. fish oil, and 5 gal. water.

A bacterial disease of grapes, A. Zschokke (*Weinbau u. Weinhandel, 20 (1902), No. 29, p. 308; abs. in Bot. Centbl., 93 (1903), No. 30, p. 89*).—The author reports observing upon grape stock small irregular dark-green or brownish spots, about 1 mm. in diameter. Later these became moist and slimy. An examination showed the presence of 2 species of bacteria, which were separated and characterized. From the appearance of the disease the author believes that this is not identical with the so-called brunissure, or California blight disease.

A new disease of mountain ash, A. von Jaczewski (*Ann. Mycol., 1 (1903), No. 1, pp. 29, 30; abs. in Bot. Centbl., 92 (1903), No. 23, p. 543*).—A report is given of the presence on the leaves of *Sorbus aucuparia*, of grayish-white round spots with concentric brown layers, which the author claims is due to a species of Leptosphæria, to which he has given the name *L. sorbi*.

Bacterial spot of carnations, A. F. Woods (*Science, n. ser., 18 (1903), No. 460, pp. 537, 538*).—A report is given of a new disease of carnations which has been under examination, specimens having been received from Pennsylvania and the District of Columbia. In the earlier stages the disease resembles stigmonose or insect puncture (E. S. R., 12, p. 460), but the small spots are usually surrounded by a narrow water-soaked area, while the center of the spot is usually light brown. As the spots grow larger they resemble the ordinary carnation spot. The spots increase in size more rapidly in soft-leaved varieties, which soon collapse and dry, leaving a brown sunken area.

Examination showed that in all stages the spots are filled with bacteria which have been isolated, cultivated on various media, and used in inoculation experiments, showing that the bacteria are the cause of the disease. They are quite different from the form described as the cause of bacteriosis of carnations (E. S. R., 8, p. 235). The bacteria seemed to gain entrance through punctures, injuries of any kind, or possibly through the stomata. When the disease has not progressed very far it may be checked by cleaning the plants of all diseased leaves and stems and spraying with a solution of 1 part formalin to 500 parts water. The disease is to be the subject of further investigation, which will be duly reported.

Sulphate of iron for chlorosis in trees and plants, H. M. Stringfellow (*Texas Farm and Ranch, 22 (1903), No. 38, p. 10*).—The author was successful in curing chlorosis of vines and fruit trees by the use of sulphate of iron dissolved in water and sprinkled about the roots. He believes that 5 to 10 lbs. would cure a large bearing tree.

ENTOMOLOGY.

Report of the entomologist, F. Sherman, Jr. (*Rpt. Comr. Agr. North Carolina, 1902, pp. 34–39*).—Brief notes are given on the methods best adapted for destroying the common injurious insects, together with a summary of the work of the entomologist for the past 2 years in the inspection of nurseries.

Injurious insects. Spraying for insects and diseases, F. Sherman, Jr. (*Bul. North Carolina State Bd. Agr., 24 (1903), No. 6, pp. 39, figs. 21*).—Short descriptive, biological, and economic notes on harlequin cabbage bug, cabbage plusia, cabbage butterfly, white grubs, Hessian fly, tobacco flea-beetle, black grain weevil, corn billbug, bagworm, elm-leaf beetle, San José scale scurfy scale, oyster-shell bark-louse, woolly aphis, codling moth, peach-tree borer, blackberry-cane borer, and plum curculio. Formulas are also given for the preparation of approved insecticides and fungicides.

The insect problem, H. OSBORN (*Jour. Columbus Hort. Soc., 18 (1903), No. 2, pp. 40–43*).—Statistics are presented for the purpose of showing the extent of losses due to insect depredations in various parts of the country. The damage caused by codling moth, plum curculio, chinch bug, and Hessian fly is specially mentioned.

Some destructive insects, D. A. SAUNDERS (*South Dakota Sta. Bul. 81, pp. 63–66*).—Brief descriptive, biological, and economic notes on wheat aphis, elm coxcomb gall, vagabond gall louse, Hessian fly, and plum gouger.

The horticultural law of Utah, T. JUDD ET AL (*Utah State Bd. Hort. Bul. 8, pp. 16*).—A copy of the horticultural law of Utah passed in 1903 is given, together with rules, formulas, and recommendations promulgated by the State Board of Horticulture for the control of dangerous insect and fungus pests.

Entomological studies in Jylland in 1902, N. FRITZ (*Hedeselsk. Tidsskr., 1903, No. 8, pp. 188–192*).—Brief notes on *Tortrix pinicolana*, *T. nemorivaga*, *Grapholitha tadella*, etc.

Report on the injurious insects of Finland for 1902, E. REUTER (*Landtbr. Styr. Meddel. [Helsingfors], 1902, No. 45, pp. 22*).—The author's report for 1902 is occupied chiefly with a discussion of insects injurious to grass, cereals, potatoes, certain garden vegetables, fruit trees, and ornamental shrubs. Notes are given on the habits and injurious attacks of *Charæas graminis*. The author discusses at some length the conditions under which the so-called white-head condition of grasses appears and mentions a considerable variety of insects which are concerned in producing this disease. Mention is made of a bacterial disease of potatoes known by the name of black shank. *Athalia spinarum* is reported as injurious to turnips. Notes are also given on cabbage butterfly, codling moth, pear-tree psylla, apple aphis, *Cheimatobia brumata*, and *Anthonomus rubi*.

Insects injurious to fruit and garden crops in Russian Poland, I. K. TARNANI (*Nasyekomuiya vrednuiya dlya plodovodstva i ogorodnichestva v guberniyakh Tzarstva Polskago. Warsaw: Novo-Alexandri Inst. Selsk. Khoz. i Lyesov, 1903, pp. 138, figs. 136*).—The author presents a general account of the economic importance of insects, their anatomy, metamorphosis, food, enemies, and causes of excessive multiplication. Special chapters are devoted to beneficial insects, Orthoptera, Hemiptera, Coleoptera, Lepidoptera, Diptera, and Hymenoptera. Notes are given on the various artificial remedies for controlling injurious insects and on fungus diseases, parasitic and predacious insects, and birds which assist in controlling injurious species. Among the various injurious insects which are discussed mention may be made of the following: Mole cricket, earwig, apple aphis, cabbage aphis, cockchafers, pea weevil, apple weevil, fruit-tree bark-beetle, asparagus beetles, cabbage butterflies, gypsy moth, brown-tail moth, cutworms, codling moth, cabbage maggots, currant sawfly, etc. A list of garden vegetables is presented, showing the most important species of injurious insects attacking them.

Insect pests, A. LEHMANN (*Dept. Agr. Mysore State, Rpt. Agr. Chem., 1901–2, pp. 17–24*).—Brief notes on insects injurious to castor bean, date palm, coffee, rice, and mango. Coffee suffered greatly from the attacks of *Lecanium viride* and a species of mealy bug. The chief insect pest of rice was *Cecidomyia oryzæ*.

Insect notes (*Agr. News [Barbados], 2 (1903), No. 37, p. 298, figs. 2*).—Notes on the changa or mole cricket, which is reported to be quite injurious in the West Indies. The insect has been controlled to some extent by placing boards on edge in the soil around seed beds, and by the use of soap and water on lawns.

The common sunflower has been found to be a valuable trap plant in combating the attacks of the fiddler beetle (*Prepodes vittatus*), which is specially injurious to orange. It is suggested that sunflowers be planted as a trap crop near orange groves.

Short notes on some insects, F. W. HILGENDORF (*Trans. and Proc. New Zealand Inst., 35 (1902), pp. 264–267*).—*Rhizobius graminis* is reported as injurious to grass roots, upon which it feeds. Notes are also given on *Plutella cruciferarum*, bumblebees, and other insects.

The Mexican cotton-boll weevil, W. C. STUBBS (*Louisiana Stas. Circ. 1, pp. 10, figs. 3, map 1*).—The boll weevil recently appeared on the experiment station grounds at Audubon Park, New Orleans, and drastic measures were taken for eradicating it. The crop of infested cotton was pulled up, dipped in kerosene, and burned; the soil was then saturated with kerosene and fired, after which it was flooded for several days. Cotton planters are urged to give close attention to their crop in order to detect the presence of the weevil at once. A brief account is given of the life history, habits, and appearance of the insect.

The Colorado potato beetle, G. W. HERRICK (*Mississippi Sta. Bul. 81, pp. 8, figs. 5*).—It is reported that this insect now occurs over all parts of the State, even to the gulf shore. Notes are given on the habits and life history of the beetle. A species of ladybug was observed feeding upon the eggs and larvæ of this pest. Arsenate of lead was used in spraying experiments, at the rate of 4 lbs. to 50 gal. of water. One application was quite effective in destroying the insects. Similar results were obtained from the use of Disparene. Brief notes are given on the methods of preparing and applying these insecticides.

The principal insect enemies of the sugar beet, F. H. CHITTENDEN (*U. S. Dept. Agr. Rpt. 74, pp. 157–221, figs. 65*).—An elaborate account is presented of the most important insect enemies of the sugar beet. These include species of flea-beetles, rootworms, carrion beetles, blister beetles, cutworms, army worm, webworms, zebra caterpillar, locusts, spinach-leaf miner, tarnished plant bug, leaf hoppers, plant lice, white grubs, wireworms, red spider (*Tetranychus bimaculatus*), etc. The various remedies which have proved effective and practical in the control of these insects are mentioned in connection with the discussion of each species.

Fungi parasitic upon Cleonus punctiventris, J. DANYSZ and K. WIZE (*Ann. Inst. Pasteur, 17 (1903), No. 6, pp. 421–446, figs. 2*).—Notes are given on the habits and life history of this enemy of sugar beets, with special reference to the requirements for the successful remedy to control the insect. A number of parasitic fungi are known to attack this pest, and special mention is made of *Oospora destructrix*, *Sorosporella uvella*, *Isaria farinosa*, and *Sporotrichum globuliferum*.

A number of experiments were made in distributing cultures of Oospora in sugar-beet fields infested with Cleonus. While the results were not all that could have been desired, the authors believe that they will be more apparent later and that the method is to be recommended on the ground that the soil will gradually become infected with the parasitic fungus and will thus have a tendency to destroy the beetles.

The root borer of sugar cane, N. B. WATSON (*West Indian Bul., 4 (1903), No. 1, pp. 37–47, figs. 3*).—Notes are given on the appearance, habits, and life history of *Diaprepes abbreviatus*. The insect is described in its various stages, and the different stages in its life history are presented in a tabular form. A number of natural enemies are known to attack this pest. The artificial remedies recommended by the author include the planting of sweet potatoes near the sugar-cane field as a trap for the beetles, and the direct use of lime as an insecticide.

The codling moth in Australia, A. DESPEISSIS (*Jour. Dept. Agr. West Australia, 7 (1903), No. 2, pp. 87–98, fig. 1*).—Until recently Western Australia has been comparatively free from the codling moth. This was due to special efforts which were made by the provincial government in preventing its introduction. Notes are given on the distribution of the codling moth in various parts of Australia, the insect is described in its various stages, and a brief account is presented of the extent of damage done by the insect. The life history of the codling moth in Australia and the external evidences of infestation are also discussed.

In combating this pest the author recommends that all rubbish in orchards, especially windfall apples, should be destroyed, that bandages be applied to the trees and regularly inspected for the detection of the larvæ, and that arsenical sprays be applied at the proper seasons. The author recommends the use of Paris green, London

purple, and arsenite of lead. Notes are also given on the natural enemies of the codling moth.

Arsenical spraying against codling moth, 1902-3, G. QUINN (*Jour. Agr. and Ind. South Australia, 6 (1903), No. 12, pp. 717–736, figs. 5*).—Extensive spraying experiments with arsenical poisons have been conducted in various parts of Australia by the fruit inspectors in combating codling moth. Detailed notes are given by the author on the conditions which prevail in different parts of Australia and on the spraying apparatus used, and other points connected with spraying operations. At the close of one test it was found that 10 per cent of the apples from trees sprayed with Paris green were infested, 5.3 per cent from those sprayed with Kedzie's formula, while 42.3 per cent of unsprayed trees were infested with codling moth. The stock solution of Kedzie's arsenite of soda was used at the rate of 1 lb. in 40 gal. limewater.

Fruit fly, G. BUCHANAN (*Jour. Dept. Agr. West Australia, 7 (1903), No. 2, pp. 109, 110*).—This insect is said to have increased in numbers greatly during the past 6 years. A test was made of the starving-out method in destroying this pest. For this purpose the fruit was removed from the trees. As a result of this action it is reported that the depredations from the fruit fly were greatly diminished during the following season.

San José scale, C. A. KEFFER (*Tennessee Sta. Bul., Vol. XVI, No. 2, pp. 23–32, figs. 9*).—This insect is said to be quite generally distributed throughout the State. The pest is described in its various stages and notes are given on insecticide experiments. These included tests of crude petroleum, lime, sulphur and salt, and lime, sulphur, and caustic soda solutions.

Crude petroleum was applied in a mechanical mixture with water in a 20 to 25 per cent solution, and also in a 10 per cent solution. Considerable difficulty was experienced in securing a constant percentage of the oil by means of the ordinary spray pumps, and in some instances the trees were injured or even killed outright. The oil was sprayed upon apple, cherry, peach, pear, and plum trees. Peach trees were most injured by applications of crude oil. In 1 experiment undiluted crude oil was sprayed on a pear tree, with the result that the tree was killed.

Lime-sulphur-salt wash, made according to the recommendations of Professor Forbes, of the Illinois Station, and applied hot to cherry, peach, plum, pear, and quince trees, was fully as effective as crude petroleum in destroying the San José scale, although the effects were not manifested so quickly. The trees were, however, not injured in any case. Frequent rains had no effect in removing the insecticide from the trees and the mixture was found to adhere better than crude petroleum. The lime, sulphur, and caustic soda solution proved to be equally effective with the lime, sulphur, and salt solution, adhered quite as long to the trees, and was more easily made, but somewhat more expensive. It is recommended for use on small orchards, while the lime, sulphur, and salt solution is recommended for large commercial orchards.

The destruction of the woolly aphis (*Jour. Agr. Prat., n. ser., 5 (1903), No. 23, p. 727*).—A number of remedies which have been recommended for combating this insect were tried without success. An experiment was then made in treating infested apple trees with a light varnish mixed with a 5 to 10 per cent solution of lysol. Infested parts of the tree were sprayed or painted with a brush. The varnish was prepared with alcohol, and as soon as the alcohol had evaporated the insects were entrapped in the varnish and were destroyed by the action of the lysol. The experiment is regarded as showing the practicability and effectiveness of this method.

Hyponomeuta padella, S. G. DE LAHARPE (*Jour. Agr. Prat., n. ser., 6 (1903), No. 35, pp. 289, 290*).—This insect is described and notes are given on its habits and life history. The caterpillars are extremely voracious, and when occurring in large numbers great damage is done to the foliage of apple trees. Considerable success

has been had in combating this insect by the use of a mixture of nicotine, soap, and water, and also by the use of a mixture of pine tar, caustic soda, ammonia, and water. A number of parasitic insects assists to some extent in checking the extension of the pest.

The rust mite of the orange (*Jour. Jamaica Agr. Soc., 7 (1903), No. 9, pp. 354–356*).—*Phytoptus oleivorus* is reported as greatly injurious to both orange and lemon. The method recommended for combating this mite consists in the application of a sulphur-lye solution to affected trees.

The pith moth (Laverna atra) (*Bd. Agr. [London], Leaflet 90, pp. 3, fig 1*).—This insect is said to be very injurious to fruit trees. Notes are given on its life history. The insect can be controlled to some extent by collecting and destroying dead shoots before the moths emerge in June. Late spraying with Paris green is also recommended.

Insects injurious in cranberry culture, J B Smith (*U. S. Dept. Agr., Farmers' Bul. 178, pp. 32, figs. 12*).—The insects which attack cranberries are classified according as they injure the leaves, stem, or fruit. The species which are most injurious to foliage are *Eudemis vacciniana, Teras minuta, Cecidomyia oxycoccana,* and *Cleora pampinaria;* the most important species injurious to the stem is *Crambus hortuellus;* while the chief insect pests of the cranberry fruit are *Mineola vaccinii* and *Scudderia texensis.* Notes are given on the habits, life history, and means of combating these various species. A number of other less important insect pests are also mentioned and notes are given on cultural methods which are best adapted to prevent insect ravages. It is suggested that an ideal cranberry bog should be as level as possible, not too extensive, and should be conveniently located to reservoirs, with which it should be connected by means of ditches.

Is the fight against phylloxera futile? J. Dufour (*Chron. Agr. Canton Vaud, 16 (1903), No. 13, pp. 375–381*).—In various parts of the Canton de Vaud it is said that this insect is on the increase, despite all measures which have been taken for combating it. Statistics are presented showing the gradual distribution of the pest. The author believes, however, that the fight against this insect should not be given up and presents reasons for holding out the hope that ultimate success may be reached by the use of American vines and approved insecticide methods.

Fumigation for the destruction of the grape-leaf roller, J. Perraud (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 24, pp. 1485–1487*).—Since the larvæ of this insect winter over under the bark of grape trunks, fumigation with sulphur was employed for destroying them. It was found to be quite safe and effective to inclose the trunks in a metallic jacket only slightly larger than the trunks and to burn sulphur in this small space. The larvæ were killed in almost all cases. It is recommended that fumigation should not be practiced under freezing temperature or immediately after rain.

A dipterous parasite of the grapevine flea-beetle, C. Vianey and H. Conte (*Bul. Agr. Algérie et Tunisie, 9 (1903), No. 14, p. 326*).—The grapevine flea-beetle is considered one of the worst enemies of grapes in Algeria, and observations made by the authors indicate that the parasitism of this insect by *Degeeria funebris* may assist materially in the destruction of the pest.

Cankerworms, W. M. Munson (*Maine Sta. Bul. 95, pp. 121–124, figs. 2*).—Brief descriptive, economic, and biological notes on spring cankerworm and fall cankerworm. The remedies recommended for this insect include the use of bands of tarred paper or other substances and spraying with Paris green or arsenate of lead.

Departmental notes on insects that affect forestry, II, E. P. Stebbing (*Calcutta: Supt. Govt. Printing, India, 1903, pp. VII+151–334, pls. 13*).—This number is a continuation of the author's extensive notes on forest insects of India (E. S. R., 14, p. 472). A large number of species belonging to various orders of insects are discussed in detail, and the majority of species are excellently illustrated. Many of the

species discussed are new to science and the material contained in the volume is as a rule original, with the observations of the author and his correspondents.

Atlas of forest entomology, E. HENRY (*Atlas d'entomologie forestière. Paris: Berger-Levrault & Co., 1903, 2. ed., pp. 56, pls. 49*).—Illustrations are given of a large number of forest insects belonging to the various orders of insects, together with explanatory notes relating to these species.

The pine beetle (Hylesinus piniperda) (*Bd. Agr. [London], Leaflet 91, pp. 6, figs. 3*).—This is said to be one of the most destructive of forest insects in England. The pest is described and notes are given on its habits and life history. In combating it, it is recommended that certain trees be left as trap trees upon which the eggs are deposited and which may be destroyed together with the insects.

Tree borer (*Jour. Dept. Agr. West Australia, 7 (1903), No. 6, pp. 440, 441, fig. 1*).—Notes on the injuries suffered by eucalyptus from the attacks of insects belonging to the genera Phoracantha and Stigmodera.

Two insect pests, R. A. COOLEY (*Montana Sta. Bul. 46, pp. 107–118, figs. 2*).—Notes are given on the rosebud curculio (*Rhynchites bicolor*), which causes injury to roses in various parts of the State. The beetles appear in June and continue until the latter part of August. The eggs are generally laid in the rosebuds. In some cases hand picking is sufficient to secure relief from this insect, but jarring and spraying with Paris green are also recommended.

A sawfly (*Pontania bozemani*) which folds the leaves of poplar is said to have been steadily increasing in numbers for several years. The insect appears to be native to the State. The adult hibernates among the leaves on the ground and emerges in May to lay its eggs on the young leaves. In combating this species it is recommended that the leaves be gathered and burned in the fall and that the trees be sprayed in July and August with Paris green or arsenate of lead.

The greenhouse aleurodes (Aleurodes vaporariorum) and the strawberry aleurodes (A. packardi), A. W. MORRILL (*Massachusetts Sta. Tech. Bul. 1, pp. 66, pls. 6*).—An elaborate account is presented of the systematic position of the genus Aleurodes and methods of study.

The greenhouse aleurodes is described in detail in all its stages and notes are given on its life history and habits. The eggs hatch within from 10 to 12 days. During the last few days of the pupal life the insect does not feed or increase in size. Experiments made by the author indicate that unfertilized eggs may hatch and develop into adult males. The adult life of the insect may extend over several weeks. Notes are given on the origin, distribution, food plants, and economic importance of this species. Before starting crops in greenhouses in the fall it is recommended that all weeds and other vegetation should be removed from the house.

Experiments were made with a large number of insecticides in combating this insect. Contact insecticides were found to be destructive to larvæ and young pupæ, less so to mature insects, and quite harmless to eggs. Lemon-oil insecticide was easy to prepare, but was too expensive; laundry soap was found to be cheap and fairly effective; Stott's fir-tree-oil soap was altogether too expensive for use; kerosene emulsion proved to be cheap and effective, while Permol kerosene soap was too expensive; Bowker's tree soap was found to be cheap and the most effective of all the contact insecticides; whale-oil soap was almost equally effective.

A number of materials were used for fumigation, including Nicoticide, Bush's Best Brand Fumigating Compound, Thripscide, carbon bisulphid, and hydrocyanic-acid gas. The last named substance proved to be cheapest and the most effective of all materials used in fumigation. Carbon bisulphid required long exposure in order to secure good results and is considered too expensive. While fumigation with hydrocyanic-acid gas is recommended as the most effective insecticide treatment, this may be combined with syringing with contact insecticides.

The strawberry aleurodes was long considered identical with the greenhouse aleurodes. This species is described in its various stages, and notes are given on its life

history and economic importance. The insect does the greatest injury to strawberries in late summer and early fall and has been reported from New York State. Infested strawberry plants should not be introduced into uninfested regions and plants for propagation should be grown in nurseries isolated from the fruiting beds. Old infested fields should be plowed under as soon as the fruit is harvested. When the insect becomes so abundant in fields as to require treatment spraying with kerosene emulsion or whale-oil soap will give good results.

Beneficial parasites, W. B. WALL (*Jour. Dept. Agr. West Australia, 7 (1903), No. 1, pp. 45, 46*).—Short notes on the beneficial effects of ladybirds and other predacious parasitic insects which have been reared and distributed for the purpose of assisting in the control of injurious insects.

The Phasmidæ, or walkingsticks, of the United States, A. N. CAUDELL (*Proc. U. S. Nat. Mus., 26 (1903), pp. 863–885, pls. 4*).—Notes are given on the anatomy of this family of insects and an analytical table is presented to assist in the identification of species belonging to the family. A brief account is presented of the habits and life history of the various species.

Contribution to a knowledge of the Coleopterous fauna of the Lower Rio Grande Valley in Texas and Tamaulipas, C. H. T. TOWNSEND (*Trans. Texas Acad. Sci., 5 (1902), pp. 51–101*).—Notes on the habits, life history, and geographical distribution of a number of beetles which occur in this region, 552 species being listed in the article.

Contribution to a monograph of the insects of the order Thysanoptera inhabiting North America, W. E. HINDS (*Proc. U. S. Nat. Mus., 26 (1903), pp. 79–242, pls. 11*).—The author's investigations on the classification, biology, and means of combating injurious members of this order of insects are systematized in this paper in a monographic form. Notes are given on the history of investigations relating to this order; systematic position of the order; methods of collecting, preserving, and mounting; external anatomy; development; and on beneficial and injurious species. Various species of thrips are found on flowering plants, grasses, and other cultivated plants.

These pests are subject to the attacks of a number of parasites, both of an insect and fungus nature, and to the injurious effects of unfavorable climatic conditions. They may be combated directly by means of whale-oil soap or other contact insecticides and by cultural methods. A bibliography of 480 titles relating to this order of insects is appended to the article.

Grasshopper destruction and white ants, H. TRYON (*Queensland Agr. Jour., 13 (1903), No. 3, pp. 282–285*).—Notes on the prevalence, life history, and means of combating grasshoppers and white ants. The methods recommended for grasshoppers include various mechanical devices, the use of poison baits, and spraying with arsenical preparations and contact insecticides. Where the white ant colonies are accessible it is possible to dig them up and destroy the ants, or to apply water or contact insecticides.

The destruction of white ants, A. LOIR (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 21, pp. 1290, 1291*).—Various remedies were tested in the destruction of these insects. The best results were obtained from the use of sulphur fumes, which were drawn through the galleries of the white ants by suction, after introducing a tube into either end of the gallery.

The white ant city, W. W. FROGGATT (*Agr. Gaz. New South Wales, 14 (1903), No. 8, pp. 726–730, pl. 1, figs. 7*).—A popular account of the habits and life history of *Termes lacteus*.

Flies, E. L. MOORE (*South Dakota Sta. Bul. 81, pp. 41, 42*).—A mixture containing fish oil, oil of tar, and crude carbolic acid is recommended for ridding animals of flies. This mixture was prepared at a cost of about 35 cts. per gallon and was applied by means of a hand spray pump. One application was found to be effective for 2 days. The milk was not tainted by the odors of the insecticide.

The structure and biology of Anopheles, G. H. F. NUTTALL and A. E. SHIPLEY (*Jour. Hyg. [Cambridge], 3 (1903), No. 2, pp. 166-215, pls. 4*).—Notes are given on the gross and microscopic anatomy of the digestive organs of Anopheles and experiments were made in testing the action of the salivary secretion of *Culex pipiens*. A bibliography relating to mosquitoes is appended to the article.

Mosquitoes and malaria, W. E. BRITTON (*Connecticut State Bd. Agr. Rpt. 1902, pp. 245-252*).—Brief notes on the habits and life history of mosquitoes with special reference to their agency in spreading malaria and means of combating them.

Mosquitoes and suggestions for their extermination, W. L. UNDERWOOD (*Pop. Sci. Mo., 63 (1903), No. 5, pp. 453-466, figs. 15*).—The author presents a popular account of the chief features in the life history of mosquitoes of various genera, including Culex, Anopheles, Eucorethra, etc. *E. underwoodi* is described in its various stages and notes are given on its larval habits and life history. As a larva it feeds upon the larvæ of other mosquitoes and it is believed to be an important natural help in checking the multiplication of these pests.

Cheese mites, H. TRYON (*Queensland Agr. Jour., 13 (1903), No. 1, pp. 56-58, figs. 3*).—Notes are given on the possible connection between this mite and a skin disease common with persons who handle cheese. The mite is described in its various stages and notes are given on means of combating it. The fumes of sulphur, bisulphid of carbon, and hydrocyanic-acid gas are all effective in destroying this species. Care must be exercised, however, in the use of bisulphid of carbon since otherwise the cheese may become tainted by absorbing this chemical.

Fumigation dosage, C. W. WOODWORTH (*California Sta. Bul. 152, pp. 17, figs. 6*).—The purpose of the studies reported in this bulletin was to determine the reliability of estimates of space in tents as made by the practical fumigators of the State. During this investigation 2,314 trees were measured, representing the estimates of 30 fumigators. The results of this study indicate that "the judgment of all fumigators is thoroughly unreliable." The estimates vary greatly in one direction or the other, the fairly good result obtained by different fumigators showing conclusively that the process of fumigation allows a wide margin of variation in the quantity of gas employed.

The author recommends a simple apparatus for measuring the volume of tents before the chemicals are placed in operation. It was found that the leakage of gas was greatest during moist days or when the tent was wet, and that this leakage was of such importance that allowance should be made for it in estimating the quantity of chemicals.

Arsenical insecticides, G. E. COLBY (*California Sta. Bul. 151, pp. 38, figs. 10*).—The author estimates that about 25 tons of Paris green are used annually in combating insects on the Pacific Coast. Tables are given showing analyses of Paris green made before and after the passage of the California law governing the sale of this chemical. Of the samples examined before the passage of the law only 20 per cent was satisfactory in composition; while in the second group 46 were satisfactory and 45 objectionable. In the examination of Paris green it is stated that any great variation in color, especially a pale shade, is an indication of adulteration, and the same may be said for any tendency to caking. The method of microscopical examination is briefly described. The amount of soluble arsenious oxid found in 50 samples of satisfactory Paris green varied from 1.69 to 4.09 per cent, while in 54 samples of objectionable Paris green this ingredient ranged from 4.7 to 29.4 per cent. Detailed notes are given on the method of determining soluble arsenious oxid and copper oxid in Paris green.

Analyses were made of a large number of arsenicals which have been proposed as substitutes for Paris green. Paragrene was found to contain nearly ¼ of its weight of soluble arsenious oxid; Laurel green is not recommended for spraying under any conditions, since the material was found to consist chiefly of gypsum and green sand;

Calco-green proved to be unsafe on account of the large amount of soluble arsenic; Gray Arsenoid and White Arsenoid are objected to on the same basis; Green Arsenoid contains the guaranteed amount of arsenious oxid, but too much of it is soluble; no objections were made to Pink Arsenoid, which was found to be no more dangerous to foliage than Paris green. The majority of these substitutes for Paris green are thus condemned. Home-made arsenicals, however, especially arsenate of lead, arsenite of lead, and the various lime compounds of arsenic are highly recommended. Disparene proved to be equally as effective as arsenate of lead, but it was found difficult to break up the paste and mix it thoroughly with water.

A table is presented showing the relative power of different arsenicals to remain in suspension. Coarse Paris green was found to remain in suspension for the shortest period, and lead arsenite the longest. Notes are also given on the cost of preparing various forms of arsenical sprays. The author recommends the extensive use of insoluble arsenate of lead, arsenite of lead, and arsenite of calcium.

Fungicides, insecticides, and spraying calendar, R. E. Rose (*Mo. Bul. Florida Dept. Agr., 13 (1903), No. 83, pp. 39–53*).—Formulas are presented for the preparation of approved insecticides and fungicides and combinations of these. A spraying calendar is also given, showing the time of application of various remedies for the more common insect and fungus diseases of cultivated plants.

Silk culture in Manchuria, H. B. Miller (*U. S. Consular Rpts., 73 (1903), No 277, pp. 274, 275*).—The amount of silk exported from Manchuria is said to be very large, although definite data can not be obtained. The autumn cocoons are kept over winter and silkworms are hatched in April. The worms are allowed to feed on the native scrub oak which is planted on rough hilly ground. The removal of the silk from the cocoon is accomplished by hand work.

Annual report of the Beekeepers' Association of the Province of Ontario for 1902 (*Ann. Rpt. Beekeepers' Assn. Ontario, 1902, pp. 84*).—At the 23rd annual meeting of the Ontario Beekeepers' Association, held at Barrie, December 16–18, 1902, a number of papers were read, a few of which are briefly mentioned in the following notes. J. D. Evans in his presidential address called attention to the importance of the association and the benefits to be derived from a large attendance and active participation in the various discussions.

J. L. Byer read a paper on market reports, in which attention was called to the necessity of giving close heed to these reports in order to avoid unwise sales as a result of sensational accounts of variations in prices. R. F. Whitesides discussed briefly the operations which are necessary in the successful management of bees in spring.

J. Fixter reported on experiments which were undertaken to determine whether bees injure sound fruit. It was found that under ordinary circumstances they do not. Experiments with brood foundation of different sizes indicated that full sheets of foundation should be used, both in sections in the supers and in the frames of the brood chambers.

F. T. Shutt read a paper on honey from capped and uncapped comb. The author found that honey from uncapped comb shows a somewhat higher moisture content and that the keeping qualities of ripe honey are superior to the immature honey in uncapped comb.

W. McEvoy discussed a method of treating foul brood. He recommended that the combs be removed in the evening and the bees shaken into their own hives, which should be provided with frames with foundation starters. After four days these frames should be removed and the bees given a fresh set of frames with foundation. It is believed that all infection with foul brood will thus be eliminated.

Parthenogenesis in bees, E. Pflüger (*Arch. Physiol. [Pflüger], 99 (1903), No. 3–4, pp. 243, 244*).—Arguments are presented against the assumption of the possibility of parthenogenesis in bees. The author believes that the cases of apparent

parthenogenesis in bees and other insects are better explained by the assumption of hermaphroditism.

Partitions in beehives, J. Crépieux-Jamin (*Rev. Internat. Apicult., 25 (1903), No. 9, pp. 162–165*).—Notes on the importance of partitions between the frames of beehives and the relationship of these structures to the preservation of warmth in the bee colonies.

Report of the bee inspector, J. Sutton (*Jour. Dept. Agr. West Australia, 7 (1903), Nos. 1, pp. 22–25; 3, pp. 177–179*).—Brief notes on the conditions of bee raising in various parts of Western Australia, together with recommendations regarding the care and management of bees.

FOODS—NUTRITION.

The baker's book, E. Braun (*New York: D. Van Nostrand Co., 1903, vol. 2, pp. 307–671, pls. 9, figs. 212*).—As was the case with the preceding volume (E. S. R., 14, p. 1102), this second volume summarizes information of use to bakers and others interested in this trade. The material has been gathered from a variety of sources, and includes recipes and practical directions for making various sorts of bread, as well as miscellaneous articles on a variety of topics connected with bread and bread making.

The complete cookbook, Marion Harland (*Indianapolis: The Bobbs-Merrill Co., 1903, pp. XIV+780, pls. 33, figs. 16*).—In addition to a large number of recipes for various foods, beverages, etc., which it is said have been carefully tested, this volume contains discussions on marketing, carving, kitchen utensils, preparation of foods, and related topics, and furnishes a large amount of useful information.

Breakfast and savory dishes, Florence B. Jack (*London: T. C. & E. C. Jack, 1903, pp. V+142*).—Concise and clear directions are given for the preparation of a number of dishes with eggs, fish, meat, cheese, vegetables, etc.

The art of cooking for invalids, Florence B. Jack (*London: T. C. & E. C. Jack, 1903, 3. ed., pp. VIII+205*).—The author discusses the general problem of cookery for invalids, and gives a number of recipes for preparing suitable dishes, the directions in every case being very explicit. In most cases the time of preparation and the probable cost of the dish are also given.

Treatise on hygiene, P. Smolensky (*Traité d'hygiène. Paris: G. Steinheil, 1904, pp. XXXII+752, figs. 119*).—This volume, which is translated from the Russian by S. Broïdo and A. Zaguelmann, is designed as a laboratory manual for the examination of foods and for the detection of adulteration or sophistication. It treats also of the general principles of nutrition and the principal groups of foods. The extended summary of Russian investigations is an interesting feature, and the work as a whole is a valuable digest of available information on the subjects treated. The volume contains notes by L. Guiraud and A. Gautié, and an extended bibliography, and is thoroughly indexed.

A study of dietaries at Lawrence, Kansas, E. H. S. Bailey (*Trans. Kansas Acad. Sci., 18 (1902), pp. 49–53*).—Two dietary studies with students' clubs at the University of Kansas are briefly reported. During the first study, which covered 1 month, the average cost of the food was 19.5 cts. per person per day, the club including 46 members, one-third being men and two-thirds women students. The fuel value of the diet was 3,923 calories per person per day, and the nutritive ratio about 1:8.

In the second and more recent study the club comprised 22 persons and records were kept for 65 days. The author states that the average cost per person per day was 17.8 cts., the fuel value 3,437 calories, and the nutritive ratio 1:7.6. The number of men and women included in the study is not stated, but from available data it was calculated that there were 10 of the former and 12 of the latter, and that the

average amount of nutrients eaten per day was 99.79 gm. protein, 136.08 gm. fat, and 449.06 gm. carbohydrates.

In another study, regarding which no details are given, it is stated that the average cost of food per person per day was 18.8 cts.

The diet at a Vienna restaurant for young men, M. HAMBURG (*Weiner Klin. Wchnschr., 1902, No. 10, p. 259; abs. in Hyg. Rundschau, 13* (*1903*), *No. 6, pp. 320, 321*).—With the aid of a large number of analyses and other data the author calculates the nutritive value of the diet studied and suggests methods for improving it, as it is regarded as inadequate.

Changes in dietary habits, GROTJAHN (*Ueber Wandlungen in der Volksernährung. Leipzig: Duncker & Humblot, 1902, pp. 72; rev. in Hyg. Rundschau, 13* (*1903*), *No. 4, pp. 193–195*).—In this treatise, which is part 2, volume 20 of the series entitled *Staats- und socialwissenschaftliche Forschungen*, edited by G. Schmoller, the effect of occupation and environment upon diet is discussed.

The food of the Italians, H. LICHTENFELT (*Arch. Physiol.* [*Pflüger*], *99* (*1903*), *No. 1–2, pp. 1–29*).—On the basis of figures given in recent statistical publications the author calculates the nutrients and energy in the diet of Italian laborers of different regions, and discusses the results at considerable length.

Food products of the Tuhoeland, E. BEST (*Trans. and Proc. New Zealand Inst., 35* (*1902*), *pp. 45–111*).—This article contains data regarding the food supplies of the nonagricultural native tribes of New Zealand, as well as notes on native customs, superstitions, etc., pertaining to foods.

Food requirements in winter at high altitudes, RANKE (*München. Med. Wchnschr., 1902, No. 19, p. 787; abs. in Hyg. Rundschau, 13* (*1903*), *No. 11, p. 573*).—A dietary study of which the author was the subject showed that at a high mountain altitude while becoming acclimated he required the same amount of fat and larger quantities of protein and carbohydrates than under usual conditions at a lower elevation.

Subsistence stores, Division of the Philippines, W. L. ALEXANDER (*Com. Gen. Subsist.* [*U. S. Army*] *Rpt. 1903, pp. 21–30*).—The sources of the food supply of the United States troops in the Philippines, the providing of fresh meat, vegetables, and ice, and related topics are discussed in this report.

The chemical composition of human foods graphically shown, C. JÜRGENSEN (*Procentische chemische Zusammensetzung der Nahrungsmittel des Menschen, graphisch dargestellt. Berlin: August Hirschwald, 1903, 2. ed. pp. 23, chart 1*).— A second edition of this work, which contains descriptive text and a colored chart showing the composition of a number of food materials.

Report of State chemist, J. HORTVET (*Minnesota State Dairy and Food Comr. Rpt. 1903, pp. 254–393, figs. 16*).—In compliance with the State law 10,119 samples of foods, condiments, etc., were examined. Of these 3,449 were adulterated or in some way failed to comply with the legal requirements. The report also contains accounts of the cases prosecuted under the State law and data regarding other work carried on during the year.

A plea for the proper medical supervision of "refreshments" purveyed on railways in the Tropics, H. D. McCULLOCH (*British Med. Jour., 1903, No. 2230, pp. 709–711, dgm. 1*).—This article contains considerable data regarding the foods and beverages sold to the traveling public in the Tropics, and points out the need of proper inspection and control.

Bleached wheat compared with unbleached wheat for flour, F. W. GUTHRIE (*Jour. Agr. and Ind. South Australia, 6* (*1903*), *No. 12, p. 759*).—Data are given regarding the yield of flour and other milling products from bleached and unbleached wheat. "The only respects in which the bleached grain is inferior to the unbleached are the weight per bushel and the amount of flour obtainable. The flour itself is very similar in all respects."

The existence of arsenic in hens' eggs, G. BERTRAND (*Ann. Inst. Pasteur, 17 (1903), No. 7, pp. 516–520*).—Minute traces of arsenic were found in the eggs of fowls, geese, and ducks, and the conclusion is drawn that arsenic is contained in appreciable quantity in eggs, the amount varying in the different parts of the egg. On an average the whole egg contained 0.005 mg., two-thirds of which was in the yolk. A goose egg weighing 150 gm. contained about the same quantity as a hen's egg, while a duck's egg weighing 75 gm. contain only 0.002 mg. The author believes that these experiments are of importance in relation to the question of the rôle of arsenic in all living cells.

Examination and valuation of food products containing egg yolk, especially egg noodles and egg cognac, A. JUCKENACK (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 18, pp. 827–834*).—The examination of these goods is discussed with special reference to a standard of valuation, the detection of artificial coloring, and related topics.

The normal occurrence of salicylic acid in vegetable food products and the consequent errors which may attend legal analyses, A. DESMOULIÈRE (*Thesis, Paris, 1902; abs. in Bul. Sci. Pharmacol., 4 (1902), pp. 204, 205; Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 16, p. 760*).—In wine 0.08 to 1 mg. of salicylic acid was found per liter, and about 1 mg. per kg. in strawberry and raspberry marmalade, these quantities representing salicylic acid occurring naturally. The method of analyses is described.

Examination of different sorts of cucumbers at various stages of development and of sour pickles made from them, B. HEINZE (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), Nos. 12, pp, 529–544; 13, pp. 577–588*).—The author made an extended study of the chemical composition of different sorts of cucumbers, fresh and pickled, and of the changes due to pickling. The process of pickling followed was similar to that used in making sauerkraut; that is, the cucumbers were allowed to ferment with or without the addition of salt.

On an average the small cucumbers weighed 80 to 90 gm., those of medium size 170 to 190 gm., and the ripe cucumbers 857 to 897 gm. As shown by the average values for a number of different varieties, small, medium, and ripe cucumbers had the following percentage composition:

Average composition of cucumbers.

Cucumbers.	Water.	Protein.	Fat.	Sugar.		Nitrogen-free extract.[a]	Crude fiber.	Ash.
				Grape sugar.	Sucrose.

[a] Aside from the sugar.

Analyses of the pickled cucumbers showed that they contained much less protein and crude fiber than when fresh, the ash being about the same after deducting the added salt. All the grape sugar was rapidly converted into acid, while the cane sugar underwent such change more slowly. Successful fermentation in this method of pickle making, according to the author, depends upon a proper diffusion of sugar in the cucumber juice, the presence of sufficient sugar to form over 0.5 per cent acid, and active lactic-acid-forming bacteria. The micro-organisms present in the fermenting cucumbers were studied in some detail. The article also contains a general discussion and a summary of the literature of the subject.

Some of the constituents of cocoa and their estimation, J. DECKER (*Ueber einige Bestandteile des Kakaos und ihre Bestimmung. Amsterdam: D. J. H. de Bussy, 1902; rev. in Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 18, pp. 842–844*).—A study of different solvents for theobromin in cocoa shells led to the conclusion that water, ethyl alcohol, and amyl alcohol were most satisfactory, water being preferred for practical reasons. As a means of detecting the presence of shells in powdered cocoa, the author made use of the pentosan content. This ranges, according to his analyses, from 2.17 to 2.41 per cent in the cocoa kernels, and from 8.18 to 9.63 per cent in the shells. Studies were also made of the amount of caffein and theobromin in the leaves of *Theobroma cacao* and *Sterculia cola*, and also of the xanthin derivatives in cocoa shells.

Nitrogenous materials in food substances, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 6 (1903), No. 30, pp. 106, 107*).—The nitrogenous constituents of different seeds are discussed.

The nutritive value of albumins and their derivatives, PLUMIER (*Bul. Acad. Roy. Belg., Cl. Sci., 1902, No. 11, pp. 650–653*).—When dogs were given albumoses and peptones only weight could be maintained, and gains in weight could not be made even if the amount consumed was very large. The products obtained from the complete artificial pancreatic digestion of albuminous bodies were found to be incapable of replacing the albumin in the diet, and the animal perished more quickly when given such materials than when given water only.

The digestibility of the albuminous constituents of human milk and that of various substitutes for it, F. W. TUNNICLIFFE (*Jour. Hyg. [Cambridge], 2 (1902), No. 4, pp. 445–451; abs. in Hyg. Rundschau, 13 (1903), No. 10, p. 525*).—On the basis of analyses and artificial digestion experiments the food value for infants of mothers' milk, cows' milk, and several sorts of modified milk is discussed.

The nature of fibrin ferments, C. A. PEKELHARING and W. HUISKAMP (*Ztschr. Physiol. Chem., 39 (1903), No. 1, pp. 22–30*).—Experimental studies of fibrin ferments are reported.

The preservation of chopped meat with neutral sodium sulphite, E. ALTSCHÜLER (*Arch. Hyg., 48 (1903), No. 22, pp. 114–139*).—A number of experiments, which are reported in detail, led to the conclusion that sodium sulphite acts as a preservative of chopped meat to a certain extent, but that its use is not desirable, since it conceals the true condition of the meat after a time by preventing fermentation yielding bodies of offensive odor, while other sorts of decomposition are not prevented.

The growth and activity of bacteria, and the fermentative processes which take place at low temperature with special reference to flesh foods, M. MÜLLER (*Arch. Hyg., 47 (1903), No. 2, pp. 127–193, figs. 2*).—The micro-organisms and ferments which affect frozen or refrigerated meat or fish were studied experimentally, and the results obtained are discussed at length with special reference to the satisfactory preservation of flesh foods. According to the author, when meat is kept at 0° C. the activity of micro-organisms is checked, but the action of ferments present in the meat still continues and it ripens, though it does not decay. While such meat is especially suited for roasting or broiling, it is not as good as fresh meat for boiling, as the broth has a peculiar flavor.

Fish can not be satisfactorily preserved, it is stated, unless it is actually frozen, since a temperature of 0° C. is not sufficient to hinder the action of the unorganized ferments, although it inhibits micro-organisms. The unorganized ferments produce bodies which are of unpleasant flavor and the fish becomes unpalatable, though it is not decayed. A bibliography is appended to the report.

The nutritive value of sugar for man and animals, L. GRANDEAU (*Ann. Sci. Agron., 2. ser., (1903), 1, No. 1, pp. 1–141*).—From an extended review of the literature of the subject and the experiments which have been reported from time to time, the conclusion is drawn that sugar is a nutrient of great value for man and animals,

especially as a source of energy, and the importance to the sugar industry of encouraging its use is pointed out.

The nutritive value of filled cheese, G. CORNALBA (*Ann. R. Staz. Sper. Caseif. Lodi, 1902, pp. 73–86*).—The nutritive value of filled cheese is discussed on the basis of analyses and artificial digestion experiments.

The capacity of man to perform physical work, M. BLIX (*Skand. Arch. Physiol., 15 (1903), No. 1–2, pp. 122–146, figs. 4*).—A number of experiments are reported. In some of these work was performed with an ergometer of special construction, in others the subjects climbed stairs.

The effect of certain coal-tar colors upon digestion, A. J. WINOGRADOW (*Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 13, pp. 589–592*).—Even when the amount present was only a few milligrams the following colors markedly diminished or entirely hindered the digestion of protein, according to artificial digestion experiments: Safranin, ponceau *rr*, azofuchsin *g*, orange II, coerulein *s*, phloxin *r. b. n.*, iodeosin, chrysanilin, magdala red, azoflavin, benzopurpurin, and cerise. The following colors were less marked in their action, but could not be called indifferent: Chinolin yellow, methyl green, acid green, iodin green, azoacid yellow *c*, yellow *t*, napthol yellow, anilin green, primulin, auramin *o*, anilin orange, martius yellow, and metanil yellow.

The chemico-physical constitution of mineral waters, W. MEYERHOFFER (*Die chemisch-physikalische Beschaffenheit der Heilquellen. Hamburg and Leipzig: Leopold Voss, 1902, pp. 32, map. 1; rev. in British Med. Jour., 1903, No. 2230, p. 752*).—Among other topics this volume includes matter which has a bearing upon the condition in which mineral matter is assimilated.

The influence of condiments upon the secretion and muscular activity of the stomach, L. R. VON KORCZYNSKI (*Wiener Klin. Wchnschr., 1902, No. 18, p. 468; abs. in Hyg. Rundschau, 13 (1903), No. 6, p. 323*).—Tests in which the stomach contents were removed and examined show that with healthy subjects the condiments studied, namely, paprika, mustard, ginger, pepper, horse-radish, and onions, at first increased and then for a considerable time diminished the stomach secretions, this depression being frequently followed by a second period of stimulation. The muscular activity of the stomach was increased by condiments. Tests were also made with subjects not in normal health.

Standards for flavoring extracts, W. L. SCOVILLE (*Amer. Jour. Pharm., 75 (1903), No. 4, pp. 151–155.*)—According to the author, the only standard that can be legally applied to flavoring extracts is that of wholesomeness, since the delicacy, correctness of flavor, and other qualifications must be determined by individual preference.

Blueberry wine, a natural iron manganese preparation, E. OSTERMAYER (*Pharm. Ztg., 47 (1902), p. 316; abs. in Hyg. Rundschau, 13 (1903), No. 4, p. 201*).—Blueberry wine is stated to contain much larger amounts of manganese and less phosphoric acid than grape wine. Analyses are reported of 2 commercial blueberry wines.

Water cress and typhoid (*British Food Jour., 5 (1903), No. 49, pp. 7, 8.*)—The possible dangers from water cress grown in polluted streams are pointed out.

International catalogue of scientific literature. Q—Physiology (*Internat. Cat. Sci. Lit., 3 (1903), pt. 2, pp. XII + 664*).—This volume of the international catalogue issued by the Royal Society of London contains titles on physiology, including experimental psychology, pharmacology, and experimental pathology. In the case of the various topics connected with the nutrition of man and animals only a very little of the important work published is referred to, although the few articles cited show that an attempt was made to cover these subjects. For instance, out of over 60 feeding experiments with farm animals reported during the period covered by the catalogue less than a dozen are noted.

ANIMAL PRODUCTION.

The isodynamic replacement of nutrients, H. P. ARMSBY (*Science, n. ser., 18 (1903), No. 459, pp. 481–487*).—On the basis of results obtained in experiments with a steer, made with the aid of a respiration calorimeter, the author discusses the replacing value of nutrients and related topics. Since different materials require varying amounts of energy for their assimilation, the fact is pointed out that they are not replaceable in a ration in direct proportion to their theoretical heat value.

The author notes that the error involved in considering food as the fuel of the vital furnace is based on the assumption that "the production of heat in the body is an end in itself. The truth appears to be that it is, in a physiological sense, an incident. The energy of the food is needed for the performance of the vital processes. During these processes it undergoes various transformations, but finally the larger part, or in the resting animal, all is degraded into heat, which incidentally serves to maintain the temperature of the body, and, as it would seem, is amply sufficient for this purpose under a wide range of conditions."

Laboratory manual of animal physiology, E. H. STEIN (*Tierphysiologisches Praktikum. Stuttgart: Ferdinand Enke, 1903, pp. VIII + 144, figs. 20*).—This volume is designed as a laboratory manual for veterinarians and agriculturists, and contains chapters on general methods, nutrients, foods and feeding stuffs, digestion, blood, urine, milk, and butter.

The influence of the retention of bile on gastric digestion, F. D'ANGELO (*Rend. e Mem. R. Accad. Sci., Let. ed. Art. Zelanti Acireale, 3. ser., 1 (1901–2), pp. 24*).—Results of experiments with dogs are reported.

The average composition of the animal body, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 5 (1903), No. 18, pp. 561, 562*).—A brief summary and discussion of analytical data.

The principal constituents of the animal body, water and mineral matters, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 5 (1903), No. 21, pp. 657, 658*).—A summary and discussion.

The iron content of the animal body, M. SCHMEY (*Ztschr. Physiol. Chem., 39 (1903), No. 3–4, pp. 215–282*).—The results of a large number of analyses of different sorts are reported of the flesh of normal animals and those fed iron preparations. The conclusion is drawn that the red color of the muscles of rabbits, chickens, and swine is not determined by the iron content. Feeding iron preparations increased the amount of iron in the body. Data are also given regarding the analyses of the eggs of hens fed on iron preparations.

Stable hygiene, E. A. A. GRANGE (*Breeders' Gaz., 43 (1903), No. 24, pp. 1173, 1174, fig. 1*).—A brief account of the successful use of a ration of 3 qts. of molasses mixed with 6 lbs. of finely chopped hay, fed 3 times a day, for bringing a horse into good condition. At the end of 2 months the horse weighed 1,000 lbs., having made a gain of 90 lbs.

New molasses products in the feeding of farm animals, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 5 (1903), No. 19, pp. 592, 593*).—One of the newer molasses feeds is described.

Sugar, molasses, and molasses products in the feeding of animals, H. VAN DE VENNE (*Brussels: Lamertin; rev. in Ing. Agr. Gembloux, 13 (1903), No. 12, p. 572*).—A summary of available data on the subject.

Sugar cane (*Agr. Jour. and Min. Rec., 6 (1903), No. 15, p. 539*).—The value of sugar cane as a fodder, especially for horses, is pointed out.

Corn silk as a feed stuff, F. D. TAYLOR (*Breeders' Gaz., 44 (1903), No. 15, p. 569*).—Analyses made at the chemical laboratory of the University of Wisconsin of a number of samples of corn silk are reported, in several of which only the protein and water were determined. The average percentage composition was as follows: Water 13.56, protein 18.28, fat 0.95, nitrogen-free extract 46.92, crude fiber 16.6, and

ash 5.06. Corn silk constitutes the principal constituent of screenings from corn elevators, which the author has noted are readily eaten by cows.

Commercial feeding stuffs, J. L. HILLS, C. H. JONES, and F. M. HOLLISTER (*Vermont Sta. Bul. 101, pp. 27–32*).—Data are briefly reported regarding the analyses, made in compliance with the State feeding stuff law, of a number of samples of cotton-seed meal and feed, linseed meal, gluten meals and feeds, distillers' grains (dried), and similar products, wheat offals, poultry feed, calf meal, mixed commercial feeds, and provenders.

The Argentine live stock show, 1902 (*An. Soc. Rural Argentina, 1902, Spec. No., pp. 122, pls. 10, figs. 50, dgm. 1*).—In this bulletin, which is edited by A. Bengolea, the exhibits of the Argentine live stock show held in September, 1902, are described, and much information given regarding the character of horses, sheep, and cattle raised in that country, the present condition and possibilities of the live stock, dairy, and leather industries, etc. An English translation of this publication has been issued by the society under the title of The Argentine Estancia.

The animal industry of Argentina, F. W. BICKNELL (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 48, pp. 72, pls. 16*).—With the object of showing the possibilities of Argentina as a market for pure-bred American live stock, the author discusses the opportunities for stock raising in Argentina, the kind of animals raised, and the general business conditions as relating to animal production, and gives data regarding exports and imports, prices obtained for live stock, and related subjects.

Experiments in cattle feeding, J. N. PRICE (*Rpt. Missouri State Bd. Agr., 35 (1902), pp. 261–267*).—Summarizing data obtained in experiments at the Missouri Station, the relative merits of different methods of cattle feeding are discussed. Information was secured from a large number of cattle feeders in Missouri, Iowa, and Illinois regarding the gains made on full feed in winter and summer. On an average the winter gain reported was 2.2 lbs. per steer per day as compared with 2.85 lbs. in summer.

Fattening steers; using cotton seed, cotton-seed meal, wheat meal, wheat straw, and hay (*Oklahoma Sta. Bul. 58, pp. 47*).—*Conditions and results, F. C. Burtis* (pp. 1–38, 42–45).—Methods of feeding cotton-seed mixtures and the length of time they should be fed were studied with 5 lots of 5 steers each, the test covering 105 days in the winter. The lots were all fed in yards with sheds open to the south, and in every case the rations selected were made up in such a way that at a minimum cost they supplied as nearly as possible the nutrients called for by the feeding standards.

Lot 1, on cotton seed and cotton-seed meal, 4 : 1, with wheat straw and prairie hay, gained on an average 1.77 lbs. per head per day, the cost of a pound of gain being 8.8 cts. On wheat meal and cotton-seed meal in about the proportion of 3 : 1, fed with the same coarse fodder as above, lot 2 made an average daily gain per head of 2.62 lbs., the cost of a pound of gain being 8.5 cts. Lot 3 on cotton seed and wheat meal in about the proportion of 2 : 1, with the same coarse fodder, gained 2.07 lbs. per steer per day at a cost of 8.1 cts. When cotton-seed meal and wheat straw 1 : 2 were fed, as in the case of lot 4, one-half the straw being cut and mixed with the meal, the average daily gain was 1.76 lbs. per head and the cost of a pound of gain 9.3 cts. In the case of lot 5, cotton seed was fed with practically an equal amount of coarse fodder (wheat straw and prairie hay), the average daily gain being 1.25 lbs. per head and the cost of a pound of gain 10.5 cts.

The grained consumed per pound of gain ranged from 5.75 lbs. in the case of lot 2 (fed the wheat meal and cotton-seed meal) to 7.32 lbs. in the case of lot 1 (cotton seed and cotton-seed meal). The amount of coarse fodder eaten per pound of gain ranged from 3.82 lbs. with lot 3 (cotton seed and wheat meal) to 10.67 lbs. with lot 5 (cotton seed with wheat straw and prairie hay).

The steers were sold and slaughtered, the net returns per lot ranging from $24.25 with lot 5 to $47.57 with lot 3. The dressed weight ranged from 53.2 per cent with lot 1

(cotton seed and cotton-seed meal) to 57.6 per cent with lot 2 (wheat meal and cotton-seed meal).

There was considerable difference in the lots and none of them was regarded as fully finished, although lots 2 and 3 were considered fairly well fattened. Feeding cotton seed often has an unfavorable effect on the appearance of the flesh, producing a dirty yellow fat, but nothing objectionable was noted as regards the color of the dressed carcass of any of the lots. Throughout the test no serious illness was noted.

Two pigs followed each lot of steers and were fed some wheat meal in addition. The daily gain per pig averaged from 0.71 lb. in the case of those following lot 2 (wheat meal and cotton-seed meal) to 0.95 lb. in the case of those following lot 5 (cotton seed, wheat straw, and prairie hay), and the grain eaten per pound of gain ranged from 3.10 lbs. with the latter lot to 4.13 lbs. with the former. The gains were regarded as very good and as adding much to the net profits. "The fact should be noted that all the pigs lived, and part of them were behind steers that were fed cotton-seed meal as grain."

On the basis of the test, "it is suggested where cotton seed is to be used in the ration of cattle that not more than 8 lbs. of it be fed per day as a maximum amount, and generally 4 to 6 lbs. will prove more satisfactory. In order to use it in the ration of the fattening steer it must be fed with other highly nutritious feeds, and preferably those belonging to the nitrogenous group, as alfalfa or cowpeas. . . .

"While many steers are fattened in the South on cotton-seed meal and cotton-seed hulls, there is no doubt but what, as a rule, much better gains would be procured and at a less cost if some grain as corn, wheat, or Kafir corn were mixed with the cotton-seed meal and hulls, and it is a question if a little of some other roughage besides the hulls should not be used for the best and most economical results."

It is stated that cotton seed and cotton-seed meal are regular constituents of the grain ration of the college and station herd, the rations being so planned that a mature cow will receive not over 2 or 3 lbs. of cotton-seed meal or 3 or 4 lbs. of cotton seed per day, corn or Kafir corn being always mixed with these feeds.

Chemical study of the experiment, *J. Fields* (pp. 39–41, 46).—Analyses are reported of the feeding stuffs used in the above tests.

Experiments on the utilization of skim milk for feeding calves, C. BESANA (*Ann. R. Staz. Sper. Caseif. Lodi, 1902, pp. 17–67, figs. 2*).—The value of skim milk as a feed for calves is discussed, as well as methods of feeding it, and related topics, and a number of experiments are reported in which this material alone or supplemented by starch, oleomargarine, or bone meal was fed to calves.

In the first test, 4 calves gained from 0.475 to 1 kg. per day on skim milk and starch, consuming from 6.77 to 22.36 liters of milk per kilogram of gain. In a second test the average daily gain of 2 calves on skim milk and starch was 0.955 kg. per head and the average consumption of skim milk per kilogram of gain was 12.42 liters, as compared with 0.850 kg. and 12.49 liters on skim milk and oleomargarine. When ground bone and oleomargarine were compared, each being fed to 2 calves, it was found that the average daily gain on the ground bone fed with skim milk was 0.709 kg. per head per day, and on the oleomargarine 0.916 kg., 15.59 liters of skim milk being required per kilogram of gain on the ground-bone ration and 11.82 liters on the oleomargarine ration.

In a 5 weeks' test it was found that 3 calves gained on an average 1.037 kg. per head per day on skim milk and oleomargarine, consuming 12.11 liters of milk per kilogram of gain.

Horse raising, C. BAUVERD (*Jour. Soc. Agr. Suisse Romande, 43 (1902), No. 12 pp. 276–282; 44 (1903), No. 1, pp. 4–11*).—Horse breeding is discussed with special reference to local possibilities and requirements.

The improvement of horse breeding in Jamaica (*Bul. Dept. Agr. Jamaica, 1 (1903), No. 9–10, pp. 193–240*).—Opinions regarding horse and mule breeding in Jamaica were gathered from a number of sources and summarized.

Poultry experiments in 1902, G. M. GOWELL (*Maine Sta. Bul. 93, pp. 69–92, figs. 12*).—The selected breeding tests at the station for egg production have been continued (E. S. R., 13, p. 982). During the 4 years covered by the work more than 1,000 hens have been tested for over 1 year each. Among them 35 were found with an egg record of 200 to 251 per year. Several have produced only 36 to 60 per year, and some others have never laid at all.

As regards the records of pullets in 1901–2, it was found that 55 Barred Plymouth Rocks laid 7,972 eggs during the year, 7 of the individual egg records being from 201 to 240. Forty White Wyandotte pullets in 10 months laid 4,607 eggs. Their average egg record, making allowance for some birds stolen, was 118, and none of these pullets reached the 200 mark. Three of the Plymouth Rock pullets and 6 of the White Wyandottes died during the year. The tests will be continued, using the best stock.

The author notes that many poultrymen believe that if a hen lays only a few eggs the first year, the egg yield will on this account be better during the second year. The data secured does not show that hens producing 120 eggs or less the first year were characterized by a satisfactory egg production the second year. Those which had produced in the neighborhood of 100 eggs the first year produced only a very few the second.

The effect of varying amounts of floor space and other conditions of housing on egg production was also studied. Ninety Barred Plymouth Rocks, kept in one-half of a poultry house and occupying a space 12 by 38 ft., averaged 103 eggs per hen in 11 months. Sixty similar birds, kept in the other half of the house, averaged 109 eggs in the same period. "Where the larger number of birds were together they did not appear to suffer from confinement during winter, as only one bird was lost from November 1 to May 1."

"It is doubtful if there are other lines of investigation where results are likely to be of greater value to practical poultrymen than the study of sizes of flocks and floor spaces for birds. If floor space can be as economically used by leaving it in one large room as by dividing it into several small ones, even though the number of surface feet remains the same per bird, the labor of feeding, cleaning, and egg collecting will be less in the undivided house. Again, the larger room offers greater field for the range of each bird, even though it be more densely populated per surface foot than does the smaller one."

The poultry house in which these lots were kept was closed at night with frames covered with oiled cotton. It was quite cold at night, and the hens did not lay much until March.

In a second test the poultry house was smaller, but was so constructed that it offered much better protection from cold. Fifty birds occupying a floor space of 250 ft. averaged 144.4 eggs each in 10 months. They began to lay in November. The curtained-front house with closet roosting room is inexpensive to construct and is regarded as satisfactory, although it is imperative that the roost room be as near air-tight as practicable when the curtain is down, so that the hens may be warm at night.

During the year a large number of incubator tests were carried out with eggs whose source was definitely known. The data accumulated showed plainly a great variability in the fertility of the total egg yield of different hens, some producing eggs that were all highly fertile and others eggs that were completely infertile. Furthermore, the eggs of some individuals varied greatly in this respect at different times. The observed facts did not indicate that a heavy egg yield was a hindrance to fertility, if the hens were allowed to rest before they began to lay again. "Although in a general way we may regard infertility as likely to result after hens have been laying long and heavily, it is by no means true that it is always so."

Farm poultry, with the results of some experiments in fattening chickens, W. R. GRAHAM (*Ontario Agr. Col. and Expt. Farm Bul. 127, pp. 40, figs. 27*).—A general discussion of feeding, care, management, marketing of poultry, and related topics.

together with some of the results of experiments which have appeared in Canadian station publications.

Artificial incubation and brooding, E. C. HUFFAKER (*Ithaca: Cornell Incubator Mfg. Co., 1903, pp. 48, figs. 25*).—Problems connected with artificial incubation of eggs and related topics are discussed. The pamphlet also includes articles giving directions for operating incubators and brooders by H. H. Blackman and by E. F. Hodgson.

Artificial incubation of chickens, O. M. WATSON (*South Carolina Sta. Bul. 81, pp. 10*).—General directions are given for the management of incubators and the rearing of artificially hatched chickens.

The care of poultry (*La cria de aves. Buenos Ayres: Alejandro Reinhold, 1903, pp. 64, figs. 30*).—A number of general articles on poultry rearing and management, incubators, and related topics are included in this pamphlet.

Methods of caring for and fattening turkeys, W. E. WRIGHT (*Ontario Dept. Agr., Rpts. Live Stock Assocs. 1902, pp. 107, 108*).—On the basis of personal experience directions are given for hatching and feeding turkeys.

Eggs fresh the year round (*Iowa Agr., 3 (1903), No. 6, pp. 166, 167*).—Directions are given for making a modified limewater pickle for use in preserving eggs, which is said to have given satisfactory results.

DAIRY FARMING—DAIRYING.

Feeding dairy cows, J. W. WILSON and H. G. SKINNER (*South Dakota Sta. Bul. 81, pp. 27–40*).—Several feeding stuffs were compared in experiments with grade and pure-bred cows. In the first test 15 cows were divided into 3 lots as nearly uniform as possible, and fed the same kind of grain ration for a period of 27 days. The roughage for lot 1 was corn silage, for lot 2 *Bromus inermis* hay, and for lot 3 alfalfa hay. The data are tabulated and notes are given on the individuality of the cows. During the test lot 1 consumed 1,575 lbs. of silage and 335 lbs. of grain, and produced 25.28 lbs. of butter fat at an average cost of 14.45 cts. per pound; lot 2 consumed 576 lbs. of brome grass hay and 340 lbs. of grain, and produced 24.58 lbs. of butter fat at 14.72 cts. per pound; and lot 3 consumed 389 lbs. of alfalfa hay and 336 lbs. of grain, and produced 19.53 lbs. of butter fat at a cost of 16.35 cts. per pound.

In 2 subsequent periods of 21 days each, spelt, barley, and corn were compared with the same lots, one cow in each, however, being replaced by a fresh one. The roughage was uniform in character during the test. The grain required for the production of 1 lb. of butter fat was, on an average, as follows: Spelt 17.5, corn 15.5, and barley 15.5 lbs. The cows gained in weight when fed spelt or barley and lost when fed corn. Fresh cows produced butter fat with less grain than cows in advanced lactation. The beef-bred cows required one-third more grain to produce a pound of butter fat than the dairy-bred cows.

Economies in dairy farming, E. MATHEWS (*London: Country Life, 1903, pp. XI+68, pls. 39*).—This book is based in part upon tests of over 1,500 cows made during a period of about 10 years, and contains many suggestions relating to the economical production of milk and butter. Some of the subjects discussed are the composition of milk, characteristics of dairy cattle, feeding dairy stock, economical disposal of milk, and hints on butter making. Under characteristics of dairy cattle, the effect of breeding and selection is illustrated by the early history of the Shorthorn and Jersey breeds, and considerable space is devoted to a discussion of the escutcheon. Methods of keeping farm accounts are also described and illustrated.

Elementary treatise on milk and milk hygiene, C. O. JENSEN (*Grundriss der Milchkunde und Milchhygiene. Stuttgart: Ferdinand Enke, 1903, pp. VII+228, figs. 22*).—This is essentially a series of lectures delivered before the Royal Veterinary and Agricultural High School in Copenhagen, parts relating especially to conditions in Den-

mark being omitted. The author discusses milk and its composition, injurious properties which milk may possess, pasteurization and sterilization of milk, preparation of milk for infant feeding, and the public control of the production and handling of milk. A Danish edition of this work is also announced.

Milk from the standpoint of economics and public health (*Die Milch und ihre Bedeutung für Volkswirtschaft und Volksgesundheit. Hamburg: C. Boysen, 1903, pp. 5??*).—This book, which was prepared under the direction of the scientific division of the Public Exhibition for Hygienic Milk Supply at Hamburg, 1903, consists of 19 articles treating in a somewhat popular manner of different subjects related to the public milk supply. A very valuable feature of the work is the extended bibliography accompanying nearly every article.

The different subjects treated are as follows: The Principal Phases in the Historical Development of the Dairy Industry during the Last Ten Years, by W. Kirchner; Statistics of the Cattle Industry and Dairy Industry in Different Countries, by H. Mohr; Elements of Stable Hygiene, by W. Stödter; Feeding Milch Cows, by Noll; The Injurious Effect of Diseases of Cows and of Certain Drugs and Unsuitable Foods with Reference to the Properties of Milk, by F. Glage; The Thorough Cooling of Milk as an Essential in Providing Hygienic Milk, by W. Helm; The Handling of Milk with Especial Reference to the Conditions at Hamburg, by G. H. Sieveking; The Rôle Played by Milk in the Spreading of Typhoid Fever, Diphtheria, and Scarlet Fever, by G. H. Sieveking; Milk and Tuberculosis, by T. Rosatzin; Milk Preservatives and Their Injurious Effects, by C. Hagemann; Milk for Infants and Milk Preparations, by Edlefsen; Infant Mortality and the Milk Supply, by von Ohlen; The Care of Milk in the Home, by W. Weichardt; Cheese Poisoning, by Lochte; The Injurious Effects of Butter and Other Milk Products due to Micro-organisms, by I. Kister; The Saprophytes of Milk and their Relation to Dairying, by H. Weigmann; Pathogenic Ba 'eria in Milk and Milk Products, by H. C. Plaut; Chemistry of Milk, by Eichloff; and Chemical Analysis of Milk, by J. Zink.

Suggestions concerning care of milk and butter making on the farm, H. E. Van Norman (*Indiana Sta. Bul. 96, pp. 36, figs. 8*).—Statistical information is given on the dairy industry in Indiana, and suggestions are made concerning the feeding of cows, care and handling of milk, washing dairy utensils, separation and ripening of cream, churning, weighing, and testing milk, etc. Figures are given showing the fertilizing elements removed in farm products and several pieces of dairy apparatus are illustrated.

Studies on milk hygiene, G. Schweitzer (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), Nos. 16–17, pp. 501–514; 18–19, pp. 563–570, fig. 1*).—The care of milk in the home is discussed in connection with a report of tests of the Kobrak pasteurizing apparatus, the morphology and culture characteristics of a number of lactic acid bacteria are described; and observations on the souring of milk at different temperatures are reported. A list of 23 references relating to this subject is appended.

Bacteria in milk and its products, M. Henseval (*Les microbes du lait et de ses dérivés. Lierre: J. Van In & Co., 1903, pp. 126; rev. in Rev. Gén. Agron. [Louvain], 12 (1903), No. 5, pp. 236–239*).—Chapters are devoted to the source of bacteria in milk, pasteurization, ripening of cream, the composition of butter and the causes of rancidity, and the ripening of cheese.

Hygiene of milk production, H. Raquet (*Conditions d'hygiène à réaliser dans la production du lait. Brussels: Lamartin, 1902, pp. 80*).

The composition of milk, H. D. Richmond (*Analyst, 28 (1903), No. 3??, pp. ??–292, fig. 1*).—The average fat content of 12,914 samples of milk as received at a milk depot in London during 1902 was 3.82 per cent. The lowest figures were obtained in May, June, and July, and the highest in October, November, and December. The percentage of total solids averaged 12.73 and the average specific gravity was 1.0321.

Paying for separator cream at the creamery, J. L. HILLS (*Vermont Sta. Bul. 100, pp. 24, figs. 3*).—The author believes that there are creameries which neither sample correctly, analyze correctly, nor pay correctly, and he has therefore prepared a bulletin of information containing suggestions in regard to sampling and testing cream, and discussing the paying for cream at creameries receiving both cream and milk. In order to promote the more thorough mixing of the cream sample, moderate warming and the use of a fine sieve and pestle are recommended. Weighing the cream in making a test is urged as the only accurate method.

Patrons furnishing cream are entitled to a larger surplus or a higher price per pound of butter or butter fat than patrons delivering milk for reasons which are clearly set forth. This extra surplus due cream patrons is estimated, upon the basis of a large amount of painstaking comparison in actual creamery practice, as ranging from 2.5 to 5 per cent and averaging about 3 per cent. The extra price is considered usually close to a half cent. Methods of estimating the cream fat and the milk fat surpluses, calculating payments, etc., with concrete examples, are given in an appendix.

The keeping quality of butter, G. L. M'KAY and C. LARSEN (*Iowa Sta. Bul. 71, pp. 30*).—The causes of deterioration in butter are briefly discussed, and experiments to determine whether the keeping quality of butter is affected by its content of moisture and by the quality of the wash water used in its manufacture are reported. The results of experiments with butter made under uniform conditions, except as regards the amount of working, were considered as indicating that the butter containing the smaller amount of moisture possessed the better keeping quality, though the individual experiments did not justify such a conclusion. Incidentally in this connection the authors discuss the effect of working upon the water content of butter, concluding that the proper time to control moisture is before or during churning rather than afterwards.

In each of 3 experiments the butter from one-half of a vat of ripened cream was washed with well water, and the butter from the other half, churned under the same conditions, was washed with well water which had been pasteurized and cooled. In each of 2 experiments 1 portion of the cream was also pasteurized before ripening. Pasteurization of the wash water improved greatly the keeping quality of the butter, and pasteurization of both cream and wash water had a still more favorable effect. In each of 3 other experiments the butter from one-half of a vat of well-ripened cream was not washed at all, while the butter from the other half was washed with unpasteurized well water. The unwashed butter kept as well as the washed butter, and in some instances it kept better. It remained normal for about 40 days.

Where the wash water is not of good quality it is therefore believed that as good or better results can be obtained by working the buttermilk well out of the butter and omitting the washing, providing the cream to be churned is of good quality and the butter can be sold within 35 days after its manufacture. The favorable action of salt upon the keeping quality of butter was also shown in other experiments. Three objectionable flavors, described as a turpentine flavor, a strong cheesy flavor, and a fishy flavor, developed in butter made in these experiments.

The purity of well water in general is briefly discussed. In the unpasteurized well water used in the above experiments the germ content averaged 113 per cubic centimeter, while in the pasteurized water it averaged 3. The methods available for the purification of wash water are filtration and pasteurization. The advantages and disadvantages of each method are considered. Filtration is deemed preferable to pasteurization inasmuch as this method removes organic matter and other impurities as well as bacteria, and is very inexpensive. In the experiments at the station continuous filtration removed 95 per cent of the germs. The filter bed used consisted of the following layers, mentioned in order beginning at the bottom: Coarse gravel 2 in., fine sand 22 in., fine coke 12 in., charcoal 9 in., and coarse gravel 2 in. Sug-

gestions are made concerning the care of filters. The cost of pasteurization of both milk and wash water was estimated at 0.1 ct. per pound of butter produced, not including the cost of the necessary apparatus.

The cold curing of cheese (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 49, pp. 88, pls. 4, figs. 22*).—This is a report upon experiments conducted by the Wisconsin and New York State stations under the auspices of the Dairy Division of the Bureau of Animal Industry.

Introduction, H. E. Alvord (pp. 7-10).—The experiments which have been made in curing cheese at lower temperatures than usual are referred to, and the conditions and objects of the present work are briefly set forth. While the main purpose was to test under commercial conditions the effect of cold curing upon the quality of cheese, data were also secured concerning loss in weight during curing and the use of paraffin in coating cheese. In the experiments conducted by both stations the cheese was cured at temperatures of 40, 50, and 60° F. The following general conclusions are drawn from the two series of experiments: "The loss of moisture is less at low temperatures, and therefore there is more cheese to sell. The commercial quality of cheese cured at low temperatures is better, and this results in giving the cheese a higher market value. Cheese can be held a long time at low temperatures without impairment of quality. By utilizing the combination of paraffining cheese and curing it at low temperatures the greatest economy can be effected."

The western experiments, S. M. Babcock, H. L. Russell, and U. S. Baer (pp. 11-70).—The cheeses used in these experiments were purchased from factories in Wisconsin, Iowa, Illinois, and Michigan, and represented various types, grouped for convenience as follows: (1) Close-bodied, firm, long-keeping type, suitable for export trade; (2) sweet-curd type; (3) soft, open-bodied, quick-curing type, suitable for early consumption. The cheeses were made with uniform quantities of rennet and salt and were shipped to Waterloo, Wisconsin, where they were placed in cold storage at temperatures averaging 36.8, 46.9, and 58.5° F. Representative cheeses were examined at intervals by a jury of commercial experts, their scores being supplemented by scores made much more frequently by U. S. Baer. The data are reported in full in an appendix, and also summarized in the text.

As regards loss in weight, the results show that cheese cured at 50 to 60° lost fully three times as much in 90 days as cheese cured at 40°. Under prevailing factory conditions it is believed that cheese loses fully four times as much in a period of 20 days as was lost during the 90-day period in cold storage. Cheese of type 1 lost much less in weight than cheese of the softer types. At 40° the loss in weight was practically independent of the size of the cheese, this result, however, being attributed to the relative humidity of the curing room, which at that temperature was 100 per cent. At higher temperature the loss in weight increased as the size of the cheese decreased. The shrinkage in cheese coated with paraffin and cured at 60° was more than 50 per cent less than that of uncoated cheese cured at the same temperature. At 40° coated cheese lost slightly more in weight than uncoated cheese. The loss in weight of cheese is not believed to be due wholly to loss of moisture.

As regards the quality of the cheese the results on the whole were decidedly in favor of cold curing. The typical Cheddar cheese constituting type 1 being manufactured nearer to the curing station afforded the best test of the influence of temperature. The cheese of this type ripened at 60° developed faster than cheese at the lower temperature and was of excellent quality, but eventually it was surpassed by the cold-cured cheese. As regards keeping quality, cold-cured cheese was far superior to that ripened at the higher temperature. The quality of the cheese was not affected by the use of paraffin.

"The production of a thoroughly broken-down Cheddar cheese of mild, delicate flavor and perfect texture meets a demand which is impossible to satisfy with cheese cured at high temperatures. Without any question, if the general market can be

supplied with this mild, well-ripened cheese, consumption will be greatly stimulated, not only by increasing the amount used by present consumers, but by largely extending the use of this valuable and nutritious article of food. The improvement in quality of cold-cured cheese, the enhanced keeping quality, and the material saving in shrinkage due to lessened evaporation are sufficient to warrant a considerable expenditure on the part of cheese producers in installing cold-curing stations."

The eastern experiments, L. L. Van Slyke, G. A. Smith, and E. B. Hart (pp. 71–88).—In these experiments representative cheeses were obtained from New York, Pennsylvania, and Ohio, and placed in storage in New York City at temperatures of 40, 50, and 60°. The cheeses were examined by a committee of experts when placed in cold storage and after 10, 20, 28, and 35 weeks. Chemical analyses were also made.

"The loss of weight increased with increase of temperature, being on an average in 20 weeks 3.8 lbs. per 100 lbs. of cheese at 40° F., 4.8 lbs. at 50° F., and 7.8 lbs. at 60° F. The large-sized cheeses lost less weight per 100 lbs. than those of smaller size. Cheese cured at 40° F. was superior in quality to the same kind cured at higher temperatures. That cured at 50° F. was superior in quality to that cured at 60° F. The general averages of the scores at the end of 20 weeks were as follows: 95.7 at 40° F., 94.2 at 50° F., and 91.7 at 60° F. The difference in quality was confined in most cases to flavor and texture, the color and finish being little or not at all affected in cheese that was in good condition at the beginning. The commercial qualities of cheese were favorably influenced after 6 months in the case of that covered with paraffin, especially in flavor. The loss of moisture was greatly lessened, amounting only to a fraction of a pound for 100 lbs. of cheese at 40° and 50° F., and being only about one-fifth the average loss found at 60° F. with cheese not so treated. The cheeses were also perfectly clean and free from mold, while all the cheeses not treated with paraffin were covered with mold."

The paracasein monolactate, averaging 57.47 per cent of the nitrogen in cheese 1 and 2 weeks old, decreased with the age of the cheese and more rapidly at higher than at lower temperatures. This decrease was accompanied by a corresponding increase in the percentage of nitrogen in form of water soluble compounds. The formation of amido and ammonia compounds possibly associated with the development of flavor in cheese increased with temperature and the age of the cheese.

Experiments in curing cheese at different temperatures, L. L. Van Slyke, G. A. Smith, and E. B. Hart (*New York State Sta. Bul. 234, pp. 97–121*).—This is the same report as that noted above under the subtitle The eastern experiments.

Cold cured cheese, II, F. H. Hall, L. L. Van Slyke, G. A. Smith, and E. B. Hart (*New York State Sta. Bul. 234, popular ed., pp. 7*).—A popular summary of the above.

Rennet enzym as a factor in cheese ripening, L. L. Van Slyke, H. A. Harding, and E. B. Hart (*New York State Sta. Bul. 233, pp. 67–96*).—The agencies so far known to take part in the normal ripening of cheese are stated to be (1) acid, usually lactic; (2) enzyms present in the milk; (3) an enzym in the rennet extract added to milk in cheese making; and (4) micro-organisms, chiefly bacteria. The investigations here reported were concerned mainly with the rennet enzym, the object being to ascertain to what extent this ferment causes the formation of soluble nitrogen compounds in cheese during the process of ripening.

In order to study the action of the rennet enzym apart from the other agencies, the milk enzyms were destroyed by heating, a method shown by experiments to be effective, and the growth of micro-organisms was prevented by the use of chloroform. The coagulability of the milk was restored by the use of calcium chlorid or carbon dioxid. The action of the rennet enzym was studied (1) in the presence and absence of acid and of salt in cheese made from milk which had been heated to destroy the milk enzyms and treated with chloroform to prevent the growth of micro-organisms; (2) in the presence of acid and liquefying organisms in cheese

made from pasteurized milk without the addition of chloroform; (3) in cheese containing commercial pepsin and micro-organisms; and (4) in comparison with commercial pepsin on casein in milk and paracasein dilactate. Detailed data for the experiments are given in an appendix. The results are summarized as follows:

"In the case of every experiment made, there was little or no digesting action by either rennet enzym or commercial pepsin in the absence of acid, while the action was marked in the presence of acid.

"In the absence of acid in cheese no paracasein lactate is found, and little or no proteolysis occurs; in the presence of acid in the cheese paracasein monolactate is formed and digestion takes place, the rennet ferment being the active agent. The ability of rennet enzym to convert paracasein into soluble nitrogen compounds appears to depend upon the presence of acid, resulting in the formation of paracasein monolactate.

"Rennet enzym and commercial pepsin act essentially alike in forming soluble nitrogen compounds when compared with each other in the case of cheese, milk, and paracasein dilactate.

"In the case of both rennet enzym and commercial pepsin, the chemical work performed by the ferments is confined mainly to the formation of the paranuclein, caseoses, and peptones, while only small amounts of amids are formed, and no ammonia.

"Rennet enzym is really a peptic ferment.

"Salt, in the proportions found in normal cheese, appears to have little effect upon the action of rennet enzym in cheese ripening. The experiments on this point are, however, not regarded as conclusive.

"The abnormal conditions present in many of the experiments, such as pasteurized milk, calcium chlorid, and chloroform, would tend, if they had any effect at all, to decrease the digestive action of rennet enzym. Our results, therefore, may properly be regarded as representing the minimum effect of rennet enzym in cheese ripening.

"The digestive action of rennet enzym does not appear to extend to the formation of compounds that produce the flavor of cheese."

Conditions affecting chemical changes in cheese ripening, L. L. VAN SLYKE and E. B. HART (*New York State Sta. Bul. 236, pp. 133–163*).—This bulletin gives the results of a study of the chemical changes taking place in the nitrogen compounds of cheese as affected by time, temperature, moisture, size of cheese, salt, rennet, and acid. The casein of milk is converted into paracasein by the action of rennet, after which paracasein monolactate, paranuclein, caseoses, peptones, amido compounds, and ammonia compounds are formed in approximately the order mentioned. The bulletin deals with the quantities of these different compounds, and their relations to one another, in Cheddar cheese, made for the most part according to usual commercial methods and ripened under controlled conditions. From 4 to 8 cheeses, weighing 10 or 30 lbs. each, were made from the same lot of milk in each experiment. Detailed analytical data are given in an appendix, and the results are summarized by the authors as follows:

"The amount of soluble nitrogen compounds increases as cheese ages. The rate of formation of these compounds is more rapid in the earlier stages of ripening, about two-thirds being formed during the first 3 months and over 90 per cent in the first 9 months of an 18-month period of study.

"Soluble nitrogen compounds increase in cheese ripening quite closely in proportion to increase of temperature. Between the limits of 32° F. and 70° F. there was an increase of 0.5 per cent of soluble nitrogen compounds for an increase of one degree of temperature. The amido compounds and ammonia were more abundantly formed, and they steadily accumulated in cheese cured at higher temperatures.

"Cheese containing more moisture, other conditions being uniform, generally contains larger amounts of soluble nitrogen compounds, especially after the early stages of ripening.

"Cheeses of large size usually form soluble nitrogen compounds more rapidly than smaller cheeses under the same conditions, because large cheeses have a higher water content after the early period of ripening.

"Cheese containing more salt forms soluble nitrogen compounds more slowly than cheese containing less salt. This appears to be due, in part, to the direct action of salt in retarding the activity of one or more of the ripening agents, and in part to the tendency of the salt to reduce the moisture content of the cheese.

"The use of increased amounts of rennet extract in cheese making, other conditions being uniform, results in producing increased quantities of soluble nitrogen compounds in a given period of time, especially such compounds as paranuclein, caseoses, and peptones.

"Acid is necessary for the formation of paracasein monolactate, from which soluble nitrogen compounds appear to be formed in normal cheese ripening; but the exact relation of varying quantities of acid to the chemical changes of the ripening process has not yet been fully studied.

"Paracasein, caseoses, and peptones usually vary within small limits and do not usually accumulate in cheese in increasing quantities, but after a while decrease, while amids and ammonia are found to accumulate continuously during the normal ripening process. Low temperatures favor some accumulation of the transient products, while high temperatures favor the more rapid accumulation of amids and ammonia.

"The accumulation of soluble nitrogen compounds in cheese appears to diminish the action of the agents causing the changes, so that cheese ripens less rapidly after the first period.

"An increased moisture content in cheese favors more active chemical change for two reasons: (1) Moisture in itself favors the activity of ripening ferments; (2) the presence of increased amounts of moisture serves to dilute the fermentation products that accumulate.

"The conditions of the manufacture of cheese and of ripening determine the rapidity and extent to which chemical changes take place in the nitrogen compounds during ripening. The following conditions promote more rapid change: (1) Increase of temperature in ripening; (2) larger amount of rennet; (3) higher moisture content of cheese; (4) decreased amount of salt; (5) large size of cheese, and (6) moderate amount of acid. Cheese made and handled so as to ripen slowly is of higher commercial value."

The regular appearance of different types of strictly anaerobic butyric-acid bacteria in hard cheese, A. RODELLA (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), Nos. 16–17, pp. 499, 500; 24–25, pp. 753–755*).—In these two articles, with slightly different titles, the author reports the regular occurrence in numerous samples of several kinds of hard cheese of anaerobic bacteria, especially forms capable of producing butyric-acid fermentation, and describes briefly the methods used in their isolation and culture. It is the author's purpose to discuss the relation of the butyric-acid bacteria to the ripening of cheese in a concluding article.

How can the East compete with the West in dairying? J. L. HILLS (*New Jersey State Bd. Agr. Rpt., 1902, pp. 175–201*).

VETERINARY SCIENCE AND PRACTICE.

Immunity and immunization, L. HOPF (*Immunität und Immunisirung. Tübingen: Franz Pietzcker, 1902, pp. VI+96*).—A general account of the subject of immunity from a historical standpoint. The author discusses immunity toward various poisons as well as toward infectious diseases. Notes are given on the methods of immunization and on the theories of immunity which have prevailed among various civilized and uncivilized races. The latter part of the volume is devoted to a discussion of the nature of immunity as understood from the recent investigations of bacteriologists.

Immunity in infectious diseases, E. METCHNIKOFF (*L'immunité dans les maladies infectieuses. Paris: Masson & Co., 1901, pp. IX+600, figs. 45*).—This volume contains an elaborate discussion of the general problem of immunity. The subjects discussed by the author include the importance of a study of immunity; immunity in unicellular organisms, in plants, in the animal kingdom; resorption of organized elements; resorption of albuminoid fluids; natural immunity against pathogenic organisms; the mechanism of natural immunity; a review of the facts of acquired immunity; rapid and temporary immunity conferred by specific and normal sera; natural and artificial immunity against toxins; immunity of the skin and mucous membranes; preventive vaccination for sheep pox, rabies, rinderpest, anthrax, blackleg, swine erysipelas, pleuro-pneumonia, tetanus, diphtheria, etc.; and a historical review of the present knowledge of immunity. The volume concludes with a résumé of the whole subject as viewed from the author's standpoint.

Toxins and antitoxins, J. BORDET (*Ann. Inst. Pasteur, 17 (1903), No. 3, pp. 161-186*).—A review of the literature of this subject indicates that the majority of authors are agreed on the proposition that antitoxins do not produce immunity by direct action upon the animal organism, but that their chief action is a partial neutralization of toxins. It has been shown, however, that a mixture of a toxin and an antitoxin is not strictly neutral, and portions of both toxin and antitoxin remain uncombined, while the remainder of the toxin and antitoxin combines and becomes neutralized in varying degrees.

The author briefly discusses the results of an experiment with an alexin and an antialexin. It is found that a quantity of antialexin insufficient for completely neutralizing more than 6 fatal doses of alexin, nevertheless exercises an influence such that in its presence 24 fatal doses of alexin produce hemolysis less rapidly than a single dose is capable of doing in the absence of the antialexin.

Cellular hemolysins, C. LEVADITI (*Ann. Inst. Pasteur, 17 (1903), No. 3, pp. 187-216*).—The objects of the experiments reported by the author in this paper were to determine the nature and method of production of hemolysins and the relative activity of macrophages and polynuclear leucocytes in the production of hemolysins. The extracts were obtained from the 2 kinds of leucocytes by a rapid and slow process.

Experiments were then made with these hemolysins as obtained by the different methods. It was found that the principal hemolysins contained in the extract obtained by the slow method were soluble in dilute and strong alcohol. The hemolysins obtained from the lymphatic ganglia can not, in the opinion of the author, be identified with the cytase of fresh sera, since the former are thermostable and may be neutralized by normal serum. It was shown during the author's experiments that the extract of polynuclear leucocytes is quite deprived of hemolytic properties with regard to the red corpuscles.

The bacteriolytic properties of this extract, however, were considerably more pronounced than those of the extract from the macrophages. It appears therefore that the macrophages of the lymphatic ganglia, as a result of the autolytic properties and the composition of the cytase in the ganglia, are an important source of hemolysins, while the polynuclear leucocytes in the peritoneal fluid are without any trace of hemolytic properties which can be demonstrated in vitro. The polynuclear leucocytes, however, play the principal part in the destruction of bacteria.

On some factors in bacteriolytic action, E. W. A. WALKER (*Jour. Hyg. [Cambridge], 3 (1903), No. 1, pp. 52-67*).—A study was made of the bacteriolytic properties of rabbit serum after inoculation with typhoid bacillus. It was found that the amount of complement in the serum undergoes a steady increase during the first few hours, provided the serum be left in contact with the clot. Serum removed from a vessel containing the clot, however, shows no such increase in the complement. It is concluded, therefore, that the complement is a product of leucocytes appearing in the blood plasma or serum as the result of the disintegration of the leucocytes.

The existence of hemolytic alexin in the blood plasma, A. FALLOISE (*Bul. Acad. Roy. Belg. Cl. Sci., 1903, No. 6, pp. 521–596*).—The author conducted experiments upon a number of mammals and birds, including dogs, rabbits, cattle, sheep, pigs, pigeons, and other species of birds. The results obtained indicate that an alexin exists in the blood plasma in all these animals. This alexin was found without regard to whether the blood had been treated with a chemical reagent or not. It is argued, therefore, that this alexin is secreted by the leucocytes in the circulating blood, and that these blood elements therefore play an important part in immunity.

The active substance of normal sera—The plurality of alexins, L. REMY (*Ann. Inst. Pasteur, 17 (1903), No. 5, pp. 343–356*).—During these experiments, which were conducted chiefly with the serum of rats, it was found that the serum of these animals when not heated exercises a destructive influence upon the majority of bacteria. The action of a temperature of 55 to 56° C. for 35 minutes attenuates without destroying the bactericidal properties of the serum. The bactericidal substance which resists the action of heat is an alexin. This alexin in the serum of rats resists a temperature of 55 to 56° C., and is therefore considered not to be hemolytic, since it does not have the power of enforcing hemosera.

Staphylococci and staphylolysin, P. VAN DURME (*Hyg. Rundschau, 13 (1903), No. 2, pp. 66–68*).—Experiments with different species of Staphylococci showed that there is a close connection between the pathogenic action and the hemolytic power of these organisms. The formation of hemolysin is much less extensive in the case of *S. albus*, as might be expected from its slighter pathogenic power.

Successful treatment of fatal intraperitoneal streptococcal infections in rabbits by means of injections of pyocyanase, R. EMMERICH and R. TROMMSDORFF, *Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 8, Orig., pp. 627–633, figs. 2*).—During a series of experiments by the authors it was found that 31 per cent of rabbits treated with pyocyanase successfully resisted fatal intraperitoneal doses of streptococci, and 46 per cent of the rabbits thus treated were favorably influenced by the treatment, but ultimately succumbed to the infection.

The influence of diphtheria and tetanus toxins on hemoglobin and on the morphology and specific gravity of the blood, H. KUCHARZEWSKI (*Centbl. Bakt. u. Par., 1. Abt., 34 (1903), No. 4, Orig., pp. 381–384*).—The experiments reported in this paper were made on rabbits. It was found that the diphtheria toxin in large or medium doses caused a diminution in the number of red blood corpuscles and in the quantity of hemoglobin. Small doses were without effect. When large doses of toxin were used the density of the blood was increased and a hyperleucocytosis was observed. Inoculation with tetanus toxin also diminished the number of red blood corpuscles and the quantity of hemoglobin, and diminished the density of the blood.

Antiferments, E. WEINLAND (*Ztschr. Biol., 44 (1902), No. 1, pp. 1–15*).—The purpose of the experiments reported in this paper was to determine the cause of resistance of intestinal worms to the action of the digestive juices of the host animals. The worms upon which experiments were made included cysticerci of a number of species, *Ascaris suilla*, *Tænia expansa*, and *T. mediocanellata*. An antiferment was extracted from the bodies of the worms, which had the effect of protecting fibrin and other readily digestible substances against the action of proteolytic ferments. The protection furnished by the antiferment was not unlimited in time or extent, but was sufficiently pronounced to indicate that the antiferment was capable of protecting the parasitic worms against the action of digestive juices. The antiferment was not readily extracted. A second extract contained more of the antiferment than the first.

The nonidentity of agglutinins acting upon the flagella and upon the body of bacteria, T. SMITH and A. L. REAGH (*Jour. Med. Research, 10 (1903), No. 1, pp. 89–100*).—During a series of experiments made by the authors it was found that the

nonmotile and the motile races of hog-cholera bacillus and also *Bacillus icteroides* show a close affinity in the presence of immune agglutinins. The action of the serum of rabbits and guinea pigs immunized with the nonmotile bacillus is quite different toward this bacillus from the action of serum produced by motile bacilli. The clumping appears later and in the form of a precipitate of granules. Agglutination appears also only after a higher degree of immunization.

During these studies it was found that the agglutinin which acts upon the flagella is quite distinct from that which acts upon the body of bacteria. The agglutinin which is active toward the bodies of nonmotile hog-cholera bacilli was found to be identical with that which acts upon the bodies of the motile race of the same species. A much higher degree of immunity is required in the experimental animal in order to obtain the agglutinin which operates upon the body of the bacilli, while flagellar agglutinins are quite easily demonstrated in the immune sera.

The agglutination affinities of related bacteria parasitic in different hosts, T. SMITH and A. L. REAGH (*Jour. Med. Research, 9 (1903), No. 3, pp. 270–300*).—An elaborate study was made of bacilli belonging to the hog cholera group of both motile and nonmotile forms. The organisms studied included typhoid bacillus, coli bacillus, *Bacillus icteroides*, hog-cholera bacillus, etc. During these investigations it was found that there are certain agglutination relationships between pathogenic bacilli which cause fermentation of dextrose. The agglutinative characters appear to be modified when the organism becomes parasitic upon different hosts. It was found possible to predict agglutinative affinities from close pathogenic relationships. Guinea pigs immunized with the same cultures in the same manner yielded sera with identical agglutinins.

The appearance of agglutinins after cutaneous infection, W. HOFFMANN (*Hyg. Rundschau, 13 (1903), No. 3, pp. 114–121*).—The author conducted experiments for the purpose of determining whether it was possible to produce agglutinins in the blood serum as a result of mere cutaneous inoculation. The experiments demonstrated that agglutinins are produced in rabbits after cutaneous inoculation with typhoid bacillus. The agglutinative standard is not as high as that which is secured by intravenous injections.

The agglutinating properties of bile, A. CANTANI (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 9, Orig., pp. 730–740*).—The author made a large number of experiments for the purpose of determining the possible agglutinating power of the bile from normal and affected animals. It was found during these experiments that the bile of normal rabbits, guinea pigs, and cattle possesses no agglutinating properties toward the majority of bacteria, while the bile of dogs exhibits slight agglutinating action. A pronounced power was observed in the bile of animals which had been immunized against certain bacterial organisms, such as the typhus and coli bacilli.

The bactericidal action of the bone marrow and the etiology of osteomyelitis, A. HENCKE (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 9, Orig., pp. 697–701*).—During the author's experiments, which were made chiefly on rabbits, it was found that the bone marrow possesses quite striking bactericidal properties. It recovers from infection more quickly and completely than the internal organs. *Staphylococcus aureus* introduced in pure cultures into the animal organism, whether into the blood or into the bone marrow, failed to produce an infectious osteomyelitis. In 4 spontaneous cases of this disease investigated by the author, in which there was no communication with the outside world, and in 1 case in which the communication existed, small bacterial rods were found and were isolated in pure cultures. These cultures were found to be capable of producing characteristic osteomyelitis when inoculated intravenously.

Determination of the bactericidal and antiseptic action of Bacillol, L. HAUMAN (*Ing. Agr. Gembloux, 13 (1903), No. 12, pp. 541–546*).—A number of experiments were made for the purpose of determining the antiseptic power of Bacillol upon the

various micro-organisms, including *Bacillus coli communis*, anthrax bacillus, typhoid bacillus, *Penicillium glaucum*, etc. It was found that this substance compared favorably in antiseptic power with carbolic acid and was more readily applied. It is less offensive in odor and presents no dangers in application, even in concentrated solutions.

Intestinal antisepsis, J. H. CRAWFORD (*Amer. Vet. Rev., 26 (1903), No. 11, pp. 1056–1058*).—A brief account is presented of the conditions under which toxic substances are developed in the intestines. Encouraging results were obtained by the author in administering an antiseptic mixture containing carbolic acid, boric acid, oil of gaultheria, fluid extract of capsicum, and alcohol.

Etiology and prevention of infectious diseases of animals, V. A. MOORE (*Amer. Vet. Rev., 26 (1903), No. 11, pp. 1030–1038*).—A general review of recent progress in the study and determination of the specific bacterial causes of infectious diseases and of the conditions which determine infection. Attention is called to the influence of certain external conditions on the health of the animals, as well as the virulence of the bacillus upon infection.

The pathology of infection, J. B. SANDERSON (*Amer. Vet. Rev., 26 (1903), No. 10, pp. 928–936*).—Attention is called to the recent advances made in microscopy, antisepsis, bacteriology, and in the study of toxins and the various bodies in the blood serum which are concerned with the production of immunity.

Bacteriology and pathological microscopy for veterinarians and veterinary stations, T. KITT (*Bacterienkunde und pathologische Mikroskopie für Thierärzte und Studierende der Thiermedicin. Vienna: Moritz Perles, 1903, 4. ed., pp. XI + 539, pls. 2, figs. 205*).—The present revised edition of the author's text-book on pathological bacteriology has been brought up to date, so far as possible, and is especially designed for the use of students of comparative pathology and veterinary bacteriology, and also as a guide and reference book for the use of practicing veterinarians. It contains a general account of the field of bacteriology, apparatus and technique, microscopic study of animal parasites (such as parasitic insects, mites, worms, and protozoa), and detailed studies of the various pathogenic bacteria.

Protozoa and disease, J. J. CLARKE (*London: Ballière, Tindall & Cox, 1903, pt. 1, pp. XIX + 177, figs. 91*).—The subjects considered in this volume include unicellular organisms and the cell, Sarcodina, Sporozoa, and the malaria parasites, Gregarinida, Coccidia and Hæmosporidia, Flagellata, Ciliata, and other groups of Protozoa, as well as a discussion of diseases to which Protozoa are subject, and methods used in studying these organisms. Detailed notes are given on the appearance and life history of various species of Protozoa parasitic in man, domesticated mammals, fish, insects, and other host animals.

Studies on Coccidium cuniculi, R. METZNER (*Arch. Protistenkunde, 2 (1903), No. 1, pp. 13–72, pl. 1*).—An elaborate account is presented of the microscopic anatomy and life history of this organism. The literature of the subject is discussed in connection with a bibliography. According to the author's investigations, the sporozöites of this organism possess a slender anterior end terminating in a sharp point, while the posterior end is more rounded and contains an ovate structure. Sporulation takes place under conditions favorable to the access of air. The pancreatic juice of rabbits and dogs sets the sporozöites free, while the gastric juice is without effect.

Plant disease and its relation to animal life, E. F. WRIGHT (*London: Swan, Sonnenschein & Co., Ltd., 1903, pp. 160*).—In this volume the author seeks to show the importance of iron in the health, growth, and development of both plants and animals. Attention is called to the relationship of iron to chlorophyll and hemoglobin, and the belief is expressed that the attacks of insects and infectious diseases upon plants as well as the existence of unfavorable soil conditions may lead to a diminished content of iron in plants. It is assumed that animals feeding upon such plants receive less iron than they require, and that consequently the hemoglobin becomes abnormal. It is argued that such animals are thereby rendered less resistant

to various diseases than they otherwise would be. These theories are discussed with illustrations and arguments upon the conditions observed in heartwater, South African horse sickness, flukeworms, tuberculosis, cancer, leprosy, etc.

Experiments on animals, S. PAGET (*London: John Murray, 1903, rev. ed., pp. XVI+387, pl. 1*).—The author's purpose in the preparation of this volume was to present a review of the important results in human and veterinary medicine which have been obtained through experiments on animals. This new edition includes, in addition to the old material, a special discussion of results which have recently been obtained in work on malaria, yellow fever, filariasis, tuberculosis, etc. In addition to the subject already mentioned the volume contains an account of experiments made on the blood, lacteals, gastric juice, glycogen, pancreas, growth of bone, nervous system, anthrax, septicemia, diphtheria, tetanus, rabies, cholera, plague, typhoid fever, action of drugs, snake venom, parasitic diseases, etc.

Report on the veterinary service for the year 1902, W. LITTLEWOOD (*Jour. Khediv. Agr. Soc. and School Agr., 5 (1903), No. 2, pp. 52–55*).—Brief notes on the various animal diseases which were observed during the year, and also on the vaccine institute, veterinary schools, abattoirs, and the importation of animals.

Report of the State veterinarian, D. F. LUCKEY (*Missouri State Bd. Agr. Rpt. 1902, pp. 29–34, 366–374*).—Brief notes on malignant catarrh in cattle, various hog and sheep diseases, blackleg, Texas fever, etc. A tabulated list is presented of the various cases of disease in animals visited by the author and his deputies.

The agreement between Austro-Hungary and Germany with regard to animal plagues (*Arch. Deut. Landw. Raths, 27 (1903), pp. 163–193*).—A copy of this agreement, which has been in force since December 6, 1891, is given. As a result of a discussion of this subject it was concluded that in the event of a future modification of commercial treaties between Germany and Austro-Hungary, no specification should be included regarding animal plagues, but that this matter should be left subject to the Animal Plague Law.

Suggestions regarding the modifications of the Animal Plague Law (*Arch. Deut. Landw. Raths, 27 (1903), pp. 227–397*).—A copy is given of the Animal Plague Law of Germany, passed June 23, 1880, and May 1, 1894. During an extended discussion of the features of this law a number of changes were suggested. It was recommended that unloading stations for animals be provided with impervious floors and that this recommendation should also be applied to markets and trading booths. It was also recommended that the compulsory notification of tuberculosis in animals should be required of laymen only in case of the presence of easily recognized clinical symptoms.

Human and bovine tuberculosis, E. NOCARD (*Rev. Gén. Méd. Vét., 1 (1903), No. 1, pp. 1–9*).—The author combats Koch's view of the nonidentity of these two forms of tuberculosis and presents arguments in support of the view that cattle are not refractory to human tuberculosis in general, but only to certain races of tubercle bacilli of human origin. The author believes that the disease is transmissible from man to animals and from animals to man, and urges that sanitary measures should still be maintained with regard to the control of tuberculous milk and meat.

Discussion of tuberculosis in children: Its relation to bovine tuberculosis, N. RAW (*British Med. Jour., 1903, No. 2226, pp. 470–474*).—A large number of cases of tuberculosis in children were critically investigated for the purpose of judging the evidence regarding the source of infection. As the result of these studies the author concludes that bovine tuberculosis is very virulent for children and is the cause of tabes mesenterica and other varieties of abdominal tuberculosis. The author inclines to accept the view that there are two forms of tuberculosis, both of which affect man, and believes that bovine tuberculosis is more virulent for children than the human form of the disease. The author's paper was discussed in detail by a number of

investigators, the majority of whom were of the opinion that tuberculosis may be transmitted from animals to man.

Tuberculosis of the dairy cow, S. STEWART (*Missouri State Bd. Agr. Rpt. 1902, pp. 268–271*).—A brief account of the symptoms of tuberculosis, prevalence of the disease in dairies, and dangers which arise from carelessness in handling tuberculous products.

Tuberculosis as a result of inoculation of animals with dead tubercle bacilli, N. PANOV (*Dissertation, Dorpat, 1902, pp. 131, pl. 1*).—An elaborate review of the literature of this subject is presented in connection with a bibliography. In the author's experiments tubercle bacilli from human patients were used, and the experimental animals were rabbits. As a result of inoculating rabbits with large quantities of dead tubercle bacilli of considerable virulence it was found that tubercles were produced in the lungs, liver, and other organs; that these formations were of short duration except in cases where the toxin was introduced in sufficient quantity to produce death.

The intermediary body of the tubercle bacillus, J. BORDET and O. GENGOU (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 5, pp. 351–353*).—In experiments conducted by these authors it was found that when guinea pigs were inoculated with living tubercle bacilli of human origin generalized tuberculosis results without the formation of an intermediary body. Negative results were uniformly obtained in testing the serum for this body. On the other hand, if guinea pigs are inoculated hypodermically 2 or 3 times with tubercle bacilli of avian origin, an intermediary body is produced in the blood of the experimental animals, and this body leads to the rapid absorption of the alexin of the blood by the bacillus.

The possibility of immunizing guinea pigs against tuberculosis, E. LEVY (*Centbl. Bakt. u. Par., 1. Abt., 33 (1903), No. 9, Orig., pp. 701–703*).—During the author's experiments, which have been prosecuted since 1888, it was found that an 80 per cent sterilized solution of glycerin was capable of destroying the virulence of tubercle bacilli within 48 hours, at a temperature of 37° C. Numerous experiments were made extending over several years, for the purpose of determining the effect of exposure to glycerin in solutions of different strength for different periods. A guinea pig was inoculated subcutaneously with an emulsion of tubercle bacilli which had been kept for 6 days in glycerin, and a similar injection was made by the intraperitoneal method in another guinea pig. After the animals had recovered completely they were inoculated with 5, 4, 3, and 2 day old cultures in succession. Finally the treated animals, together with 2 control guinea pigs, were inoculated with virulent tubercle bacilli. Abscesses were formed at the point of inoculation on the treated animals, but within a period of 4 weeks these abscesses healed entirely, while the tuberculous processes developed with fatal consequences in the 2 control guinea pigs. Both of the treated guinea pigs were killed and carefully examined without finding a trace of tuberculosis.

An experiment in the use of air and oxygen in checking the course of tuberculosis in tuberculin-reacting cattle, V. A. MOORE (*Amer. Vet. Rev., 27 (1903), No. 4, pp. 289–300*).—During the experiment reported in this paper 19 cattle were divided into 3 lots of 5, 7, and 7, respectively, the lot containing 5 being untreated, while the other 2 lots were inflated with air or oxygen in the abdominal and pleural cavities. All of the animals were affected with generalized tuberculosis in different degrees. A few fatalities resulted from the inflation of the pleural cavity.

In all cases the immediate effects of the inflation were an increased pulse and rate of respiration and occasionally a slight rise in temperature. During the first 3 months of treatment the animals which received oxygen thrived better than those in the other 2 lots. When the treated animals were killed and examined it was found that they were still affected with generalized tuberculosis, and inoculation experiments in guinea pigs with material obtained from the tubercles showed that the tubercle bacillus was still present in a virulent condition.

The animals which were inflated with air failed to react toward the end of the experiment and seemed to be benefited by the treatment more than those which received oxygen. The results obtained in these experiments, however, are not considered as sufficient for drawing general conclusions regarding the value of this method of treatment.

The fight against tuberculosis in the Australian Colonies and New Zealand, J. P. D. LEAHY (*Trans. and Proc. New Zealand Inst., 35 (1902), pp. 220-225*).—The usual means of distribution of tubercle bacilli are briefly mentioned and notes are given on the legislative and sanitary work which has been done in controlling this disease in the various Australian colonies and in New Zealand. The legislation with regard to meat and milk of tuberculous animals is considered as quite defective.

The etiology and treatment of tetanus, E. THIERRY (*Jour. Agr. Prat., n. ser., 6 (1903), No. 30, p. 127*).—Notes are given on the tetanus bacillus and on methods which have been tested in devising a cure for tetanus. In cases where the masticatory muscles are not affected the animal usually recovers, while the majority of cases in which these muscles are attacked ultimately die. Favorable results are obtained in some cases from the use of a chloral or belladona ointment applied to the muscles of mastication.

Two cases of tetanus, T. A. KRAGNESS (*Amer. Vet. Rev., 26 (1903), No. 11, pp. 1060-1062*).—The author reports success in treating 2 cases of tetanus without recourse to the serum method. Calomel and fluid extract of gelsemium were administered, followed by anodynes, enemas, and other symptomatic treatment.

Plague in domestic animals, J. CANTLIE (*British Med. Jour., 1903, No. 2230, pp. 715, 716*).—Attention is called to the fact that a considerable number of domestic animals are subject to plague and that the disease may exist in them for a considerable time without developing any pronounced symptoms. After infection turkeys may live 44 days, ducks 54, geese 35, sheep 34, and other animals may also resist the action of the disease for long periods. The prophylaxis of plague is therefore believed to be a more difficult matter than has been assumed, and will in the author's opinion remain so until a method has been devised for diagnosing plague in its early stages in the domestic animals.

A disease of cattle as seen in south-central Nebraska during 1899 and 1900, A. BOSTROM (*Amer. Vet. Rev., 27 (1903), No. 4, pp. 331, 332*).—A description is given of a disease which appears suddenly and affects about 10 per cent of the herd. A stiffness is noticed at first, combined with an appearance of lesions in the mouth, and sore eyes. The sucking calves of affected cows did not take the disease. The course of the disease is from 2 to 3 weeks, and the rate of mortality is about [illegible] per cent. The author is uncertain as to the nature of this disease, but believes it to be contagious.

Common ailments of breeding cattle, C. L. WILLOUGHBY (*Georgia Sta. Bul. 60, pp. 44, figs. 16*).—The purpose of this bulletin is to present in a popular and convenient form an account of the more important diseases to which cattle are subject, together with a discussion of the most efficient remedies. The subjects discussed include breeding, pregnancy, abortion, parturition, parturient paresis, uterine diseases, affections of the udder, bloating, and impaction.

An account is given of the causes of barrenness, and brief notes are presented on the more important farm medicines and the methods of administering them. In the treatment of parturient paresis success was had in 2 cases from the application of Schmidt's method. In a discussion of the various diseases many practical suggestions are made which can be readily utilized to good advantage by the farmer and dairyman.

Milk fever, abortion, diarrhea (*Jersey cattle, their feeding and management. London: Vinton & Co., Ltd., 1903, 2. ed., pp. 29-73*).—A detailed account is given of the symptoms and treatment of these diseases. A number of members of the English

Jersey Cattle Society have tried experiments in the treatment of cows before calving in order to prevent the development of milk fever. This preventive treatment, which has proved to be quite satisfactory, consists in giving special attention to the comfort, temperature conditions, etc., of cows for a period of 4 to 6 weeks before calving. During the latter part of this period it is considered desirable to take the temperature of cows daily, or oftener if any abnormal conditions appear.

It is recommended that some laxative feed be given, but that otherwise the feed should be somewhat reduced in order to prevent excessive development of internal fat. It is also recommended that cows be dried off at least 4 weeks before calving. In treating cases of milk fever success is reported from the application of drastic poultices to the spinal cord, ice about the head, and giving laxative drinks. Schmidt's treatment also proved successful.

Reports are given from various members of the society concerning the prevalence and treatment of abortion. Several members report success from the application of external antiseptic washes. Prevention is considered better than treatment, however, since treatment is not always uniform in results. The best method of prevention, in the experience of the members of the society, consists in giving attention to the hygienic conditions of the animal and the application of strict disinfectant measures in case of an outbreak of the disease.

The form of diarrhea which was investigated was found to be due to the presence of stomach worms. A number of experiments were made in testing the action of ammonia upon these worms. This substance was found to exercise a very rapid effect upon the worms. The parasites were killed within 3 minutes when placed in a solution containing 1 part ammonia to 2,400 parts of water, and in 90 minutes in a solution containing 1 part of ammonia to 30,000 parts of water.

Milk fever, J. W. CONNAWAY (*Missouri State Bd. Agr. Rpt., 1902, pp. 332–334*).—A short account of the prevention and treatment of this disease. It is recommended that cows be put on short rations for a week or so before calving. In treating the disease the Schmidt method is recommended, combined with the use of Epsom salts as a laxative.

Parturient paresis, A. W. BAKER (*Amer. Vet. Rev., 27 (1903), No. 3, p. 235*).—The author frequently has occasion to treat cases of this disease and has had best success from the administration of magnesium sulphate together with infusion of potassium iodid and creolin every 8 hours. If necessary this treatment may be followed by stimulants, such as nux vomica, belladonna, or aromatic spirits of ammonia.

Parturient paresis, D. R. KOHLER (*Amer. Vet. Rev., 26 (1903), No. 11, pp. 1053–1055*).—Notes on the cause, symptoms, course, and treatment of this disease. In the author's experience the best results were obtained in the administration of strychnin, Barbados aloes, nitrous ether, and aromatic spirits of ammonia followed by infusions of potassium iodid.

Preliminary report on a new method of preventing milk fever, A. S. WHEELER (*Amer. Vet. Rev., 27 (1903), No. 1, pp. 57, 58*).—An experiment was made on 30 cows in testing the method used by certain dairymen in England in the treatment of milk fever. The method consists in partially milking the cows every 6 hours after calving for the first 3 or 4 days. The purpose of this treatment is to partly relieve the pressure in the udder, but not to reduce it too quickly. None of the 30 cows developed milk fever, and this result is considered as highly satisfactory, since heretofore it has been impossible to avoid the occurrence of the disease. Further experiments will be made with this method.

The treatment of parturient paresis, J. B. CAUGHEY (*Amer. Vet. Rev., 26 (1903), No. 10, pp. 958, 959*).—Excellent results are reported from the use of potassium iodid in treating this disease. The author states, however, that where any drench is used unsatisfactory results are obtained in a large percentage of cases. The author is inclined to believe from his experience that considerable danger attaches to the use of magnesium sulphate as a drench in cases of parturient paresis.

Tricresol in the treatment of parturient paresis, S. Brenton (*Amer. Vet. Rev.*, *26* (*1903*), *No. 12*, *pp. 1124, 1125*).—The author has had good success in treating cases of this disease with a mixture containing 2 gm. of tricresol and glycerin in a quart of sterilized water. This mixture is injected in equal quantities into each quarter of the udder. In the majority of cases 1 injection is all that is required, but the treatment may be repeated at intervals of 6 to 8 hours if necessary.

Contagious vaginitis in cattle, E. Thierry (*Jour. Agr. Prat.*, *n. ser.*, *5* (*1903*), *No. 23*, *pp. 737–739*).—The symptoms and distribution of this disease are briefly noted and a short description is given of its various forms. Spontaneous recovery takes place in some cases after 4 to 5 weeks. Injections of permanganate of potash were effective in controlling the disease, but are considered rather difficult to apply. The simplest and most economic method of treating the disease is believed to be found in quarantining and retiring from service all infected bulls.

Hygienic conditions of parturition as a prevention of calf diseases, M. G. de Bruin (*Fortschr. Vet. Hyg.*, *1* (*1903*), *No. 6*, *pp. 181–186*).—The author briefly describes the natural provisions by which the calf is protected against infection during the process of parturition. In order to prevent infection of calves it is suggested that attention be given to the following matters: Promotion of a normal course of parturition, prevention of contact of the umbilical cord with soil or other substance, and rapid drying of the umbilical cord.

Blackleg and malignant edema, from the standpoint of differential diagnosis, G. Gutzeit (*Fortschr. Vet. Hyg.*, *1* (*1903*), *No. 5*, *pp. 157–159*).—Blackleg appears to be confined to certain districts which are permanently infected, while malignant edema may appear anywhere without relation to particular districts. The clinical symptoms of both diseases are very similar, but the pathological anatomy furnishes a surer basis for differential diagnosis. Conspicuous differences can also be demonstrated by cultivation of the pathological organisms. Finally, the surest method of differentiating between these diseases is found in inoculation of experimental animals. Rabbits and mice are not susceptible to blackleg, but readily become infected with malignant edema.

Psoroptic scabies in cattle (*Bul. Missouri State Bd. Agr.*, *3* (*1903*), *No. 5*, *pp. 12–16*, *figs. 2*).—Descriptive and biological notes on the mite which causes this disease and a short account of symptoms and treatment. The author recommends dipping in creolin, chloro-naphtholeum, or the lime and sulphur dip.

The cattle tick and its relation to the cattle industry of North Carolina, T. Butler (*Bul. North Carolina State Bd. Agr.*, *24* (*1903*), *No. 5*, *pp. 28*, *figs. 2*).—Notes are given on the appearance, habits, and life history of the cattle tick and on the losses due to its attacks upon cattle. In exterminating the tick it is recommended that cattle, horses, and mules be kept out of tick-infested pastures after September 1, that such pastures be divided by fences with a tight board along the ground so as to allow alternation of grazing. Where it is practicable it is also recommended that infested pastures be burned over.

Notes are also given on the Federal quarantine line, State quarantine line, and the hardships which cattle raisers of the State suffer on account of these restrictions. Attention is called to the fact that much better conditions for cattle raisers would exist if ticks were exterminated. Notes are also given on the immunization of cattle to Texas fever, and a brief account is presented of the symptoms of this disease.

Trichodectes geomydis expansus, and the ticks of Mexico, A. Dugès (*Mem. y Rev. Soc. Cient. "Antonio Alzate,"* *18* (*1902*), *No. 4–5*, *pp. 185–195*, *figs. 35*).—A description is given of *Trichodectes geomydis*, and notes are given on its life history. It lives as a parasite on *Geomys mexicanus*. Brief notes are also presented on *Amblyomma cajannense*, *Ornithodoros megnini*, *O. turicata*, and the common cattle tick.

Wasting diseases caused by animal parasites, W. A. Knight (*Amer. Vet. Rev.*, *27* (*1903*), *No. 6*, *pp. 522–525*).—The common lung and stomach worms of sheep and

cattle are *Strongylus filaria*, *S. micrurus*, and *S. contortus*. The animals upon which the author made his observations in Texas were also infested with *Uncinaria radia* and *Œsophagostoma columbianum*. These worms appeared to be so well protected against vermicide treatment that quite unsatisfactory results were obtained from the use of turpentine, chloroform, carbolic acid, benzine, creosote, liquid sulphur, and formalin. The post-mortem appearances of infested animals are briefly described. In preventing the spread of the disease the author recommends isolation of affected animals, drainage of pastures, and a pure water supply.

Dipping tanks, G. S. Armstrong (*Agr. Jour. and Min. Rec., 6 (1903), No. 15, pp. 566–568, fig. 1*).—Attention is called to the necessity of dipping cattle and to the use of certain dipping vats and chemicals. The author describes the details of construction of a dipping tank for cattle which has been found to give satisfaction in operation. The cost of the dipping tank will vary, according to the materials used, between \$350 and \$500.

Dipping tanks, G. D. Alexander (*Agr. Jour. and Min. Rec., 6 (1903), No. 14, pp. 519–524*).—A number of opinions were secured from various people who have had experience in dipping cattle as to the effectiveness of this process. It was found that cattle could be freed from ticks for a period of 3 or 4 weeks during the worst season as the result of one dipping. The dip which was used most extensively contained arsenic, soap, and Stockholm tar.

The loco and some other poisonous plants in Montana, J. W. Blankinship (*Montana Sta. Bul. 45, pp. 75–104, figs. 7*).—The conditions under which plant poisoning occurs in Montana are briefly outlined. The distribution of the loco plant is briefly described and notes are given on its symptoms. In combating this trouble it is recommended that lambs be prevented from grazing on loco areas until late in the season, when the plant becomes less palatable.

W. A. Tudor made an experiment in the extermination of loco. He employed 2 men for a period of about 1 month, during which they succeeded in digging up the loco plants on an area of 16 square miles. The plants were cut off just below the crown by means of a heavy hoe. Where this was properly done the loco plants did not sprout again and have not appeared during the present season.

Descriptive and biological notes are also given on lupine, water hemlock, death camas, larkspur, and wild parsnip (*Pteryxia thapsoides*). All of these plants are believed to cause greater or less loss of stock in Montana. Brief notes are also given on the effect of alkali upon stock. The author presents an analytical synopsis of symptoms for the determination of the cause of poisoning. A brief bibliography of poisonous plants is appended.

Plants injurious to stock, T. N. Willing (*Rpt. Dept. Agr. Northwest Territories, 1902, pp. 33–44, figs. 9*).—A number of plants have been found to be poisonous or have been suspected of causing the death of domesticated animals in the Northwest Territories. Notes are given on some of the more important species, including horsetail, larkspur, corn cockle, lupines, loco weeds, water hemlock, death camas, etc. The symptoms produced by eating these plants are briefly described.

Hog cholera, C. L. Willoughby (*Georgia Sta. Press Bul. 41, pp. 4*).—Notes are given on the nature, cause, means of distribution, symptoms, and treatment of this disease. Suggestions are also made regarding sanitary measures, disinfection, disposal of dead animals, preventive regulations, and the control of the disease by State laws.

Hog cholera, D. Hutcheon (*Agr. Jour. Cape Good Hope, 23 (1903), No. 2, pp. 134–137*).—Brief notes on the symptoms and post-mortem appearances observed in this disease.

Hog cholera, W. C. Quinnell (*Queensland Agr. Jour., 13 (1903), No. 2, p. 92, pls. 2*).—Notes on the symptoms and etiology of this disease, which is shown to be distinct from swine plague and swine erysipelas.

Lungworms in swine, C. F. DAWSON (*Mo. Bul. Florida Dept. Agr., 13 (1903), No. 82, pp. 66, 67*).—A study of an outbreak of a fatal disease in pigs revealed the fact that the disease was due to the presence of a lungworm, *Strongylus paradoxus*. The disease is locally known in Florida as thumps. Young animals are more susceptible than older ones. The symptoms vary according to the number of worms present. The method of treatment recommended by the author is that of fumigation with irritating substances for the purpose of causing the expulsion of the worms by coughing.

The etiology of heaves, W. L. WILLIAMS (*Amer. Vet. Rev., 26 (1903), No. 10, pp. 955–957*).—While veterinarians are generally agreed that musty clover and timothy hay, especially if cut very ripe, are the usual cause of this disease, the author calls attention to the fact that the animals recover when proper care is taken of the diet. The fact is cited that clover and timothy raised under a system of irrigation never cause heaves, even if these crops are allowed to become very ripe before cutting. The author believes that it is possible that heaves may be due to some parasitic organism which is developed upon the feed in the field under certain conditions.

Purpura hæmorrhagica, J. W. COOK (*Amer. Vet. Rev., 27 (1903), No. 3, pp. 209–212*).—In treating cases of this disease in the horse the author reports satisfactory results from making numerous deep incisions in the various swellings which appear during the progress of the disease. This remedy led to recovery in all except 1 case.

Cerebro-spinal meningitis, B. K. DOW (*Amer. Vet. Rev., 27 (1903), No. 6, pp. 515–521*).—A general account of the cause and treatment of this disease. Notes are given on the treatment of cases in the horse. Strychnin, ginger, and belladona were administered without noteworthy beneficial effects.

Biliary fever or malarial fever in the horse, A. THEILER (*Transvaal Agr. Jour., 1 (1903), No. 3, pp. 11–14*).—This disease has long been known in South Africa, and its name is due to certain of the most conspicuous symptoms. It resembles Texas fever in cattle and is not contagious. The disease occurs in a chronic and acute form. Notes are given on the differential diagnosis of this disease. One of the most conspicuous post-mortem appearances is a brownish-yellow discoloration of the muscle tissue. Recovery from one attack appears to confer immunity in the majority of cases.

Ulcerative enteritis in the horse, G. L. BUFFINGTON (*Amer. Vet. Rev., 27 (1903), No. 2, pp. 124–128*).—The author describes the symptoms of this disease and outlines the conditions under which it occurs. Ulcerative enteritis runs a course of from 1 to 3 days and is fatal in a large percentage of cases. When the form of the disease is not too acute some benefit is derived from the administration of gentian powder, subnitrate of bismuth, prepared chalk, potassium chlorate, and powdered ginger.

Some facts and theories regarding surra and ulcerative lymphangitis, C. NOCKOLDS (*Amer. Vet. Rev., 27 (1903), No. 2, pp. 129–131*).—In the Philippines surra appears to be a rainy weather disease and persists for from 4 to 6 weeks after the dry season begins. The disease still prevails greatly in the Philippines and is the cause of enormous losses in horses. Brief notes are given on the possible agency of insects in carrying the disease. Ulcerative lymphangitis is said to be on the increase. More cases occur during the wet season than during the dry season. This disease appears to be caused by an organism which gains entrance in wounds.

The tsetse-fly disease and other related diseases, C. SCHILLING (*Arch. Schiffs u. Tropen-Hyg., 7 (1903), No. 6, pp. 255–262*).—Notes on the nature and cause of various diseases of animals and man due to infection with species of Trypanosoma.

The action of human serum on the Trypanosoma of nagana, mal de caderas, and surra, A. LAVERAN (*Compt. Rend. Acad. Sci. Paris, 137 (1903), No. 1, pp. 15–19*).—Human serum when injected into animals infected with nagana has already been shown by the author to be very effective in destroying the blood parasite.

Similar results have been obtained and are reported in this article in experiments with surra and mal de caderas. The action of human serum was shown to be very similar toward all 3 species of Trypanosoma. When 0.5 to 1 cc. of human serum is injected hypodermically into mice inoculated with nagana, the blood parasites disappear within 24 to 36 hours.

Nagana, surra, and mal de caderas as three distinct diseases, A. LAVERAN and F. MESNIL (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 25, pp. 1529–1532*).—Evidence is presented to show that these diseases are all distinct from one another. They are due to 3 distinct species of Trypanosoma, viz: *T. evansi*, *T. brucei*, and *T. equinum*. Animals immunized against 1 species of Trypanosoma were found not to be immune to the other species.

Glanders in camels, A. P. PATROVSKI (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), Nos. 6, pp. 613–667; 7, pp. 712–765, pls. 5*).—The author conducted an elaborate series of experiments and made numerous observations on the development of glanders in camels from natural infection and also from artificial inoculation. Material obtained from glanderous camels was inoculated by various methods into small experimental animals and also into cattle and horses. The disease was found to be identical in all these animals.

Notes are given on the symptoms and post-mortem findings in glanders in camels, and on experiments made for the purpose of developing a rapid method for diagnosing glanders in these animals. The inoculation of guinea pigs was found to be one of the more successful and rapid methods of diagnosis. The question of the agglutination of glanders bacilli was studied and it was found possible to produce this process by treatment with serum of diseased animals, but the method is not recommended as reliable in all cases.

Rabies or hydrophobia, H. F. PALMER (*Amer. Vet. Rev., 27 (1903), No. 4, pp. 328–330*).—Brief notes on the etiology and treatment of this disease.

Malignant enzootic anemia of kennel dogs due to infection with blood-consuming worms (Dochmius trigonacephalus), F. H. MILLER (*Amer. Vet. Rev., 27 (1903), No. 6, pp. 491–511, figs. 4*).—While distemper is the most important disease to which dogs are subject, a great loss is suffered from intestinal parasitic worms. Notes are given on the appearance and life history of *D. trigonacephalus*, which is parasitic in the small intestines of young dogs. This disease is, according to the author's experience, very prevalent in New York City and neighboring localities and has proved to be very difficult to treat. The disease is most frequent in young puppies up to 10 weeks of age, since up to that age the animals apparently have no resisting power to the disease.

The parasitic worm which causes this disease has been found almost as abundantly in kennels maintained under the best sanitary conditions as in filthy locations. The disease appears suddenly, and the chief symptoms are depression, loss of appetite, staring coat, weak pulse, subnormal temperature, and anemia. The pathological anatomy of this disease resembles closely that of *D. duodenalis* in man. The author believes that the dog is the only host of *D. trigonacephalus*. Little success was had in treating this disease. Experiments were made with thymol, male shield fern, creolin, and other antiseptic substances, but the results were not very satisfactory. For preventing infestation with this worm the author recommends that the kennel should be provided with concrete floors, which would thus be impervious to worms.

Diseases of poultry, F. H. ROBERTSON (*Jour. Dept. Agr. West Australia, 7 (1903), No. 5, pp. 357–362*).—An account is presented of the symptoms, cause, and treatment of apoplexy, bronchitis, bumble foot, chicken pox, chicken cholera, canker, roup, leg weakness, and other diseases to which chickens are susceptible. Various recommendations are also made regarding the general sanitary conditions which should prevail in poultry houses in order to prevent the spread of diseases.

AGRICULTURAL ENGINEERING.

Egyptian irrigation, C. T. JOHNSTON (*U. S. Dept. Agr., Office of Experiment Stations Bul. 130, pp. 100, pls. 24, figs. 9*).—This bulletin gives the results of observations made during the winter of 1901–2 of the irrigation works, practices, and administrative system of Egypt, discussed with reference to their applicability to American conditions.

An irrigation project, J. CREVAT (*Jour. Agr. Prat., n. ser., 5 (1903), Nos. 16, pp. 513–515; 17, pp. 532–535; 18, pp. 566–568; 20, pp. 635–638, figs. 5; 6 (1903), Nos. 32, pp. 185–187, fig. 1; 34, pp. 249–254, fig. 1*).—This article discusses the general features of a plan for irrigating the plain of Loyettes from the River Ain, with formulas and tables relating to velocity of flow in canals, capacity of canals, etc.

Irrigation works (*Nature [London], 68 (1903), No. 1765, pp. 404–406*).—Notes on recent reports on irrigation in India, South Africa, and elsewhere.

Irrigation on the Murray: Utilization of the swamp lands, A. J. PERKINS (*Jour. Agr. and Ind. South Australia, 6 (1903), Nos. 8, pp. 489–494, figs. 5; 9, pp. 532–536; 10, pp. 592–595; 11, pp. 659–664*).—The possibility and means of reclaiming the swamp lands along the Murray and the physical and chemical properties and fertilizer requirements of the reclaimed soils are discussed, special attention being given to the soluble salts present.

The relation of rainfall to run-off, G. W. RAFTER (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 80, pp. 104, figs. 23*).—This bulletin discusses the cause, measurement, variation, and distribution of rainfall; the measurement of run-off and the calculation of the results; evaporation as affecting run-off; the movement of ground water, and the relation of geological structure and forest growth to run-off.

The author claims that the cause of rainfall, beyond the cooling of the air below the dew point, is not well understood, and that it is uncertain whether rainfall is to any extent increasing. He holds that there is no general expression giving accurately the relation of rainfall to run-off, every stream being in effect a law unto itself. For convenience of discussion the rainfall and run-off records given in the bulletin are divided into storage, growing, and replenishing periods, and it is shown that a large percentage of the total water supply runs off during the storage period. It is claimed, however, that the run-off of streams has been generally overestimated. Evaporation is shown to be a very uniform element, the largest evaporation occurring in deforested catchment areas. A study of ground water is shown to be of importance in explaining the peculiarities of stream flow. Forests exert an important influence in increasing ground water flow, so that it may be said that the removal of forests notably decreases the minimum flow of the stream. From the evidence adduced it is uncertain whether forests in any way influence the quantity of rainfall.

California hydrography, J. B. LIPPINCOTT (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 81, pp. 488, figs. 4, map 1*).—This is "a summary of as much of the data concerning the water supply of California as is available from printed records and from observations of other engineers and investigations made by this Survey. . . . The discharge measurements include both low-water and flood records and are accompanied by useful precipitation data." Summaries of observations on evaporation at a number of places in Nevada and California are included in the bulletin.

Water conservation, H. G. MCKINNEY (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 12, pp. 429, 430*).—This article discusses the advantages and disadvantages of the construction of dams on an extended scale for the conservation of water in Natal.

Riparian rights and the necessity to declare and define the law with respect to natural water, W. DEACON (*Queensland Agr. Jour., 13 (1903), No. 3, pp. 130–133*).—A brief discussion of this question as applied to Queensland.

Rural hydraulics, V. NICCOLI (*Idraulica rurale. Firenze: G. Barbèra, 1902, pp. 337, figs. 70*).

Historic highways of America, A. B. HULBERT (*Cleveland, Ohio: Arthur H. Clark Co., 1903, vols. 4, pp. 213, pls. 4, maps 4; 5, pp. 205, pl. 1, maps 3; 6, pp. 207, pls. 2, map 1; 7, pp. 194, maps 2*).—Volume 4 deals with Braddock's road and three relative papers; volume 5, the old glade (Forbes's) road (Pennsylvania State road); volume 6, Boone's Wilderness road; and volume 7, portage paths, the keys of the continent. These historic highways are described and discussed in their relation to national development. For a notice of previous volumes of this series see E. S. R., 14, p. 928.

Proceedings of the National Good Roads Convention held at St. Louis, Mo., April 27 to 29, 1903 (*U. S. Dept. Agr., Office of Public Road Inquiries Bul. 26, pp. 80*).—This convention was largely attended, most of the States and Territories being represented. Among the papers and addresses included in the bulletin are The History and Purposes of the Good Roads Movement, by W. H. Moore; Our National Policy, by M. Dodge; Congress and the People, by A. C. Latimer; Improvement of Our Highways, by J. B. Killebrew; Good Roads and Civilization, by N. A. Miles; The Farmers' Right to Recognition, by R. H. Kern; The Relation of Roads to Schools, by R. H. Jesse; Remarks on Ways and Means, by J. Hogg; Factors in America's Progress, by S. Hill; The Road Problem, by W. J. Bryan; The Press and the Roads, by R. W. Wright; Good Roads and How to Get Them, by R. Stone; Pennsylvania's New Road Law, by W. L. Rhodes; Bitumen as a Road Material, by F. J. Warren; Road Laws, by M. R. Campbell; Practical Road Building under the State-aid Plan, by W. L. Dickinson; What the South Wants, by C. P. Lane; Earth Roads by the Missouri Method, by G. W. Waters; Self-help better than Government Aid, by L. Young; Education of the People on the Good Roads Question, by J. H. Brigham; The Iowa Idea of the Good Roads Problem, by A. B. Cummins; and Good Roads as an Element in National Greatness, by T. Roosevelt.

Seventh annual report of the commissioner of highways, Ontario, 1902, A. W. CAMPBELL (*Toronto: Ontario Dept. Public Works, 1903, pp. 152, pl. 1, figs. 37*).—This is a report on road and street improvement in Ontario during 1902, and contains articles dealing with the following subjects: The good roads movement in Ontario; county roads; various laws of the province affecting road making; township reports on progress in highway improvement; modern road making, including brief discussions of road surfacing, drainage, use of broken stone and gravel, dirt roads, repair of roads, use of graders, crushers, rollers, and scrapers, hauling and spreading road metal, location with reference to hills, tile and concrete culverts, highway bridges, and snow roads; and reports from various towns on methods and progress of road improvement. There are also given specifications for macadam streets, concrete sidewalks, concrete curb and gutter, and for testing Portland cement.

Road dragging (*Mo. Bul. Missouri State Bd. Agr., 3 (1903), No. 1, pp. 42, figs. 7*).—This bulletin discusses the method of road dragging proposed and successfully practiced by D. W. King, of Maitland, Mo. The construction and use of the road drag is thus described: "The drag is made by splitting a log, placing the two pieces about 30 in. apart (with the flat sides both facing in the same direction), and pinning them together. The lower edge of the front piece is protected with iron; an old wagon tire will do. The log should be 10 or 12 in. thick and about 10 ft. long. Fasten a chain or heavy wire a foot or 18 in. from each end by which to haul it. Hitch the team so the drag will move the dirt toward the center of the road. The hitch is next in importance to the time at which the dragging is done. The right time is just as the road dries after a rain or when it is thawed on top during the winter and spring, and it should be dragged every time."

The bulletin also contains articles on The Best Application of Our Road Laws, by G. W. Waters, and The General Interest of the United States Government in the Improvement of Public Roads, by W. R. Richardson.

A proposed agricultural vehicle of the Arabian type, MARÉCHAL (*Bul. Dir. Agr. et Com. [Tunis], 8 (1903), No. 28, pp. 312–339, figs. 12*).—A two-wheel cart is described in detail, with results of tests of draft on different kinds of roads and descriptions of harness to be used with the cart.

The utility of motor cars for the carriage of produce in country districts, J. T. BELL ET AL. (*Queensland Agr. Jour., 13 (1903), No. 2, pp. 110–121*).—A general discussion of the proposition to substitute motor freight cars for the so-called agricultural railways, which are claimed to have been unprofitable in Queensland.

Applications of electricity to agriculture, E. GUARINI (*Engineer. Mag. and Ind. Rev., 25 (1903), No. 4, pp. 550–561, figs. 9*).—The agricultural applications of electricity discussed in this article are measurement of rainfall and for storm warning (Lancetta's apparatus), telegraphy and telephony, operating plows, appliances for felling trees, thrashing machines, etc. An electrically operated farm at Crottorf, Saxony, is described, especial attention being given to the installation of the electrical apparatus. Figures are quoted to show that the cost of electric plowing has been reduced as low as $2 to $2.50 per acre. Two systems are employed—single motor and double motor.

Farm power, R. HOGGAN ET AL. (*Queensland Agr. Jour., 13 (1903), No. 2, pp. 123–130*).—A discussion of the adaptability of gasoline engines to farm work, with an account of the construction and operation of such engines.

Farm engines and how to run them, J. H. STEPHENSON (*Chicago: Frederick J. Drake & Co., 1903, pp. 215, pl. 1, figs. 63*).—"A simple, practical handbook, for experts as well as for amateurs, fully describing every part of an engine and boiler, giving full directions for the safe and economical management of both; also several hundred questions and answers often given in examinations for an engineer's license, and chapters on farm engine economy, with special attention to traction and gasoline farm engines, and a chapter on the science of successful thrashing."

The use of agricultural machinery in the United States, G. FISCHER (*Deut. Landw. Presse, 29 (1902), Nos. 101, pp. 813, 814, figs. 2; 102, pp. 821, 822, figs. 6; 30 (1903), Nos. 1, p. 4, fig. 1; 3, pp. 20, 21, fig. 1; 4, p. 26; 7, pp. 47, 48, fig. 1; 10, p. 74, figs. 6; 12, pp. 91, 92, figs. 11; 16, p. 127, figs. 5; 18, p. 148, figs. 2; 20, pp. 164, 165, figs. 6; 22, p. 184, figs. 7; 25, p. 211, figs. 2*).—The implements and machinery discussed include plows, harrows, fertilizer distributers, seeding machines, harvesting machines, thrashing machines, elevators, hay handling and loading apparatus, windmills, cold storage and drying rooms, road shovels, silos, machines used in maize culture, dairy apparatus and utensils, and apparatus for preserving and canning fruit.

Markets for agricultural implements and vehicles in foreign countries, (*Spec. [U. S.] Consular Rpts. 27, 1903, pp. XLVIII + 181, figs. 34*).—The questions considered in these reports are the cost of hand labor as related to labor-saving machinery; suitability of roads and draft animals in foreign countries to American vehicles; the extent to which agricultural implements, vehicles, etc., are used in the different countries; and the possibility and means of extending the trade in these articles.

MISCELLANEOUS.

Twelfth Annual Report of Oklahoma Station, 1903 (*Oklahoma Sta. Rpt. 1903, pp. 15–71*).—This includes a report of the director, a summary of the press bulletins issued during the year, meteorological data noted elsewhere, and a financial statement for the fiscal year ended June 30, 1903. The press bulletins, which are to a certain extent a repetition of matter contained in the regular bulletins of the station, deal with a variety of subjects, including the culture of wheat, oats, alfalfa, and peanuts, making lawns, testing seeds, comparative feeding value of cotton seed and cotton-seed meal, feeding experiments with steers and pigs, Texas fever, pink-eye, borers in trees, Hessian fly, body blight of pears, grapevine-leaf hopper, melon louse, striped cucum-

ber beetle, bagworms, chinch bug, planting seeds of forest trees, peach culture, and varieties of fruit for Oklahoma.

Thirteenth Annual Report of Wyoming Station, 1903 (*Wyoming Sta. Rpt. 1903, pp. 68*).—This includes the organization list of the station, a report of the director, a financial statement for the fiscal year ended June 30, 1903, and reports of members of the station staff, parts of which are noted elsewhere. The report of the director discusses, among other subjects, the origin and purpose of the station; cooperative work; station equipment and buildings, and lines of work that may profitably be undertaken by the station, especially in stock feeding and breeding; and includes abstracts of the regular bulletins issued during the year, and reprints of press bulletins dealing with storage reservoirs, food adulteration and inspection, the prevention of grain smut, and the Rhizoctonia disease of potatoes.

Index to Wyoming Station bulletins, GRACE R. HEBARD (*Wyoming Sta. Index Bul. C, pp. 33*).—A list of the publications of the station since its organization, and a subject index to Bulletins 38–53, issued from September, 1898, to June, 1902.

Crop Reporter (*U. S. Dept. Agr., Bureau of Statistics Crop Reporter, vol. 5, Nos. 4, pp. 25–32; 5, pp. 33–40; 6, pp. 41–48*).—These numbers, for August, September, and October, 1903, contain the usual statistical information on the condition of crops in the United States and foreign countries.

Sources of the agricultural imports of the United States, 1898–1902, F. H. HITCHCOCK (*U. S. Dept. Agr., Division of Foreign Markets Bul. 31, pp. 150*).—The total value of the agricultural imports during the fiscal year 1902 was $413,744,557 and the average value for the 5 years covered by this report was $379,124,315. Of the imports for 1902 Brazil supplied 15.07, the United Kingdom 8.74, Cuba 7.09, Japan 6.32, France 5.56, and Italy 5.19 per cent. The principal agricultural imports were coffee, animal fibers, hides and skins, sugar, vegetable fibers, fruits and nuts, alcoholic liquors, tobacco, tea, vegetable oils, and cocoa and chocolate. A similar statistical report for the years 1897–1901 was published as Bulletin 28 of the Section (E. S. R., 14, p. 508).

Distribution of the agricultural exports of the United States, 1898–1902, F. H. HITCHCOCK (*U. S. Dept. Agr., Division of Foreign Markets Bul. 32, pp. 224*).—The total value of the agricultural exports of the United States during the fiscal year 1902 was $857,113,533 and the average value for the 5 years covered by this report was $861,037,815. Of the agricultural exports during 1902 the United Kingdom received 48.62, Germany 15.39, the Netherlands 5.56, and France 5.34 per cent. Cotton constituted 34.02 per cent of the total agricultural exports, grain and grain products 24.9 per cent, and meat and meat products 22.85 per cent. A similar statistical report for the years 1897–1901 was published as Bulletin 29 of the Section (E. S. R., 14, p. 508).

Belgium's foreign trade in agricultural products for 1902 (*U. S. Dept. Agr., Division of Foreign Markets Circ. 26, pp. 8*).

Agricultural returns for Great Britain for 1902 (*London: Bd. Agr., 1903, pp. XL + 264, fig. 1, maps 2*).—A report on the agricultural returns relating to acreage and produce of crops and number of live stock in Great Britain, with summaries for the United Kingdom, British possessions, and foreign countries, and particulars of prices, imports, and exports of agricultural produce.

Letters on agriculture in the West Indies, Spain, and the Orient, D. G. FAIRCHILD (*U. S. Dept. Agr., Bureau of Plant Industry Bul 27, pp. 40, pls. 5*).—This contains the author's observations on agricultural conditions in the British West Indies, the Philippine Islands, Spain, China, the Persian Gulf region, and Japan. Comments are made especially upon the preparation being made in the British West Indies for the establishment of experiment stations and agricultural colleges, the culture of yams in Jamaica, the opportunities for agricultural and botanical research in the Philippine Islands, and breeds of milch cattle and carabaos for these islands. The author speaks very highly of the Jamaica yam, especially the variety Yampie.

Handbook for settlers (*Pretoria, Transvaal: Dept. Agr., 1902, pp. 96+XV, fig. 1*).—This publication, which is edited by A. R. E. Burton and designed to aid settlers in the Transvaal, contains descriptive and statistical matter regarding the country, discussions of the possibilities of various agricultural and live stock industries, and much miscellaneous information. A glossary of South African words, including many agricultural terms, is also given.

List of State directors of farmers' institutes and farmers' institute lecturers of the United States, J. HAMILTON (*U. S. Dept. Agr., Office of Experiment Stations Circ. 51, pp. 23*).

Bibliographia agronomica universalis, E. OTTAVI, A. MARESCALCHI ET AL. (*Casale: Ottavi Bros., 1903, No. 1, pp. 56*).—This is a list of 445 publications relating to agriculture which have appeared since January 1, 1903. The publications are for the most part in Italian, the intention being to include the foreign publications in the second number, soon to appear. The references are arranged alphabetically by authors under the following headings: General agriculture; soils, agricultural machinery, crops and their utilization; pests and diseases of cultivated plants; special crops; forestry; horticulture; zootechny; animal products; beneficial insects; hunting, fishing, pisciculture, and miscellaneous.

List of journals, with abbreviations used in the catalogue as references (*Internat. Cat. Sci. Lit., List of Journals, 1903, pp. XV+312*).—This contains lists of periodicals in different countries as prepared by the regional bureaus engaged in the preparation of the International Catalogue of Scientific Literature. Some 4,500 periodicals are listed. Instructions for the use of the regional bureaus are appended.

NOTES.

California Station.—A press report states that it has been decided to close the substation near Jackson, known as the Amador or Sierra Foothill Station. The station has been in existence for 6 years.

Georgia College.—Science Hall was completely destroyed by fire the night of November 19. The building was insured for $25,000 and some additional insurance was carried on the apparatus.

Iowa College.—W. W. Smith has been appointed to a fellowship in animal husbandry.

Missouri Station.—The Missouri Louisiana Purchase Commission has appropriated $7,000 to be given in prizes for Missouri corn. Each county is to hold a corn show, and the best corn from the several counties will be exhibited at St. Louis in December, where $1,000 will be distributed in prizes for corn. In connection with each county corn show a farmers' institute will be held, at which corn experts will give thorough instruction in breeding, growing, and harvesting corn. As a climax to this effort to interest Missouri farmers in better methods of corn growing, the College of Agriculture will give a ten-days' corn school. Important results are expected to follow these organized efforts.

South Carolina College and Station.—B. H. Rawl, B. S., has succeeded C. O. Upton in charge of dairy and animal husbandry work in the college and station, Professor Upton having resigned at the beginning of the college year, as previously noted.

Tennessee Station.—A new wing has been added to the dairy barn, which provides ample room for young calves, heifers, and dry cows. It is a three-story structure with stable below, storage for implements on the second floor, and seed room on the third floor. H. H. Hampton, a graduate of the university, has been appointed fertilizer chemist, the samples collected in the fertilizer inspection now being turned over to the station for analysis. The station has recently received several gifts of pure-bred cattle and hogs, and this winter will feed 32 head of beef cattle, 16 of which are grade Herefords from native cows. This is the first attempt the station has made to study the benefits from crossing the pure-bred Hereford sire on native stock. Under the appropriation made by the last legislature for farmers' institutes an endeavor is being made to hold an institute in every county in the State. These institutes are much appreciated, as is evidenced by the very large attendance.

Wyoming University and Station.—E. E. Slosson, chemist, has resigned to engage in literary work.

Plant and Animal Breeders' Association.—The call has been issued for a meeting of plant and animal breeders at St. Louis, December 29 and 30, 1903, with a view to organizing an association. The objects of the proposed association are to study the laws of heredity; to devise better methods of breeding plants and animals; to bring about cooperation in breeding, testing, and increasing the use of improved animals and plants; to better develop the work of registry associations and competitive shows of animals and plants, and, in general, to perfect the knowledge of breeding, and to aid in the better organization of the business of plant and animal breeding. It is proposed to divide into two sections—a plant section and an animal section.

The programme for the St. Louis meeting will provide general sessions for perfecting an organization and for the discussion of topics of interest alike to animal and plant breeders and biologists, and sessions of the two sections.

Agricultural Schools and Experimental Farms in Quebec.—A royal school has been incorporated under the laws of the Province of Quebec for the purpose of establishing and carrying on agricultural schools and experimental farms. The school is to maintain two or more schools and experimental farms in the province, one to be located in the district of Montreal and one in the district of Quebec. Each school will contain accommodations for at least 50 pupils and will give a 3-years' course, tuition and board being free of charge. The course will include all branches of agriculture, horticulture, aboriculture, dairying, slaughtering and curing of meats, carpentering, blacksmithing, and such other trades as may be useful to farmers. The school will establish experimental farms and "farms for tuition purposes," will clear and improve land and dispose of the same to its graduates and others, and will make advances to settlers to enable them to take up lands.

Primary Agricultural Schools in Saxony.—According to a recent issue of the Consular Reports there are 12 primary agricultural schools in Saxony and 2 horticultural schools. Candidates for admission to these schools must be at least 14 years of age, and no one will be considered who has not completed the prescribed course at some ordinary public school. The subjects taught in the primary agricultural school at Meissen, for example, include German, arithmetic, surveying, general agriculture, bookkeeping, writing, geometry, natural history, fruit raising, political economy, history, drawing, agricultural history, and stock raising.

New Correspondence Agricultural College.—A correspondence college for agriculture has been organized at Sioux City, Iowa, with the following professional staff: Director, Carl C. Magee, Sioux City, Iowa; dean of agricultural department, W. A. Linklater, Sioux City, Iowa; animal husbandry, W. J. Kennedy, of Iowa College of Agriculture and Mechanic Arts; agronomy, P. G. Holden, of the same institution; and veterinary science, A. T. Peters, of the Nebraska Experiment Station. The courses of study offered include animal husbandry, agronomy, veterinary science, stock feeding, stock judging, and short courses in castration, obstetrics, spaying, and sanitary and preventive medicine.

Miscellaneous.—According to a recent announcement a colonial school has been established in connection with the University of Nancy, France, in which instruction is given in forestry, agriculture, economics, etc., the object being to prepare students for positions in the French colonies. The number of students matriculated for 1902–3 was 34. In connection with this school biweekly conferences are held which are open to the public and have been quite largely attended. The director of the new school is Edmond Gain.

The commission appointed to inquire into the steps to be taken toward the establishment of a university for the Transvaal has recommended the acquisition of a site within a convenient distance of Johannesburg and Pretoria, upon which shall be located the teaching university, an agricultural school, and state laboratories for chemistry and animal and vegetable pathology. The appointment of a principal of the highest scientific attainments and approved organizing capacity is urged. Meanwhile H. S. Hele-Shaw, professor of engineering in Liverpool University, has been appointed to organize technical education in the Transvaal and the Orange River Colony.

Thomas Kosutány, director of the Chemical Experiment Station at Altenburg, Hungary, has been appointed director of the Chemical Agricultural Institute and Central Chemical Experiment Station at Budapest, and Josef Adorján has been appointed head chemist in the above institute.

O

EXPERIMENT STATION RECORD.

VOL. XV. JANUARY, 1904. No. 5.

The meeting of the American Association for the Advancement of Science brought together at St. Louis, during the closing week of the year, nearly five hundred persons interested in various lines of scientific inquiry. Although the attendance was smaller than last year, it was a typical gathering of representatives of pure and applied science as related to the heavens above and the earth beneath and, it should be added, upon the earth, for agriculture was there, not in a single section or affiliated society, but in so many of the meetings as to be much in evidence. It had the unusual distinction, for it, of a prominent place in the presidential address, which was upon the subject of Scientific Investigation and Progress.

In considering what the world gains by scientific investigation, Dr. Remsen emphasized the importance of investigations relating to the problem of food supply. Referring to Berthelot's dream of the synthetic preparation of food from water and the carbonic acid of the air, he concluded that "although science is not likely, within periods that we may venture to think of, to do away with the necessity of cultivating the soil, it is likely to teach us how to get more out of the soil than we now do, and thus put us in a position to provide for the generations that are to follow us. And this carries with it the thought that unless scientific investigation is kept up these coming generations will not be provided for."

That there is to be no abatement of this investigation was indicated by the inauguration of two new societies whose fields are distinctly agricultural, and by the programmes of the Society for the Promotion of Agricultural Science and the Association of Economic Entomologists, as well as several sections of the association proper. The American Breeders' Association, as it was finally decided to call the new organization for plant and animal breeders, effected an organization of which the Honorable Secretary of Agriculture was chosen president, which provides for two sections, for plant breeding and animal breeding, respectively. An interesting programme of papers and discussions, relating for the most part to plant breeding, was

presented; and the Society for Horticultural Science formed at Boston last summer carried out a quite lengthy programme.

The initial meetings of these organizations developed an enthusiasm for earnest work which promises to make them useful factors in promoting investigation and advancement along their respective lines. They also increased the general confusion and conflict of programmes which has been evident in the past, and made it increasingly difficult to follow up the papers in a particular line. This became so apparent that joint sessions of several of the associations were held to listen to papers covering common ground.

A brief account of the papers relating to agricultural science which were presented at the St. Louis meeting will be given in the next issue.

The attention which the subject of rural economics received is worthy of special mention, in view of the increasing interest on the part of associations of various sorts in matters pertaining to agriculture and rural life. This is an encouraging indication of the impress being made in directing popular attention to agricultural education and investigation, and the improvement of farm life.

One session of the section on Social and Economic Science was given up to the economic aspects of agriculture. Four papers were read. In the first, on The Function of Forestry in the New Agriculture, T. H. Sherrard called attention to the fact that from one-third to one-half of the forests of the United States belong to farmers, and that their interest in forestry is primarily concerned with the maintenance of wood lots in a productive condition. The method of cooperation which the Bureau of Forestry carries on with farmers in managing forest areas was outlined, and a brief account given of the science of sylviculture as related to farming.

C. F. Curtiss, of Iowa, discussed The Economic Functions of Live Stock, pointing out the relationship between live stock and the maintenance of fertility of the soil, and urging the advantages to the soil and from a business standpoint of combining crop growing and animal production. Animal by-products, which were at first used solely as fertilizers, have nearly all been found to be valuable feeding stuffs for farm animals. They are now first fed to animals and later returned to the soil as manure. The speaker expressed the hope that when diversified farming and animal industry are properly combined the use of artificial fertilizers may become unnecessary.

Agricultural Economics was the subject of a paper by H. C. Taylor of Wisconsin, which was treated from the standpoint of instruction and of agricultural practice. The chief problem in agriculture is how to secure the largest net return from the land. The productive efficiency of the farmer was stated to vary as greatly as the fertility of the soil, and it was urged that theoretically the degree of efficiency of the

farming should be regulated to the productivity of the land. The lack of such an equilibrium was held to be responsible for the dissatisfaction of the farmer and the attempt to better his condition by making a change. This was thought to be reflected in a general way in the ownership of land. It was shown from the statistics compiled by the recent census that the percentage of land-owning farmers has been on a decline for the last twenty years. The causes for this decline apparently vary in different localities. In some cases the great advance in the price of land has brought about an increase in the tenant system, while in other localities the loss of productivity of the soil has necessitated the combination of farms into larger areas under the ownership of fewer individuals, with tenants. Land is often retained for sentimental reasons long after it has become so infertile as to render other occupations necessary for the support of the family. The showing of decline in land ownership caused surprise and led to considerable discussion of the causes and effects.

In a paper on Improvement in Farm Management, W. M. Hays, of Minnesota, urged the desirability of improving the social and educational conditions of farmers, in order to make their living conditions more pleasant and to retain the most active and progressive boys upon the farm. Attention was called to the various factors operating for the development of scientific agriculture and increasing farm production, and thus making the business of farming more attractive from a financial standpoint. The problem of arranging a rotation of crops and making combinations of profitable crops was discussed in considerable detail. The methods followed at the Minnesota Agricultural College in teaching farm management were described, in which the students are required to prepare plans for the laying out and management of their home farms, with the proposed crops for a period of ten years in advance. The preparation of these plans in a definite form necessitates a careful consideration of all the practical problems of farm management, as applied especially to each individual's farm. The adoption of a definite system of farm management, with a simple system of bookkeeping, it was urged would enable farmers to estimate accurately the profits derived from various lines of work, and to abandon the production of unprofitable crops.

The discussion which followed the presentation of these papers evidenced the interest which they aroused in the economic and sentimental features of agriculture and the conditions of rural life. It was agreed that the practical solution of the problems concerned in maintaining a large percentage of farming population and in securing the greatest net returns from the farm is to be accomplished along educational lines.

Ever since the discovery by Priestley and Cavendish in 1785 that the nitrogen and oxygen of the air can be made to combine under the

influence of the electric spark, the question of preparing nitrogenous compounds from the free nitrogen of the air has engaged the attention of scientific men from time to time. It is only within comparatively recent years, however, that the great industrial importance of utilizing this vast store of nitrogen has been fully realized, and serious attempts made to develop practical processes of rendering it available for commercial purposes.

The matter is highly important from an agricultural standpoint, for, as every one knows, nitrogen is the most expensive of the fertilizing constituents and is restricted in supply. The exhaustion of the nitrate deposits which constitute so prominent a source of supply has been placed by reliable estimates at a matter of only a generation or so distant. The air contains nitrogen enough for all, and it has seemed highly probable that ultimately a way would be found for utilizing it for other plants than legumes.

Siemens and Lovejoy and Bradley have made important advances in this direction by the use of high power electric currents for producing nitric acid from the nitrogen of the air. The development in 1894 by Moissan and Willson of an efficient electrical method for preparing calcium carbid has done much to insure the success of a very different process of fixing the free nitrogen of the air, namely, in the form of cyanamids of the alkaline earths. The recent work of Frank and Caro, Pfleger, Erlwein, Rothe, and others in the development of this method gives reasonable ground for hope that the problem of the manufacture of nitrogenous compounds from the nitrogen of the air in a practical way has to a large extent been solved.

The investigations of these men, which have been briefly reviewed in the *Record*, show that by fusion of the carbids of the alkaline earths, especially calcium carbid, in the presence of atmospheric nitrogen freed from the larger part of the associated oxygen, calcium cyanamid is produced. In practice it is found best to combine the preparation of the calcium carbid and of the cyanamid into a single operation, by starting with a mixture of calcium carbonate and coal (as in the making of carbid) and fusing these in the presence of the deoxygenized air. The crude product formed has admixed with it more or less lime and carbon, and contains from 10 to 22 per cent of nitrogen. By further treatment this product can be made to yield free ammonia, cyanid, or a dicyanamid containing 66 per cent of nitrogen, and other compounds. The experiments of Gerlach and Wagner, however, indicate this to be unnecessary from an agricultural standpoint, since the cyanamid can be used directly as a fertilizer. It has no injurious effects on plants, and shows an efficiency fully equal to, if not exceeding, that of the ammonium salts, and but slightly inferior to that of nitrate of soda.

The preparation of the calcium cyanamid is comparatively simple and cheap. A company has been organized in Berlin for the manufacture of nitrogenous compounds by this process, and if further experience fulfills the promise of the earlier work, it seems quite probable that this new source of nitrogen for fertilizing purposes will soon find its way into the markets, and the experiment stations will be called upon to definitely determine its agricultural value.

It is worthy of note that Dr. Remsen, in his presidential address before the Association for the Advancement of Science at St. Louis last month, referred at considerable length to this new discovery in its relation to the nitrogen supply of farm crops, and pronounced it to be "full of promise."

The list of grants made by the Carnegie Institution for research during the past year affords little ground for congratulation to those interested in the promotion of agricultural science. The great field of agriculture has no representation in this list, and the grants made to the related sciences are, from the nature of the subjects to be investigated, of only remote and indefinite application to agriculture.

In all fifty-five separate grants were made, aggregating $147,670, and in addition the sum of $25,000 was set aside for research assistants. Of these grants botany, zoology, and physiology received a total of $41,200, and the physical sciences over $64,000, while engineering received $8,620, anthropology and exploration $6,500 each, psychology $3,600, history $2,000, and bibliography $15,000.

These grants were mainly for research in the domain of theoretical and pure science, rather than for investigations bearing directly on any phase of science as applied to the arts and industries. This is true of the investigations provided for in the biological sciences, as well as in chemistry, astronomy, geology, etc. In botany, for example, the work authorized is mainly systematic and cytological, and for the maintenance of the desert botanical laboratory at Tucson, Arizona; and the two grants under physiology are for researches in connection with human nutrition. Zoology received the largest number of grants among the biological sciences, aggregating $18,000, none of which was for economic work. Among the principal topics in zoology are a study of recent and fossil corals, the blind fishes of Cuba, a monograph on American mosquitoes, investigations in experimental embryology, morphology and classification of deep sea sponges, and $11,000 for the maintenance of twenty tables at the Marine Biological Laboratory at Woods Hole and two at Naples.

The foundation of the composite science of agriculture is so wide that in a broad sense nearly all progress of general knowledge in the natural sciences may ultimately contribute toward the advancement of

agricultural science. But there is such need for fundamental researches on scientific problems immediately related to agriculture, and there are at present so few agencies through which this higher research can be carried on, that it was hoped some of the funds of the Carnegie Institution might be turned in that direction. Such researches are for the most part beyond the means of the individual experiment stations, whose very work has developed the need for them and has brought us to a point in the development of agricultural science where they are well-nigh indispensable to progress. This is true in the nutrition of farm animals, for example, the biology of the soil, the improvement and the nutrition of agricultural plants, the complex operations of cheese making and ripening, and a score of other subjects which are too large and too far-reaching for an experiment station to undertake single handed. In this field especially would the problems seem to be so broad and fundamental in their character, and so far-reaching in their relations to human life, as to "show the application of knowledge to the improvement of mankind."

It would appear that the workers in agricultural science have been very modest in their requests for aid, as the list of applications received up to the close of October, 1903, shows only four under the head of agriculture; three of the applicants did not state the amount desired, and the fourth named $5,000. A larger number of definite topics for investigation would have made the need of aid more evident and imperative, and impressed the claims of agriculture more forcibly upon the attention of the authorities of the institution.

The largest number of applications for grants were in zoology (109), chemistry (89), botany (60), and astronomy and physics (58 each). The total amount of the 142 applications received aggregates $2,200,398, which far exceeds the present income of the institution. The recommendations of the advisory committee carried an additional $900,000 per annum, $400,000 of which was for physics and geophysics, $230,000 for astronomy (with a plan for $2,000,000, extending over twelve or fourteen years), and $120,000 for explorations.

While the report of the institution for the past year may perhaps be taken as an indication of its tendencies, the aggregate amount of these grants and recommendations ($3,111,898) clearly shows that the Carnegie Institution will not be able to cover the ground of general science, let alone the special field of science as applied to agriculture. This emphasizes the great need of special provision for research in agriculture, in a form which will insure to the workers a large measure of freedom from distracting influences and from direct responsibility to a popular constituency.

CONVENTION OF ASSOCIATION OF OFFICIAL AGRICULTURAL CHEMISTS, 1903.

H. W. LAWSON,
Office of Experiment Stations.

The twentieth annual convention of the Association of Official Agricultural Chemists was held at the Columbian University, Washington, D. C., November 19–21, 1903, the president of the association, R. J. Davidson, presiding. In his opening address the president called attention to the desirability of uniform fertilizer laws and proper standards for use in inspection work. An examination of the fertilizer laws of 23 States showed no mutual agreement as regards requirements or the form of statement of composition of fertilizers. The association was urged to exert its influence in bringing about a conformity of fertilizer laws to some definite standard, and having plain, simple, and intelligent statements made regarding fertilizer constituents. The limit of error or deficiency allowable in the percentage composition of fertilizers was considered, and attention was called anew to the resolution adopted by the association in 1900 recommending that the form of nitrogen in fertilizers be determined and reported upon. The speaker commended to the consideration of the association the matter of a uniform method of stating the results of investigations, a change in the temperature used for the graduation of measuring apparatus, and the republishing of Battle and Dancy's chemical conversion tables; and urged the importance of a more hearty cooperation by members of the association in the testing of methods.

The latter point was also emphasized in a brief address by H. W. Wiley, bearing on the needs of the association. The matter of republishing the conversion tables was referred to a committee consisting of H. B. McDonnell, C. B. Williams, and B. B. Ross, with directions to report upon this subject to the secretary of the association.

Hon. James Wilson, Secretary of Agriculture, and Dr. Charles W. Needham, president of Columbian University, were present upon invitation, and addressed the association. Secretary Wilson characterized the work of the association as of great value to the country, and spoke briefly of the progress being made in the execution of the law regarding the importation of food products, declaring that we have

come to the conclusion in this country that food products not good enough for the people in the countries in which they are produced are not good enough for us. The enforcement of the law was reported as being heartily welcomed by American merchants. The establishment by the Federal Government of interstate pure food laws was considered desirable.

The total attendance at the convention exceeded that in previous years. Nevertheless, toward the close, when final action was taken upon the more important matters, such as the adoption of methods, the actual attendance was quite small. Reports were received from all of the referees and from many of the associate referees, and several papers were read. These and the action of the association are referred to in the following summary under appropriate headings.

PHOSPHORIC ACID.

The referee on this subject, B. H. Hite, reported that no cooperative work was undertaken by him during the year, but that attention had been paid in his laboratory to certain modifications of well-known methods, involving the weighing of the yellow precipitate, a report upon which was considered inadvisable at the present time. The report of the associate referee dealt with comparative tests of the gravimetric and volumetric methods for the determination of total phosphoric acid in soils. The determination of phosphoric acid in different classes of phosphates was discussed by several members of the association.

In a communication from E. W. Hilgard, attention was called to the desirability of a better method for the valuation of basic phosphatic slags, and on account of the growing commercial importance of this class of fertilizers the association was urged to take up again the consideration of this question. The referee for next year was accordingly instructed to reconsider this question, with special regard to the establishment of a standard for total phosphoric acid and degree of fineness. Further study of Redonda and precipitated phosphates was also recommended. A paper on the determination of phosphorus in organic materials was presented in this connection.

Report of associate referee, C. B. Williams.—The volumetric and gravimetric methods for the determination of total phosphoric acid in soils were compared by the associate referee and two other analysts. The average results by the gravimetric method were higher than by the volumetric method. The volumetric method was believed to be preferable to the gravimetric method, and was recommended for adoption as an optional method for the determination of total phosphoric acid in soils. Further study of different solvents for phosphoric acid in soils was also recommended.

The determination of organic and inorganic phosphorus in vegetable and animal materials, E. B. Hart and W. H. Andrews.—The work reported was directed mainly to the elaboration of a method for the determination of inorganic

phosphorus. Uniform results for total phosphorus were obtained by the magnesium nitrate and Neumann methods.

The method finally adopted as giving best results in the determination of inorganic phosphorus consisted in extracting 5 gm. of the sample with 125 cc. of 0.2 per cent hydrochloric acid, the mixture being shaken vigorously for 15 minutes, decanting through a filter paper, and washing the residue with water until 500 cc. of filtrate was obtained; neutralizing 200 cc. of the filtrate with ammonia, using litmus as an indicator; adding 10 gm. of ammonium nitrate; warming the solution to 65° C., and adding 2 cc. of nitric acid and 25 cc. of neutral ammonium molybdate, the solution being kept at 65° for 15 minutes and filtered after 1 hour. After ignition and purification by dissolving in dilute nitric acid the phosphorus was weighed as magnesium pyrophosphate.

This article has also appeared in Bulletin 238 of the New York State Station, and an abstract setting forth more fully the results obtained by the use of these methods is given on page 496.

DETERMINATION OF NITROGEN.

The referee reported further tests of methods for determining available organic nitrogen in fertilizers. A change in the neutral permanganate method providing for the use of 2 gm. of material in the case of mixed fertilizers, and as heretofore an amount containing approximately 0.075 gm. of nitrogen in concentrated goods was approved. Further study of methods for available nitrogen was recommended. A paper on the electrolytic reduction of nitrates was read.

Report of referee, F. W. Morse.—Eight laboratories cooperated in testing modifications of the alkaline permanganate method in comparison with the neutral permanganate method for determining available organic nitrogen as used last year. Preliminary work with the alkaline permanganate method showed the necessity of a fixed amount of distillate and the probable advantage of a larger volume of solution. Samples of dried blood and cotton-seed meal were sent out with the request for tests of 3 modifications of the permanganate method.

Nine analysts reported on total nitrogen and 8 on the methods for available nitrogen. The determinations of total nitrogen agreed closely. The percentages of total nitrogen recovered from blood as available were 86.5 by the neutral method, 63.4 by the alkaline method as given in the report of the referee last year, and 69.4 by the alkaline method modified by the use of 150 cc. of the alkaline permanganate solution and distilling off 100 cc. The corresponding percentages in the case of cotton-seed meal were, respectively, 91.6, 46.1, and 58.1.

The referee recommended that in the neutral method a 300 cc. low-form Griffin beaker be used and that 2 gm. of material be taken if the sample is a mixed fertilizer, and also that the study of methods for the determination of available organic nitrogen be continued.

The electrolytic reduction of nitrogen in metallic nitrates, S. H. Sheib.—The electrolytic reduction of nitrates to ammonia, as described by Easton (see p. 444), was tried by Sheib on chemically pure and commercial sodium nitrate and on potassium nitrate with results stated by him to be far from satisfactory

SEPARATION OF NITROGENOUS BODIES.

The referee, L. L. Van Slyke, reported investigations on the separation of nitrogenous bodies in milk and cheese, giving methods for

the estimation of casein monolactate and casein dilactate which were adopted provisionally by the association. The report of R. Harcourt, associate referee on vegetable proteids, was not ready for presentation, but by vote of the association will be included in the proceedings. It was announced that this report would consist largely of compiled matter. W. D. Bigelow, as associate referee on meat proteids, called attention to the comparisons made by H. S. Grindley of the amounts of proteids in the water extracts of raw and cooked meats precipitated by various reagents, and reported investigations made by himself and F. C. Cook during the year.

In the examination of meat proteids the association recommended that further trial be made of phosphotungstic acid alone in hot and cold solutions, phosphotungstic acid followed by bromin, phosphotungstic acid followed by zinc sulphate, and tannin and salt followed by zinc sulphate; and that precipitation by bromin alone and by bromin in the filtrate from zinc sulphate be discontinued. The work by Dr. Grindley is noted below, as is also a paper on the determination of gliadin and glutenin which was presented in this connection.

Report of referee on milk and cheese proteids, L. L. Van Slyke.—A preliminary report was made upon a study of the official method for the determination of casein in milk, explanations being offered for some of the reactions met with in the use of that method. It was believed that the official method could be improved, and the referee announced that the results of the completed investigation along this line would be ready for presentation another year.

A study was made of the relation of casein monolactate and casein dilactate to the Hess and Doolittle method of detecting process or renovated butter. It was pointed out that the characteristics of the curd upon which this test is based depend upon the presence of one or the other of these compounds, and furthermore, that these compounds are dependent upon the amount of acid produced in the ripening of the cream. It was found possible to make genuine butter which would respond to the Hess and Doolittle test for process butter or vice versa, and also that different reactions could be obtained with butter when fresh and when several weeks old. It was believed, therefore, that the test must be regarded as worthless.

The methods devised by the referee and E. B. Hart for the separation and estimation of casein, casein monolactate, and casein dilactate in milk are given below in the form presented: (1) *Determination of casein monolactate in milk.* Casein monolactate in milk coagulates readily at 40° C. Hence, in a milk containing only casein and casein monolactate, the monolactate can be separated by heating the milk to about 40° C., filtering the precipitate formed, washing, and determining the nitrogen in the precipitate. Ten gm. of milk diluted with 90 cc. of water give good results. (2) *Separation of casein monolactate and casein dilactate.* Casein dilactate coagulates completely at 40° C. and below. In milk containing casein mono- and dilactates, we heat 10 gm. of milk diluted with 90 cc. of water to 40° C., and these two salts precipitate and are separated from the milk casein by filtration. The washed precipitate is then treated with 100 cc. of a 5 per cent solution of sodium chlorid and the whole heated to 55° C. with frequent agitation for 2 hours. The process is facilitated somewhat by the presence of pure quartz sand. The casein monolactate goes into solution and is separated from the casein dilactate by filtration and washing. (3) *Separation and determination of casein, casein monolactate, and casein dilactate in milk.* (a) The total amount of nitrogen precipitated by acid is determined by the official method

prescribed for determining casein in milk. (b) We heat 10 gm. of milk diluted with 90 cc. of water to 40° C. for 15 or 20 minutes, filter the precipitate formed, and wash with distilled water. The precipitate is then transferred to a small Erlenmeyer flask, provided with a stopper, treated with 100 cc. of a 5 per cent solution of sodium chlorid, and heated at 55° C. for 2 hours, with frequent agitation. The mixture is then filtered, the remaining precipitate washed with water, and the nitrogen determined in both the precipitate and filtrate. The nitrogen in the precipitate represents casein dilactate; that in the filtrate, casein monolactate. The sum of these two, subtracted from the total nitrogen found by precipitation with acid, gives the amount of nitrogen as casein.

Report of associate referee on meat proteids, W. D. BIGELOW.—Data are given for the earlier work of the associate referee and R. Harcourt, heretofore published only in part, and studies made during the year by the associate referee and F. C. Cook are reported. Solutions were made of commercial products, including meat extracts, beef juice, digested meat powder, and commercial peptones, and aliquot portions were subjected to the action of bromin, zinc sulphate, phosphotungstic acid, and tannin and salt. The filtrates from the precipitates obtained by the last three reagents were divided into aliquot parts and treated with the four reagents mentioned in different combinations. The amount of nitrogen precipitated by phosphotungstic acid was greater than that precipitated by any other single reagent, except in the products containing large amounts of peptones. The use of bromin alone was again shown to be unreliable.

The highest results from reagents in combinations were obtained from the tannin-salt reagent followed by zinc sulphate in the case of the filtrate from zinc sulphate. A marked influence was apparently exerted by the order in which the various reagents were employed. While tannin and salt followed by zinc sulphate gave the highest results, zinc sulphate followed by tannin and salt gave the lowest results. The author cautioned against drawing conclusions from the data which were presented merely as preliminary. A further study of the combinations of various reagents was deemed advisable.

A study of the nitrogenous constituents of meats, H. S. GRINDLEY.—Cold water extracts of raw and cooked meats were examined by methods which were described in detail. The different determinations expressed in percentages of the weight of original substance and in percentages of the total nitrogen soluble in water were given.

Eight samples of raw meats, 6 of boiled, and 6 of broiled or roasted meats were examined. In the case of the raw meats the average percentages of total nitrogen soluble in cold water by the different methods of analysis were as follows: (1) Coagulated by heat, 45.51; (2) precipitated by zinc sulphate, 4.18; (3) precipitated by bromin in filtrate from zinc sulphate, 1.31; (4) proteid nitrogen, 50.99; (5) non-proteid nitrogen, 49.01; (6) precipitated by bromin directly, 39.45; (7) precipitated by phosphotungstic acid in hot solution, 42.95; (8) precipitated by tannin and salt, 48.80; (9) precipitated by phosphotungstic acid in cold solution, 49.17; (10) as free ammonia, 2.86. In the case of boiled meats the average percentages were as follows: (1) 3.24, (2) 15.15, (3) 5.42, (4) 23.79, (5) 76.21, (6) 11.97, (7) 10.21, (8) 22.71, (9) 26.79, (10) 6.16. The averages for all determinations were (1) 22.23, (2) 8.09, (3) 2.85, (4) 33.16, (5) 66.84, (6) 23.50, (7) 24.73, (8) 30.87, (9) 32.05, (10) 3.69 per cent.

It was stated that while in general the triplicate determinations upon each sample agreed fairly well, the results obtained by different methods upon different samples varied greatly. The author considered it desirable to determine directly the amount of coagulable proteids contained in water extracts of meats and announced that further studies were being made upon this subject. Precipitation by bromin was found unsatisfactory and precipitation by phosphotungstic acid gave but slightly higher results.

Determination of gliadin and glutenin in flour by the Fleurent-Manget method, J. S. CHAMBERLAIN.—This method was believed to give too high results for gliadin, and, consequently, too low results for glutenin. Based upon the results of his study, which were reported in detail, the author gave a method for the determination of the proteids of flour, which is in substance as follows:

(1) Moisture is determined at 105° C. in an atmosphere of hydrogen or coal gas. (2) All determinations are made upon air-dry flour, either standard milled, or capable of passing through bolting cloth 90 to 100 meshes to the inch. (3) Four to six grams of the flour is placed in a 150 or 200 cc. flask and exactly 100 cc. of a 5 per cent solution of potassium sulphate is introduced. The mixture is shaken frequently for 18 to 24 hours, or placed in a shaker for 6 hours. After settling, 50 cc. is filtered off and the nitrogen determined in this by the Kjeldahl method. The nitrogen multiplied by 2 gives the nitrogen in the original sample. The nitrogen in the flour multiplied by 5.68 gives the proteids in the flour soluble in the dilute salt solution. (4) Two to four grams of flour is extracted in a similar manner with 100 cc. of 70 per cent alcohol, a digestion flask being used. The liquid is filtered off and the residue washed several times into the filter paper and the whole thoroughly washed with alcohol. The filtrate is acidified with sulphuric acid and evaporated almost to dryness when the nitrogen is determined. The nitrogen multiplied by 5.68 gives the proteids soluble in 70 per cent alcohol. (5) Nitrogen is determined in the residue (including filter paper) from the alcohol extraction, which, multiplied by 5.68, gives the proteids insoluble in 70 per cent alcohol. (6) The residue from a second alcohol extraction is extracted with 5 per cent sulphuric acid solution, as described above, and the nitrogen determined. The nitrogen multiplied by 5.68 gives the proteids in the residue from alcohol extraction soluble in the dilute salt solution. (7) The difference between the proteids obtained in (6) and (5) is glutenin. The difference between the proteids obtained in (3) and (6) subtracted from the proteids obtained in (4) gives the gliadin.

POTASH.

The work on this subject during the year was confined to the determination of potash in mixed fertilizers and moisture in potash salts. The reading of the report of the referee was followed by a general discussion. No action was taken by the association other than to refer the suggestions and recommendations contained in the report to the referee for next year.

Report of referee, F. B. CARPENTER.—Samples were sent to a large number of chemists, of whom 18 reported results. With one or two exceptions results by the official method for determining potash were fairly concordant, though in most cases considerably below the theoretical amounts present. A modification of the official method gave higher percentages of potash, but with less uniformity. A modification of the optional method of the association was tried, with the conclusion that it was too troublesome for practical work.

Numerous experiments were made by the referee for the purpose of determining the cause of low results on potash, and of devising some method for overcoming this difficulty. Neutralization with sodium hydrate instead of ammonium hydrate was tried with promising results. In this modification of the official method a small amount of hydrochloric acid is added to liberate any occluded potash in the substance, and sodium hydrate is used instead of ammonium hydrate to prevent any occlusion or absorption of potash in the precipitate.

No definite conclusions were considered warranted from the amount of work done. Further study of this modification was suggested. The results on moisture by the

official method were not very concordant. It was suggested that possibly better results might be obtained with a temperature somewhat lower than 130° C. The referee recommended that the association take some action as to the determination of moisture in potash salts by drying at a stated temperature or by ignition, and that the method thought most desirable be studied further, with a view to securing more concordant results.

SOILS.

The work on this subject under the direction of the referee related to the determination of available potash and phosphoric acid in soils, methods for the analysis of alkali soils, and a study of soil acidity. The association approved the referee's recommendation that tests be made of greater concentrations than $\frac{N}{200}$ hydrochloric acid for determining available phosphoric acid. The suggestions for further work on the solubility of phosphoric acid and potash in the different soil layers, an investigation of methods for determining total phosphoric acid, and the proposed method for the determination of water-soluble constituents in alkali soils were left to the discretion of the next referee.

Several changes in the official methods for the analysis of soils proposed by the referee were approved. These are two evaporations and filtrations for the removal of silica from acid solutions, the introduction of the volumetric method for phosphoric acid as an alternate method, and the requirement that in the determination of humus the filtered ammonia extract be clear and free from turbidity. The referee for next year was requested to test the value of proposed methods for comparing the ability of different soils to support the growth of nitrifying organisms under different conditions. The matter of testing the methods for determining water-soluble plant food in soils described in Bulletin 22 of the Bureau of Soils was brought up and referred to the next referee.

A report of investigations relating to the fixation of atmospheric nitrogen was presented by J. G. Lipman, and remarks concerning the use of Redonda phosphate on acid soils were made by H. J. Wheeler.

Report of referee, F. P. Veitch.—In a number of soils examined by the referee and C. C. Moore, potash and phosphoric acid were determined in extracts made with $\frac{N}{200}$ hydrochloric acid, and potash was also determined in aqueous extracts. The results indicated that the acid extraction usually removed less phosphoric acid and more potash than were removed by the crops grown. The referee therefore recommended that tests be made of stronger acid solutions in the determination of phosphoric acid.

The results with water as a solvent for potash were not considered as bearing out the indications of preliminary work, but were believed to be of sufficient significance to justify further tests with the ratio of solvent to soil changed from 5 to 1 to 10 to 1. Methods for determining total phosphoric acid were also believed to need further investigation. The methods for alkali soils were tested by A. Seidell and B. E. Brown, attention being paid to the ratio of soil to water and the effect of time on the solu-

bility of alkali salts. No advantage resulted in extending the time of digestion beyond one day. The evidence obtained was considered as favoring the use of 50 gm. of soil to 1 liter of water. Provisional methods for the analysis of alkali soils were submitted by the referee.

Soil acidity was studied by the referee, whose report upon this subject contained a discussion of the relation of soil reaction to plant growth, a review of the experimental work done in this country on partial and complete neutralization, results of extended tests of the sodium chlorid and lime-water methods proposed at the last meeting of the association and described in the proceedings, and a consideration of the nature of soil acidity. From the results of his own experiments relating to the effects of acid and alkaline reactions upon plant growth and a study of available data on this subject, the referee tentatively concluded that a soil slightly alkaline from carbonate of lime furnishes the best condition for the economical production of crops, and that any method for estimating the acidity or the lime requirements of soils should be based upon this hypothesis. The results by the sodium chlorid and lime-water methods diverged as the amount of organic matter in the soil increased, in most instances higher results, except possibly in soils deficient in organic matter, being obtained by the lime-water method.

Data were submitted which indicate that acidity as determined by the sodium-chlorid method is due to the solution in sodium chlorid of acid-salt-forming bases, plus the water-soluble acids, and that but little, if any, of the difficultly soluble organic acid material is estimated by this method. Only traces of free hydrochloric acid were found in any of the sodium chlorid filtrates from the soil. The lime-water method was believed to show beyond a doubt the amount of lime required under the most favorable condition of distribution to render the soil alkaline.

The referee believed that work should be directed toward determining how much of the total apparent acidity of soils must be neutralized in order to produce maximum yields economically rather than to further study of these methods.

The fixation of atmospheric nitrogen by bacteria, J. G. LIPMAN.—The literature of this subject was reviewed and several series of laboratory experiments were reported in detail. The behavior of *Azobacter vinelandii* isolated by Dr. Lipman was illustrated by the results of experiments in which the organism was grown in solutions containing either no nitrogen or only a small quantity of nitrogen. The fixation of nitrogen in cultures was found to increase as the surface exposure increased. The evidence was not conclusive as to the utilization or nonutilization of filter paper by the bacteria as a source of carbon. The presence of filter paper in small quantities seemed to increase nitrogen fixation, but when the amount was increased beyond a certain point a retarding effect was observed. A similar influence was noticed as the result of using different quantities of mannite.

The fixation of nitrogen by *A. vinelandii* was increased when this species was grown in the presence of a bacillus designated *B. 30.* A number of other organisms grown with *A. vinelandii* seemed to exert no influence. The intention of extending the experimental work to actual soil conditions was announced.

Redonda phosphate, H. J. WHEELER.—It was reported that Redonda phosphate, which contains from 35 to 40 per cent of reverted phosphoric acid, had been found, in experiments extending over a period of years, to have very little value when used upon an acid soil. When applied to a limed soil the results were very much better. Upon soil limed sufficiently to enable the growth of all ordinary crops in a satisfactory manner, but probably not alkaline in reaction, this phosphate was nearly equal in value for certain crops to some of the soluble phosphates. This was true of grass during a period of 4 years, but not true of Swedish turnips and beets. Millet and some other plants seemed to possess exceptional ability to use this phosphate on both limed and unlimed soils.

The after effect of Redonda phosphate on acid soils was practically nothing, but on limed soils was relatively much better, though poor in comparison with other phosphates. The common occurrence of acid soils in the United States and the reports that Redonda phosphate is used extensively in the manufacture of mixed fertilizers were pointed out as making this subject one of the utmost importance. It was believed that soils must be put in such a condition as to render Redonda phosphate effective or else methods of chemical analysis must be devised for discriminating against this material. In view of the facts stated it was considered desirable that the association take under immediate consideration the methods for the determination of phosphoric acid in commercial fertilizers.

DAIRY PRODUCTS.

G. W. Cavanaugh, as referee on this subject, made no formal report, but recommended further study of the effect of preservatives upon the albumin of milk, with special reference to the quantitative determination of albumin. This recommendation was approved. The paper noted below was presented in this connection.

Note on the Waterhouse test, modified, for the detection of renovated butter, G. E. Patrick.—In the Waterhouse test, as used by the author, the sample is melted in water instead of milk. It was reported that 4 samples of canned oleomargarine from Europe were found to granulate in this test the same as genuine butter, which modified somewhat views based upon earlier work and reported to the association 2 years ago. The results of several tests led the author to suggest that the granulation of butter in this test may possibly be affected by the pasteurization of the cream from which it is made.

FOODS AND FEEDING STUFFS.

The cooperative work done on feeding stuffs during the year was directed to the determination of fat and crude fiber. The association requested further study by the referee of the composition of the ether extract obtained from the residue from fat determination by the official method after this residue has been digested with pepsin, and a further comparison of the König and official methods for the determination of crude fiber and the determination of pentosans in the crude residue. A paper submitted by C. A. Browne reported work relating to the occlusion of fat as a source of error in analytical work, and to the determination of acidity in feeding materials. The attention of the association was called by H. W. Wiley to the work of the international committee on fertilizers and feeding stuffs concerning uniform methods for sampling.

Report of referee, F. D. Fuller.—Samples of distillers' grains and bran were sent to 11 analysts with directions for determining ether extract and crude fiber. In the determination of ether extract a comparison was made of the official method and the Dormeyer method. The average results obtained by the official method were 11.33 per cent for distillers' grains and 5.43 per cent for bran, the calculation being made to water-free substance. The corresponding percentages by the Dormeyer method were 11.84 and 5.52, showing higher results on both materials by the Dormeyer method.

In the estimation of crude fiber, the official method, the König method, and the König method modified by the additional treatment of the fiber with sodium hydrate as in the official method, were compared. The average results by the official method were 14.96 per cent for distillers' grains and 11.74 per cent for bran, by the König method 19.73 per cent for distillers' grains and 12.49 for bran, and by the modified König method 12.12 per cent for distillers' grains and 10.48 for bran. Inasmuch as the official method does not remove the pentosans and the König method fails to remove albuminoids, the two methods were not considered comparable. The modified König method gives a much purer fiber.

The nitrogen content of the crude fiber obtained from distillers' grains by the official method was 0.27, by the König method 1.94, and by the modified König method 0.26 per cent. In the crude fiber obtained from wheat bran by the König method the nitrogen content was 0.195, none being obtained from the crude fiber by the other two methods. The referee did not believe that the higher results by the official method were due entirely to the presence of pentosans, but that the glycerol-sulphuric acid mixture exerted a hydrolytic action upon the fiber in the König methods. From practically pure cellulose prepared by treating absorbent cotton successively with dilute sulphuric acid and dilute sodium hydrate only about 87.6 per cent of crude fiber was recovered by the König method.

The referee recommended research work to determine the true nature of the ether extract obtained after digesting the residue from the official method of fat extraction with pepsin and to prove or disprove that the glycerol-acid mixture of the modified König method has a hydrolytic action upon crude fiber.

Notes upon the analysis of feeding materials, C. A. Browne, Jr.—The attention of the association was directed one year ago by Dr. Browne as referee on cattle feeds to work by Beger, in which additional quantities of fat were obtained from certain materials rich in protein by subjecting the residues from ordinary ether extraction to digestion with pepsin and again extracting. During the year pepsin digestion before extraction was compared with the official method of the association on samples of rice bran and rice polish, the results showing no appreciative differences.

In the examination of the feces from steers fed these materials, on the contrary, very decided differences were obtained, the excess of fat extracted by the pepsin method amounting in one instance to over 4 per cent. In this particular case the coefficient of digestion of the feeding stuff calculated from the results obtained by the official method was 78.2 per cent and from the results obtained by the pepsin method 66 per cent, indicating the possibility of introducing a serious error in tables of digestive coefficients by the incomplete extraction of the fat. A similar source of error was observed in mixed feeds containing molasses, the occlusion in this case being attributed to the dried residue of sugars instead of to the protein constituents.

In determining the total acidity of feeding stuffs the author found extraction with 90 per cent alcohol and titration with deci-normal alkali very satisfactory. The results by this method in the case of rice meal were slightly higher than those calculated from the acid number of the fat, indicating the presence of other acids than free fatty acids.

FOOD ADULTERATION.

Upon the suggestion of the referee, W. D. Bigelow, the reports and papers on this subject were this year considered by the association as a whole, instead of in committee as heretofore. No reports were presented by the associate referees on saccharin products, wine, beer, vinegar, baking powder and baking chemicals, meat and fish, cereal

products, infants' and invalids' foods, vegetables, condiments other than spices, and tea and coffee. Attention was called to the report on cocoa and cocoa products, which is to be printed and submitted to the referees for criticism and approval before being formally presented to the association. Considerable work was done during the year on meat products and cereal products, but as the reports or papers upon these subjects related mainly to the separation of nitrogenous bodies they were considered under that heading. The reports were presented by the associate referees on colors, fruit products, distilled liquors, flavoring extracts, spices, oils and fats, dairy products, and preservatives. The four recommendations of the associate referee on distilled liquors, noted below, were approved. The report of the committee, favoring the insertion of the Hanus method of determining iodin absorption as a provisional method, was accepted. The methods recommended by the associate referee for the detection of preservatives and coloring matters in dairy products, the estimation of fat in cheese, and the analysis of condensed milk, were adopted provisionally, as was also a modification of the provisional method for determining glucose. A paper on the subject of saccharin products was read by A. E. Leach.

Report of associate referee on colors, W. G. Berry.—Owing to the large amount of work required in the preparation of a complete and systematic résumé of the subject of colors in connection with food stuffs, the associate referee presented only a provisional report upon this subject, deferring the complete report until another year. Some portions of the synopsis were elaborated. Collaboration was requested on the following points: (1) Solubility of the coal tar and vegetable dyes in various solvents; (2) extractive values of the various solvents for dyes in neutral, acid, and alkaline solutions; (3) characteristics of the natural coloring matters in fresh fruits, vegetables, and wines; (4) testing new methods noted in the various chemical journals.

Report of associate referee on fruit products, L. S. Munson.—It was stated that practically nothing had been done on this subject during the year. Several changes in the provisional methods necessitated by changes recently made in the official methods were recommended.

Report of associate referee on distilled liquors, C. A. Crampton.—Letters requesting cooperation were sent to a number of chemists, but reports were received from only two. These reports contained analytical data and suggestions for the determination of free and combined acids, aldehydes, furfurol, and coloring matters, and were given in full. The associate referee had expected to report upon a line of work relating to the establishment of standards which had been carried on by him for 5 years, and which formed the subject of a preliminary communication to the American Chemical Society at its last annual meeting (E. S. R., 14, p. 524), but found it necessary to postpone the report for another year.

The following modifications of the provisional methods of the association were recommended: (1) In the determination of alcohol, a higher dilution of the liquor before distillation; (2) in the determination of extract, evaporating nearly to dryness on the water bath, then transferring to a water oven and drying at a temperature of boiling water; (3) in the determination of fusel oil, the distillation of the sample with alkali to remove free acids and saponified esters; (4) in the determination of

ethereal salts, the titration of the excess of mineral acid and allowing for the subtraction of the volatile from the total acids.

The associate referee indorsed a recommendation of H. E. Sawyer that in the determination of acidity a change be made from sodium hydrate to barium hydrate for titration. He suggested that a comparative study be made of other methods of fusel oil determination. References to recent information concerning distilled liquors were given in the report.

Report of associate referee on flavoring extracts, A. L. Winton.—The methods outlined by the previous associate referee were considered as needing only slight changes. It was believed that in the near future certain new lines of work must be taken up, and special mention was made in this connection of lemon extracts and the artificial fruit ethers. The matter of lemon extracts was brought to the attention of the associate referee by the work of the Dairy and Food Department of Michigan. It was found in that State that an extract was being manufactured by treating lemon oil with dilute alcohol, which process removed the citral, but did not dissolve out any appreciable quantity of the oil. A second extract could then be made with the oil.

It was the opinion of the associate referee that the citral is not the only valuable ingredient of a lemon extract, but that the terpenes have a decided value. It was considered highly desirable that methods be devised for recognizing these two extracts, one designated the washed-out extract and containing only the citral and the other the extract made with the washed-out oil and containing only the terpenes.

By request of the associate referee the State analyst of Michigan, R. E. Doolittle, explained more in detail the legal features of the work mentioned. While the United States Pharmacopœia was accepted by the Supreme Court of Michigan as the standard in the preparation of lemon extracts, it was also held by the court that there was no violation of the statute in eliminating such ingredients as could be dispensed with without injury to the product as a food product. The manufacturers of washed-out extracts claimed a positive advantage in the total exclusion of the terpenes from the extract. In the test case a new trial was ordered, but as the defendant pleaded guilty no legal decision was reached as to the status of terpene-free lemon extract. Owing, therefore, to this decision and the absence of methods for determining citral, nothing further is being done in the State on the lemon-extract question.

Report of associate referee on spices, R. E. Doolittle.—The associate referee received no collaboration by members of the association during the year. Analyses were made by him of samples of pure pepper, the methods employed being those adopted provisionally by the association, and his comments were based upon this work. In the determination of starch by the diastase method the use of a pancreatic diastase was adopted in place of powdered malt. Inasmuch as the animal diastase gave no reduction on Fehling solution, one source of error was thereby eliminated. It was suggested that the use of this diastase be a subject for investigation by the associate referee on spices for the coming year. In the determination of the amount of copper reduced, the associate referee preferred weighing as cuprous oxid, as described by Munson last year. It was recommended that the various kinds of filters and containers suggested in the provisional method for the determination of crude fiber be thoroughly studied.

Report of associate referee on oils and fats, L. M. Tolman.—In work upon iodin absorption the Hübl method, the official method of the association, was compared with the Hanus and Wijs methods in collaboration with a number of analysts. The 3 methods did not give very concordant results on oils with high iodin numbers. On 51 samples of butter and 14 of oleomargarine examined by G. E. Patrick, the Hanus method invariably gave slightly higher results, the average differences being 1.01 and 1.14, respectively, in the 2 series. Eleven samples of pure olive oil were examined by 3 analysts, the average differences in the determinations being 1.8 by

the Hübl method, 1.2 by the Hanus method, and 1.7 by the Wijs method. The maximum differences were, respectively, 3.3, 1.9, and 2.8.

In the extended investigations of the associate referee comparative tests were made of the Wijs solution of iodin monochlorid in glacial acetic acid, the Hanus solution of iodin monobromid in glacial acetic acid, and the McIlhiney solution of bromin in carbon tetrachlorid. The objects in testing the Wijs and Hanus solutions were to determine the excess of reagent necessary, the length of time required, and the effect of light on the reaction. In tests on linseed oil an excess of the Wijs solution of 37 per cent gave the same results in 30 minutes as an excess of 62 per cent. An excess of the Hanus solution of about 70 per cent was found necessary to insure complete absorption in that time. Neither solution was appreciably affected by light in 30 minutes. It required 30 minutes with the Hanus solution to reach the constant stage reached by the Wijs solution in 10 minutes, after which the absorption was constant in both cases to the end of one hour, when a gradual rise occurred.

Tests were also made of the bromin solution and of the substitution of carbon tetrachlorid for acetic acid in the preparation of the Hanus and Wijs solutions. It was shown that good results could be obtained by the bromin solution only with dry reagents and in the dark, and furthermore, that the figures could not be compared with those of other methods. While solutions of iodin monochlorid and iodin monobromid in carbon tetrachlorid gave more reliable results, their use was also considered unsatisfactory for ordinary purposes.

Work on the Dalican titer test was carried on with the cooperation of the chemists of a number of packing houses. The detailed report upon this work was presented as preliminary. The larger number of chemists cooperating used practically the same modification of the Dalican test which was described. Particular attention was paid to the effect of the two methods of saponification in use, the use of tubes and air baths of different sizes, and the results obtained by different methods of stirring. The need of a uniform method of procedure was considered evident from the work so far done.

The associate referee recommended the adoption of the Hanus method in place of the Hübl method, a change in the official method for determining the index of refraction of oils and fats, as regards the factor used in the correction for temperature, and certain changes in the provisional methods as regards Halpen's test for cottonseed oil, and Renard's test for peanut oil.

Report of associate referee on dairy products, A. E. Leach.—The associate referee gave several methods to supplement those already included in the provisional methods of the Association for the analysis of foods, and recommended their adoption as provisional methods. These methods relate to the detection of formaldehyde, benzoic acid, and salicylic acid in milk; the detection of annatto in butter; the detection of azo dyes and annatto in oleomargarine; the detection of boric acid in butter; the determination of fat in cheese, and the analysis of condensed milk.

Report of associate referee on preservatives, W. D. Bigelow.—It was reported that no definite results had been obtained. No field in connection with food chemistry was considered to be more in need of study than the determination of preservatives. It was thought that in the near future it would be important to determine the amount of preservatives present in foods, and the methods suggested for this purpose were considered inadequate. During the year considerable attention was given to qualitative methods for the detection of formaldehyde and quantitative methods for the determination of salicylic acid and benzoic acid, the intention being to continue this work during the coming year. The referee requested as full collaboration as possible.

The determination of commercial glucose in some saccharine products, A. E. Leach.—The determination of commercial glucose in such products as honey,

jams, and jellies by the provisional method of the Association was reported as presenting certain difficulties due in part to the action of the acid used in inversion upon the maltose and dextrin. To obviate this it was recommended to neutralize the sample immediately after inversion. This method as elaborated was applied to 5 samples of commercial glucose, the polarization at 87° C. after inversion averaging 95.6 per cent of that at 22° after inversion and 93.3 per cent of the direct reading. To express results in terms of commercial glucose polarizing at an assumed figure, it was therefore considered necessary in the case of jellies and jams to divide the reading at 87° by 93 per cent of the assumed factor. It was announced that the study of this problem was being continued with the hope of working out a reliable formula for the calculation of invert sugar in the presence of commercial glucose.

E. Gudeman compared the methods given by himself and by Dr. Leach in the proceedings of last year's meeting, claiming greater accuracy for his method. Dr. Gudeman believed that the Association should adopt a constant for the polarization of glucose or accept a constant for the percentage of water and use these factors irrespective of the article under examination. He also contended that but one grade of glucose is manufactured in the United States at the present time, which statement met with considerable objection. The proposition to express results in terms of glucose polarizing at a definite figure seemed to meet with general approval. L. S. Munson considered the factor 175 too high.

SUGAR.

It was stated by the referee that very little work had been done on this subject during the year. The associate referee, L. S. Munson, reported progress on work with reducing sugars, stating that he had prepared a solution which had about one-third the action on cane sugar as the regular Soxhlet solution. The associate referee on reducing sugars for next year was instructed to communicate with a committee of the International Commission for Uniform Methods of Sugar Analysis with a view to cooperating in obtaining a uniform method for determining reducing sugars.

The appointment of an associate referee on molasses was authorized and a continuation of the work on beet-sugar methods was also requested. The method of determining the copper reduced by direct weighing of the cuprous oxid and the German official method for the determination of sucrose and raffinose were adopted as official methods in essentially the same form as recommended last year. The methods recommended last year as provisional methods were this year adopted as such. The principal recommendations made by the International Commission were briefly explained by H. W. Wiley. One paper relating to the analysis of molasses was presented.

Report of referee, L. M. Tolman.—This consisted of brief statements concerning the work on sugar during the year and of the several recommendations for next year's work noted above.

Remarks on molasses analysis, H. E. Sawyer.—The methods in use for testing molasses were considered unsatisfactory when applied to low-grade goods. In clarifying such molasses it was found more satisfactory to use a solution of basic lead acetate of greater dilution (26 gm. in 500 cc.) than that required in the official method. Tests were made of this method during a period of 2 years; and while it

was not claimed that sucrose could be determined by it with absolute accuracy in the case of a dark molasses, nevertheless the method was believed to insure increased accuracy, and the association was asked to give it consideration.

TANNIN.

Cooperative tests of methods for the determination of soluble solids and acidity in extracts were reported by the referee and several recommendations were made. The proposed changes in methods were referred to the referee for next year for consideration.

Report of referee, G. A. Kerr.—Samples of a fluid chestnut extract and a quebracho extract were sent to 16 analysts for the purpose of making comparative tests of the single filter paper in determining the soluble solids, investigating the correction for filter paper absorption adopted by the International Association of Leather Trades Chemists, and comparing a specified dilution with the variation allowed by the official method. Samples of hemlock liquor acidified by the addition of 0.15 per cent of acetic acid were also sent out for the purpose of testing methods for determining acidity.

Reports were received from 12 analysts. The results favored the use of the single-filter paper, confirming the work of the previous referee. The evidence relating to the correction of the tannin absorbed by the filter paper was not conclusive. Favorable results were obtained by diluting 1.6 gm. of the chestnut extract to 100 cc. and 0.6 gm. of the quebracho extract to 100 cc. and determining solids by the official method. The referee suggested that further experiments with varying quantities of extract be made for the purpose of comparing the total solids and assumed tannin content as bases for dilution. The acidity of the hemlock liquor averaged 0.1668 per cent by the provisional method and 0.1368 per cent by the animal charcoal method tested by the referee last year. The apparent loss of acid in the charcoal method was considered worthy of further study. Changes recommended by the referee in the official method were aimed to prevent the loss from evaporation during the weighing and filtering.

INSECTICIDES AND FUNGICIDES.

The referee reported considerable cooperative work, and made a number of recommendations concerning the adoption of methods and regarding work for next year. Method I for the determination of total arsenious oxid in Paris green as given in Circular 10 of the Bureau of Chemistry was adopted as an official method. The suggestions of the referee for future work were in the main approved. The general discussion relating to the determination of nicotin indicated a desire for an improved method. The subject of disinfectants was assigned to the next referee for investigation.

Report of referee, J. K. Haywood.—Further tests of old methods modified in some cases and of new methods were made by several analysts in collaboration with the referee. Reports were received from 8 analysts on Paris green, 8 on London purple, 4 on copper carbonate, 4 on potassium cyanid, 3 on soda lye, 2 on tobacco extract, and 3 on formalin. The analytical data with the comments of the analysts were reported in full.

The referee recommended that the following methods, given in Circular 10 of the Bureau of Chemistry and reported upon by the referee last year, be adopted as offi-

cial methods: Method I for total arsenious oxid in Paris green; the electrolytic method for determining copper in Paris green and copper carbonate; the volumetric silver nitrate method for determining cyanogen in potassium cyanid, $\frac{N}{20}$ silver nitrate being substituted for the $\frac{N}{10}$ solution; and the Kessling method for determining nicotin. It was also recommended that further study be made of the 4 modifications of the Avery-Beans method referred to in the report for determining total arsenic in Paris green, with a view to the adoption of the best modification as an optional official method; the volumetric method for determining copper in Paris green and copper carbonate; the removal of some of the organic matter in the analysis of London purple; the methods for the examination of soda lye; and especially the methods for determining formaldehyde.

ASH.

The vacancy caused during the year by the resignation of E. G. Runyan as referee on ash was filled by the appointment of G. S. Fraps, whose report dealt with the determination of sulphur and sulphates. The report called forth some discussion on the suitability of the sodium peroxid method for determining total sulphur. It was stated by G. E. Patrick that the use of sodium peroxid free from sulphur was found by him to give good results. The method for the determination of sulphates, which was described in the report of the referee last year, and which provides for the extraction of the substance with 1 per cent hydrochloric acid, was adopted provisionally. The Association approved the referee's recommendation for further study of the sodium peroxid method.

Report of referee, G. S. Fraps.—The nitric acid method, which is the provisional method of the Association, and the sodium peroxid method for the determination of total sulphur were compared by 5 analysts on samples of cowpeas and cotton-seed meal sent out by the referee. The average results showed that 0.466 per cent of sulphur as SO_3 was obtained by the nitric acid method and 0.544 per cent by the peroxid method in the case of cowpeas, and 1.048 and 1.135 per cent, respectively, in the case of cotton-seed meal, showing that the nitric acid method gave lower results than the peroxid method.

Considerable difficulty was experienced by some of the analysts in the use of the peroxid method. Sulphates were determined in a sample of sorghum by 4 analysts, the method used being that described in the report of the referee on ash last year. The results obtained by the different analysts ranged from 0.324 to 0.4 per cent and were considered fairly satisfactory. The referee recommended that the method referred to for the determination of sulphates be adopted provisionally, and that the peroxid method of determining sulphur be subjected to further study with a view of replacing the nitric acid method by it.

MISCELLANEOUS.

W. Frear as chairman of the committee on food standards reported upon the work of this committee during the year. Definitions and standards were formulated by the committee and submitted to the Secretary of Agriculture for his approval and use in fixing standards

for food products as required by law. The report of the committee was accepted and the committee continued.

H. W. Wiley as chairman of the committee on fertilizer legislation reported that the members of the committee were individually in favor of National legislation on the subject of fertilizers, but that there had been no expression on the part of the committee as to the form which this legislation should assume. The committee upon motion of the chairman was therefore instructed to confer with interested parties with a view to presenting at the next meeting a definite report upon this subject.

A committee of the American Chemical Society, appointed for the purpose of investigating the purity of chemicals, held a meeting in Washington, November 20 and 21, and by request presented to the Association an outline of the work being done.

A resolution was adopted inviting the Bureau of Standards to coöperate with the referees as far as possible in establishing the accuracy of methods of analysis.

Provision was made for the appointment of an additional referee next year on the subject of medicinal plants and the drugs made therefrom.

By a resolution introduced by L. L. Van Slyke the secretary was requested to print the recommendations of the referees as approved by the association for distribution at as early a date as possible.

A resolution in favor of holding the next convention of the Association at St. Louis was adopted.

OFFICERS AND REFEREES.

The following officers were elected:

President, M. E. Jaffa, Berkeley, Cal.; *Vice-President*, C. L. Penny, Newark, Del.; *Secretary*, H. W. Wiley, Washington, D. C.; *Additional members of executive committee*, W. P. Headden, Fort Collins, Colo., and W. R. Perkins, Agricultural College, Miss. The referees and associate referees have not as yet been appointed. They will be announced later.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The determination of small amounts of potassium in aqueous solutions, F. K. Cameron and G. H. Failyer (*Jour. Amer. Chem. Soc., 25 (1903), No. 10, pp. 1063–1073*).—The method proposed is based on a suggestion of Morrell, and in brief "is to separate the potassium from other bases in the form of the potassium platinic chlorid, carefully free from an excess of reagents, take up in water and then add an excess of potassium iodid, when, on standing, a beautiful pink or rose color develops, which gradually deepens to a maximum intensity. By matching the intensity of the color against that which would be developed in a standard solution of known concentration, a measure of the amount of potassium present could be obtained."

Tests of different modifications of the method under a variety of conditions, which are reported, lead to the conclusion that the method is simple, easy of manipulation, and susceptible of a high degree of accuracy in the determination of minute quantities of potassium.

The volumetric determination of potash as potassium bismuth thiosulphate, F. W. Küster and M. Grüters (*Ztschr. Anorgan. Chem., 36 (1903), pp. 325–331; abs. in Chem. Centbl., 1903, II, No. 16, p. 908*).—As a result of numerous tests of Carnot's method of determining potash as potassium bismuth thiosulphate the authors conclude that it is impossible to obtain this salt free from the sodium salt, and therefore the method is unreliable.

On a colorimetric method for the estimation of phosphates in the presence of silica, O. Schreiner (*Jour. Amer. Chem. Soc., 25 (1903), No. 10, pp. 1056–1062*).—The method here described in full has already been noted (E. S. R., 14, p. 524).

The reduction of nitric acid in metallic nitrates to ammonia by the electric current, W. H. Easton (*Jour. Amer. Chem. Soc., 25 (1903), No. 10, pp. 1042–1044*).—A brief account is here given of a study of the precautions to be observed in using Vortmann's modification[a] of Luckow's method,[b] which is as follows: "The solution of the nitrate is placed in a platinum vessel with a sufficient amount of pure copper sulphate and it is then electrolyzed. It is advantageous to use a feeble current (1 to 2 cc. of oxyhydrogen gas per minute). When all of the copper is deposited, the residual liquid is evaporated to a small bulk and the ammonia distilled off as usual."

A small improvement in the Kjeldahl method, Grégoire and Carpiaux (*Bul. Assoc. Belge Chim., 17 (1903), No. 1, p. 36; abs. in Bul. Soc. Chim. Paris, 3. ser., 30 (1903), No. 18–19, p. 1102*).—It is suggested that the difficulty due to frothing in case of substances rich in fat may be overcome by adding to the liquid in the distilling flask a small quantity of calcium chlorid.

The relation between the solubility of lime in the presence of alkalis and the caustification of alkaline carbonates, A. D'Anselme (*Bul. Soc. Chim. Paris, 3. ser., 29 (1903), No. 18–19, pp. 936–939, fig. 1*).

[a] Ber. Deut. Chem. Gesell., 23 (1890), pp. 2798–2801.
[b] Ztschr. Analyt. Chem., 19 (1880), pp. 324–327.

Solubility of gypsum in the presence of metallic chlorids, N. A. Orlov (*Zhur. Russ. Fiz. Khim. Obshch., 34 (1902), pp. 949–951; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 2, p. 199*).—The author studied quantitatively the influence of varying quantities of the chlorids of sodium, calcium, and magnesium on the solubility of gypsum in water. Solubility decreased with an increase in concentration of the calcium chlorid solution and increased with an increase of the strength of the sodium chlorid solution up to 10 to 15 per cent. The solubility in the latter was much greater than in the former, and in magnesium chlorid was greater than in either, being about 10 times as great as in calcium chlorid solution of 10 per cent strength.—P. FIREMAN.

The standardization of potassium permanganate solution for determining calcium and oxalic acid, H. Walland (*Chem. Ztg., 27 (1903), No. 76, pp. 922, 923*).

Laboratory method for ordinary chemical examination of waters for irrigation and domestic purposes (*California Sta. Circ. 8, pp. 4*).—Quick methods, mainly volumetric, are given for the determination of total residue, soluble and insoluble salts, chlorin, sodium carbonate, and nitrogen as nitrates. The methods are based mainly on those of Sutton, and it is stated that they "are intended merely for tests of waters for ordinary purposes, such as irrigation and domestic use, and are nowise intended to supersede the more elaborate and accurate methods given in books on water analysis, when such are necessary."

The use of calcined magnesia in the incineration of organic substances, H. Klein (*Chem. Ztg., 27 (1903), No. 76, p. 923*).—An admixture of 60 to 75 per cent of calcined magnesia is recommended.

Studies on the vegetable proteins, T. B. Osborne and I. F. Harris (*Connecticut State Sta. Rpt. 1902, pt. 4, pp. 448–467*).—This article is made up of abstracts of a series of papers which have already been noted from another source (E. S. R., 15, pp. 221–223), with the exception of one article, which is noted below.

The solubility of globulin in salt solutions, T. B. Osborne and I. F. Harris (*Connecticut State Sta. Rpt. 1902, pt. 4, pp. 464–467*).—This is a brief account of investigations which it is the intention to extend and report upon in detail. Statements are made concerning the solvent action upon edestin of each of a large number of salts. Many unexpected relations between protein and salts were found to exist. A further study is considered necessary before generalizations can be made.

Concerning avenin, St. Weiser (*Arch. Physiol. [Pflüger], 98 (1903), No. 11–12, pp. 623–630*).—An alkaloid called avenin has been reported by earlier investigators as present in oats. A repetition of such work and additional studies led to negative results, and the author concludes that no alkaloid is present in oats.

The sulphur contents of gelatin and its estimation with the Mahler bomb calorimeter, O. Krummacher (*Ztschr. Biol., 45 (1903), No. 3, pp. 310–323*).—According to the author's investigation commercial gelatin contains, on the dry matter basis, 0.62 per cent sulphur, of which 0.36 per cent is present as sulphate and 0.04 per cent as sulphite, and purified gelatin 0.28 per cent sulphur, 0.01 per cent being sulphate and a like amount sulphite. The organic forms in which sulphur can occur in gelatin are spoken of, together with the bearing of the analytical data reported on the use of gelatin in feeding experiments. The determinations of sulphur were made after the combustion of a sample in the bomb calorimeter and this method of analysis is described and discussed.

Action of diastase on the starch granules of raw and malted barley, A. R. Ling (*Chem. News, 88 (1903), No. 2288, pp. 168, 169*).—"The starches of barley and other cereals differ from that of the potato in being readily attacked by a solution of diastase in the ungelatinized condition." Different barleys give different constants, and it is probable that the products formed in barley mashes differ from those resulting from the hydrolysis of starch paste.

Animal and vegetable fixed oils, fats, butters, and waxes, C. R. A. WRIGHT (*London, 1903, 2. ed., pp. XVI+804, figs. 154*).—This work has been edited and partly rewritten by C. A. Mitchell, mainly with a view to rendering it capable of being used as an analytical text-book.

Thermodynamics and chemistry, P. DUHEM, trans. by G. K. BURGESS (*New York: John Wiley & Sons; London: Chapman & Hall, Ltd., 1903, pp. XXI+445, figs. 140*).—The topics treated are work and energy, quantity of heat and internal energy, chemical calorimetry, chemical equilibrium and the reversible transformation, the principles of chemical statics, the phase rule, multivariant systems, monovariant systems, multiple points or transformation points, displacement of equilibrium, bivariant systems, mixed crystals, critical states, chemical mechanics of perfect gases, capillary actions and apparent false equilibria, genuine false equilibria, unequally heated spaces, and chemical dynamics and explosions.

BOTANY.

Morphology of angiosperms, J. M. COULTER and C. J. CHAMBERLAIN (*New York: D. Appleton & Co., 1903, pp. X+348, figs. 113*).—This volume supplements that by the same authors on the Morphology of Gymnosperms, but must be considered as an independent treatise, Gymnosperms and Angiosperms being recognized as independent groups coordinate with Pteridophytes. The work is the outgrowth of lectures and laboratory work given graduate students at the University of Chicago, and while a vast amount of material is brought together in an orderly arrangement, the book must not be considered in any sense a mere compilation, since the same ground has been repeatedly gone over by the authors and their students, their results serving as checks to other investigations, as well as contributing a considerable amount of new material.

No attempt is made to include the elementary details of floral structure, anatomy, etc., which are well described in many of the older text-books, but where anatomy contributes to phylogeny, a nearly neglected field in this country, chapters have been prepared by Prof. E. C. Jeffrey. The volume seeks to give to the advanced student a continuous account of the structures involved, and to the research student the details of groups and bibliography that he needs. The bibliographies, which are an important feature of the work, are arranged chronologically at the end of each chapter and all the citations are brought together at the close of the volume, the arrangement being alphabetical by authors.

Concerning stimulants to plant growth and their practical application, O. LOEW (*Landw. Jahrb., 32 (1903), No. 3, pp. 437–448, pls. 2*).—The results of pot and plat experiments with barley, Chinese cabbage, spinach, rice, peas, oats, and radishes are given in which the stimulating effect of a number of chemicals is shown. Among the chemicals tested were rubidium chlorid, sodium fluorid, potassium iodid, manganese oxid, uranium nitrate, and iron sulphate, all of which were found to be injurious to plant growth when used in considerable strength, but weak solutions showed a decidedly stimulating effect. Based upon the results obtained with manganese oxid and sodium fluorid, the author claims that under the conditions of the experiments, notwithstanding the high price of these chemicals, they have a distinct value in agricultural practice.

A study of the production of electricity in living organisms, L. QUERTON (*Trav. Lab. Phys. Inst. Solvay, 5 (1902), No. 2, pp. 81–185; abs. in Bot. Centbl., 93 (1903), No. 7, pp. 145–147*).—After considering the general electrical phenomena as exhibited by living organisms, such as electric fish, muscles, nerves, plants, etc., the author gives an account of experiments with plants and the application of the electric manifestations to biology and irritability. He examined the plants by exposing them to light, testing the electric impulse by a specially devised apparatus. The

leaves of iris, begonia, and tobacco were found to agree essentially in the illuminated portion forming the negative pole, the current reversing itself after the illumination had ceased. The leaves of the garden tropæolum and Mathiola were the reverse of the preceding, the illuminated portion being the positive pole.

The experiments seem to show that the difference in electric potentiality in plants, when acted upon by light, is due to the chemical activity of the leaf, being particularly associated with the phenomena of chlorophyll assimilation. The electric phenomena were observed in living plants only. When the green leaves had been subjected to boiling water or destroyed by dry heat there was no electric response. Temperature was found to favor the production of electrical phenomena, and about 25°C., the same temperature as the optimum for assimilation, proved to be the optimum for electrical response.

In a second series of experiments the effect of chemical reagents on the electrical response was investigated. Oxalic acid, hydroquinone, and laccase are being tested. The general conclusion is drawn that whatever the organism examined the electric response is intimately connected with the chemical reaction of the organism.

A transpiration model, H. H. Dixon (*Sci. Proc. Roy. Dublin Soc., n. ser., 10 (1903), I, No. 9, pp. 114–121, fig. 1*).—A description is given of a form of apparatus in which the phenomena of turgidity of leaves of tall trees during the active transpiration and transpiration into saturated atmospheres may be observed. From the phenomena shown by the action of this model it is concluded that with imperfectly semipermeable membranes, such as leaf cells are supposed to possess, transpiration into saturated spaces is possible over long periods of time, and if photosynthesis is permitted such transpiration may be indefinitely prolonged.

The decomposition and regeneration of albuminous materials in plants, G. Balicka-Iwanowska (*Compt. Rend. Acad. Sci. Cracovie, 1903; abs. in Bot. Centbl., 93 (1903), No. 41, pp. 369–372*).—The author gives an extended review of the investigations of Pfeffer, Schulze, Prianishnikov, and others on the decomposition of albuminous materials in plants, followed by an account of experiments conducted by himself to test the accuracy of their conclusions. The methods of analysis adopted were those usually employed in such studies, and the author found that asparagin, which is formed during the decomposition of albuminous material, is a secondary product, the primary products of decomposition being amido acids and hexose bases.

The regeneration of albuminous material was found to be influenced to a very appreciable degree by the salts present in the soils. In the absence of lime there was found a decided diminution in the amount of albuminous material formed. Assimilation on the part of the plant was found to play a very important rôle in the formation of albuminoids, and his investigations confirmed those of Godlewski, who found that under the influence of light the increase in albuminoids depends to a large extent on the nitrates present without reference to the assimilative processes of the plant.

The localization of the active principles of certain plants during their winter stages, W. Russell (*Rev. Gén. Bot., 15 (1903), No. 172, pp. 160–165*).—A study was made of quite a number of species of trees, shrubs, and other plants during their dormant period, to determine the localization of alkaloids and other active principles which are characteristic of the plants. As a result of the investigations it seems that the alkaloids, glucosids, and other active principles are stored by the plant similarly to the ordinary reserve material, and that in certain plants there may be a slight transfer of the material during the dormant period. With those plants whose aerial portions are annual the active principles are localized in the subterranean organs. With those having perennial stems the concentration of the active principles is in the region of the buds, although frequently deposited to considerable extent in the underground organs.

Investigations on the presence of alkaloids and glucosids in the Ranunculaceæ, E. Vanderlinden (*Rec. Inst. Bot. Univ. Bruxelles, 5 (1902), pp. 135–178, pls. 2; abs. in Bot. Centbl., 92 (1903), No. 8, pp. 167, 168*).—A report is given of investigations of 39 species which represent the more important types of the Ranunculaceæ. The methods for recognizing the presence of alkaloids and glucosids are described, and the author reports the presence of alkaloids in *Caltha palustris, Delphinium hybridum, D. consolida, D. ajacis, D. staphisagria, D. grandiflorum, Aconitum lycoctonum, A. anthora, A. napellus, Nigella damascena,* and *Adonis vernalis.* In the case of the last species the substance found was an alkaloid glucosid. Glucosid reactions were observed in *Helleborus niger, Nigella sativa,* and *Aquilegia vulgaris,* while neither alkaloid nor glucosid was found in a number of other specimens examined.

In pursuing his studies the author found the alkaloids localized in the woody tissue and parenchyma of the roots, in the epidermis, and in the woody tissue and pith of the aerial organs. As a rule, the alkaloids were not found in the growing tips of the plants, but they appeared later in the developed portions. The alkaloids seem to be present as a waste product, and are found in the tissues which store up the starch, and when the carbohydrates are utilized by the plant they are left behind. On the contrary, the glucosids seem to be present as reserve material.

Microscopical examinations of some glucosids and tannins, A. Goris (*Thesis, Paris, 1903; abs. in Bot. Centbl., 93 (1903), No. 37, pp. 261–263*).—The principal investigation reported in this thesis is a study of esculin and tannin in *Æsculus hippocastanum* and *Pavia rubra.* The microchemical reactions of esculin and its compounds are described, and from the experiments the author is led to believe that esculin is formed by the plant without any direct action of light. It occurs in the embryo of the seed sprouted in darkness as well as in the light. The glucosid does not seem to be a reserve material, notwithstanding that during the autumn it disappears from the leaves, being transferred to the adjacent branches.

In addition to esculin a tannin is found in the horse-chestnut, which was also studied. This seems to be usually more or less modified, occurring in the same cells with the esculin, the glucosid often being found in combination with the tannin.

In the concluding part of the thesis the author reports studies on a number of analogous glucosids from other plants. Those studied were fustin, fraxin, daphnin, salicin, and cafein. These glucosids are, with the exception of daphnin, analogous to that observed in the horse-chestnut and are usually found in composition with the tannic acid. The author believes that probably most glucosids and alkaloids exist in the plant in combination with tannin, forming tannin glucosids or tannin alkaloids which are very soluble in water and alcohol and very unstable. The medicinal principles of many plants are believed to be present in these forms.

Investigations on the physiology of a green alga, P. G. Charpentier (*Ann. Inst. Pasteur, 17 (1903), No. 6, pp. 369–420*).—Based upon an extended series of experiments with *Cystococcus humicola,* the author claims that this alga is able to take carbon from glucose, inverted sugar, levulose, and saccharose solutions, as is done by cultures of molds and other fungi. In these cultures the coefficient of the utilization of carbon is higher for the alga than any mold or yeast investigated.

When grown in a confined atmosphere the early growth of the alga resembles that of a fungus, but later it behaves identically like that of other green plants. The Cystococcus was found to be able to synthesize its chlorophyll in darkness, and like other chlorophyll-bearing plants it stores its reserve starch in its cells. In its ability to take nitrogen from nitrates, and under certain conditions from ammonia, it resembles ordinary green plants.

A study of the structure of Botrytis cinerea, J. Beauverie and A. Guilliermond (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), Nos. 9, pp. 275–281; 10, pp. 311–320, figs. 14*).—As a result of their studies the authors claim that there are 3 forms of *Botrytis*

cinerea, a typical spore-bearing form, an intermediate or transitory form, and one that is wholly sterile. These different forms, the authors maintain, are due to the nature of the medium in which the fungus is grown.

The poisonous mushrooms of France and Europe, O. GROSJEAN (*Les champignons vénéneux de France et d'Europe. Saint-Hilaire, Roulans (Doubs): Author, 1903, pp. 48, pls. 8, figs. 2, chart 1*).—A manual for schools as well as for private use, in which directions are given for the recognition of the poisonous or suspected species of mushrooms.

Synoptical tables of edible and poisonous mushrooms, C. MANGET (*Tableaux synoptiques des champignons comestibles et vénéneux. Paris: J. B. Baillière & Son, 1903, pp. 128, pls. 6, figs. 23*).—Synoptical tables are given for the determination and recognition of a large number of edible and poisonous mushrooms. Notes on their food value and suggestions for counteracting the poisonous effects when eaten are also given.

FERMENTATION—BACTERIOLOGY.

The classification and identification of bacteria, S. DE M. GAGE and E. B. PHELPS (*Reprint from Proc. Amer. Pub. Health Assoc., 1902, pp. 12–23*).—An outline is given of a scheme for the classification and identification of bacteria, with special reference to a description of the card catalogue system in use at the Lawrence Experiment Station for the records of species. These cards, which are specially prepared, are arranged to show all the necessary data for the classification and identification of species of bacteria and may be arranged by any system of grouping that is desired.

Experiments with nitrogen-assimilating bacteria, M. GERLACH and I. VOGEL (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 20–21, pp. 636–643*).—In previous publications the authors have shown the necessity of grape sugar in nutrient solutions for the best growth of bacteria of the Azotobacter group (E. S. R., 14, p. 1048). Continuing their investigations on this group of nitrogen-assimilating bacteria, the necessity for other materials in the culture media was studied. The organisms were shown in flasks containing the same quantity of a nutrient medium to which was added various forms of potash, soda, and lime, and the growth and nitrogen assimilation noted.

In those flasks which contained neither lime, phosphoric acid, nor potash there was no growth of bacteria nor gain of nitrogen. In flasks to which neither potash nor soda was added, but the other compounds were supplied, it was found that limited growth and nitrogen assimilation could take place. The effect of age on the organisms was studied and cultures from 18 to 328 days old were compared, the greatest gains in nitrogen being shown for the younger cultures. As reported in the previous paper, increasing the content of grape sugar increased the amount of nitrogen added by the organisms to the solution.

The presence of a number of yeasts and molds in the cultures was investigated, indicating that some of these organisms were apparently able to independently add small quantities of free nitrogen to their solutions. When grown in connection with Azotobacter the efficiency of the latter organisms to assimilate free atmospheric nitrogen seemed to be diminished.

Assimilation of atmospheric nitrogen by bacteria, E. DE FREUDENREICH (*Ann. Agr. Suisse, 4 (1903), No. 4, pp. 207–214; also in Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 16–17, pp. 514–522*).—The results of the studies of *Azotobacter chroococcum* are given, in which the author demonstrates the ability of this microorganism to assimilate free atmospheric nitrogen when grown either in liquid cultures or upon gypsum culture plates. Flasks containing liquid culture media inoculated with the bacteria added about 3.5 mg. of nitrogen in 9 weeks. When grown on gypsum the amount of nitrogen added was considerably in excess of that assimilated in the liquid media. The investigation shows that soils rich in bacteria are undoubtedly able to assimilate and fix free atmospheric nitrogen.

Concerning bacteria which assimilate carbon from the air, M. W. BEIJERINCK and A. VAN DELDEN (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 2, pp. 33–47*).—The results of a biological study of *Bacillus oligocarbophilus*, an organism said to be capable of deriving its carbon from the air, probably from volatile hydrocarbons and not from the carbon dioxid of the air. The organism has been cultivated on a number of media containing no source of carbon except that found in the air, and favorable growth was made under such conditions when all carbon dioxid was eliminated.

Recent progress in the field of soil bacteriology, H. BUHLERT (*Fühling's Landw. Ztg., 52 (1903), Nos. 13, pp. 451–457; 14, pp. 494–500*).—A review of work along this line, including a reference to the recent work of Beijerinck on *Bacillus oligocarbophilus*, which is capable of deriving its carbon from the carbon compounds of the air (not carbon dioxid). (See above.)

Some experiments with luminous bacteria, B. ISSATCHENKO (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 16–17, pp. 497–499*).—Attention is called to experiments by the author on some of the phenomena exhibited by luminous bacteria. Cultures of *Photobacterium phosphorescens* were made, and after several days' growth in culture tubes were placed with etiolated seedlings of clover, rye, and oats in an absolutely light-proof chamber. After remaining in this chamber from 24 to 48 hours the seedlings were examined, and it was found that the intensity of the light given off by the bacteria was sufficient for the formation of chlorophyll in the plants. This would seem to indicate that the quality of the light rays plays little part in the process of chlorophyll formation if the light is of sufficient intensity.

Notes on Bacillus coli and allied forms, S. DE M. GAGE and E. B. PHELPS (*Reprint from Proc. Amer. Pub. Health Assoc., 1902, pp. 1–11*).—Studies with *Bacillus coli* and allied forms, with special reference to the neutral red reaction, have been carried on at the Lawrence Experiment Station, at Lawrence, Mass., for a number of years. The authors found from their investigations that as a preliminary test the neutral red reaction is as sensitive and accurate as any which has been hitherto proposed. This reaction, however, has given positive results for other organisms than *B. coli*. For more delicate tests the authors recommend the dextrose broth method, which is fully described.

The spore germination of Bacillus subtilis and B. megatherium, L. F. RETTGER (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 14–15, pp. 433–438, figs. 3*).—The purpose of this paper is to draw attention to a "hanging-block" method recently described for the morphological study of micro-organisms, and to present in some detail the processes involved in the germination of these 2 species of organisms. The author finds that although these 2 species resemble each other closely in most respects, they differ very conspicuously in their method of spore germination. These differences may be readily made out in "hanging-block" cultures.

The cleavage of nitrogenous organic substances by bacteria, O. EMMERLING (*Die Zersetzung stickstoffreier organischer Substanzen durch Bakterien. Brunswick: Friedrich Vieweg & Son, 1902, pp. 141, pls. 7; rev. in Ztschr. Untersuch. Nahr. u. Genussmtl., 6 (1903), No. 12, p. 574*).

Fermentation organisms, A. KLÖCKER, trans. by G. E. ALLAN and J. H. MILLAR (*New York: Longmans, Green & Co., 1903, pp. XX+381, figs. 146*).—In this text-book the author gives a review of the biology of fermentation organisms, especially in the manufacture of beer. In spite of this limitation, the book is varied in character and treats of the general phenomena of fermentation.

The subject-matter is divided into 3 sections, the first of which traces the development of the science of fermentation. This is followed by descriptions of laboratory equipment and methods, special attention being given to the preparation of pure yeasts upon a commercial scale, after which the more important micro-organisms of alcoholic fermentation are treated at length. Bibliographies of the more important

researches in each department treated are given, and in many instances the experiments cited have been verified by the author. The practical applications are treated as well as the theoretical aspects of chemistry and botany in their relations to the science of fermentation.

Fermentation investigations, L. MATRUCHOT and M. MOLLIARD (*Rev. Gén. Bot., 15 (1903), Nos. 173, pp. 193–220; 174, pp. 253–274; 175, pp. 310–327, pls. 4, figs. 10*).—In addition to the fermentation produced by yeast and similar organisms the authors, following investigations by Pasteur, Lechartier, and Bellamy, show that there is a fermentation which takes place in fleshy fruits, tubers, etc., that is independent of yeast or other foreign organisms. The methods of the experiment are described in detail, fruits of pumpkins and apples, onion bulbs, beet roots, etc., being kept under aseptic conditions for a considerable time, and the alcoholic fermentation and carbon-dioxid evolution determined. In the first part of the report a morphological study is given of the cells undergoing self-fermentation, after which the results of cytological studies are given.

A critical review of the theory of fermentation, A. RICHTER (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 14–15, pp. 438–451, fig. 1*).—A critical review of the fermentation of sugars by yeast.

The micro-organisms of black bread fermentation, L. BUDINOFF (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 14–15, pp. 458–463*).—A review is given of the work of Halliger on the bacteriological investigations of bread fermentation, and the results of the author's investigations, particularly with Russian black bread, are reported.

Notes on recent work on vegetable ferments, W. G. FREEMAN (*West Indian Bul., 4 (1903), No. 1, pp. 22–28*).—A summary is given of some of the more recent investigations relating to vegetable ferments, particular attention being paid the ferments which have been discovered in the papaw (*Carica papaya*), the pineapple, and pitcher plants. In addition notes are given on various oxidizing ferments such as oxidases, laccase, tobacco ferments, etc.

The ferment of the tea leaf, II, H. H. MANN (*Calcutta: Indian Tea Assoc., 1903, pp. 15, figs. 2*).—In a previous publication (E. S. R., 14, p. 741) the author called attention to the nature of the ferment of the tea leaf, which was said to be an oxydase, the quantity present in the leaf depending in some way upon the percentage of available phosphoric acid in the soil. The action of this ferment in producing the tea of commerce was shown, and in the present publication the author considers the subject in some of its practical applications.

The question of adding enzyms from some other source to fermenting tea leaves was considered, but no advantage was found to follow such treatment. The increase of ferment during the withering of the tea leaves, as well as the changes taking place in the leaves, are described, and the conclusion is drawn that there is a point in the withering of the leaf when the enzym which causes the fermentation of the leaf is present in greatest quantity. The effect of withering too quickly or too slowly upon the action of the enzym and the chemical content of the leaves was examined, and it was found that by a loss of moisture the leaves may become withered before the proper amount of oxidizing enzym is present, or in wet weather it may become chemically ready for rolling long before the leaves are properly withered.

Investigations were continued on the effect of light and darkness in the production of the enzyms, and it was found that leaves exposed to ordinarily diffused daylight gave slightly better results than those kept in darkness. In a second experiment, where the bushes were covered, no difference could be detected after 2 weeks in the amount of oxidizing enzyms in 2 lots of leaves. It was found, however, that leaves plucked early in the morning contained a much larger amount of total enzyms than those gathered late in the afternoon. Whether this can be turned to practical account can not yet be told.

Experiments were conducted on the fermentation of tea under aseptic conditions which resulted in the discovery that the addition of a small quantity of salicylic acid to the fermenting tea leaves, by excluding foreign organisms, produced an improved quality of tea.

Some notes on proteolytic enzyms associated with rennet in plants, M. JAVILLIER (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 17, pp. 1013–1015*).—In a previous publication (E. S. R., 14, p. 549) the author has shown the presence of rennet or an analogous substance in certain plants, and in the present communication an account is given of certain proteolytic ferments which were found associated with the rennet in his studies on plants.

In experimenting with the expressed juice of darnel under aseptic conditions it was found that the coagulum formed by the rennet was gradually dissolved and in its place was formed a semitransparent liquid, upon the surface of which floated globules of milk fat. This substance was not precipitated by acids, and gave, in general, the reaction of peptones. The diastase which has been found in a large number of plants is a casease comparable with that previously described as occurring in liquid cultures of Tyrothrix. The plant juice of darnel contains a gelatinase which liquifies gelatin, but does not coagulate egg albumen nor fibrin.

In these experiments the author has shown that certain of the higher plants possess ferments similar to those discovered in experiments with bacteria, yeasts, molds, etc., and that the casease and gelatinase present in the plants studied are quite similar, if not identical. The diastatic precipitate separated from the darnel was found after a few days to dissolve peptone in a way quite similar to that of the diastase occurring in the mucus membrane of the intestinal canal of certain mammals.

A study of the proteolytic enzyms of malt, F. WEIS (*Compt. Rend. Trav. Lab. Carlsberg, 5 (1903), No. 3, pp. 133–285, pls. 17*).—After giving a historical résumé of the study of proteolytic enzyms and their presence in various plants, the author describes the methods of his investigations on the proteolytic enzyms of malt. As a result of his experiments he states that an aqueous solution of fresh malt was found to contain marked proteolytic properties, as is shown by the self-digestion of the malt and by the splitting up of albuminoid materials which may be added to the solution.

By means of precipitations with tin chlorid and tannic acid 2 phases were recognized in the proteolysis of protein separated from wheat, one a hydrolytic phase resulting in the formation of albumoses, the other a tryptic phase producing nonproteid crystalline compounds. These 2 phases are supposed to be caused by separate enzyms, peptase and tryptase. The action of various elements, such as temperature, moisture, acids, alkalis, etc., on these enzyms is shown, as well as the physical and chemical properties of each.

In the unsprouted barley grain the author was unable to demonstrate the presence of these ferments, but on the fourth day of germination they appeared quite abundant and increased to a maximum production in 16 days. There appeared to be proenzyms present in the unsprouted grain which at the proper temperature were rendered quite active upon the addition of very dilute acetic acid.

Investigations on the two kinds of catalase, O. LOEW (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 6, pp. 177–179*).—In the previous investigations of the author 2 forms of catalase were recognized, one of which is insoluble and the other a slightly soluble form. The insoluble form has been held to be a chemical combination of the soluble form with some nucleo-proteids. Criticisms having been made against this statement, the author has reviewed his experiments, arriving again at practically the same conclusion.

The catalytic decomposition of hydrogen peroxid, and nature and function of catalase, A. S. LOEVENHART and J. H. KASTLE (*Amer. Chem. Jour., 29 (1903), Nos. 5, pp. 397–437, fig. 1; 6, pp. 563–588*).—According to the authors it has

been found that in many instances the inhibition of the catalytic decomposition of hydrogen peroxid by various metals is due to the formation of thin insoluble protective films over the surface of the metal, the formation of which is brought about by the action of the inhibitor on the metal.

During the decomposition of hydrogen peroxid, the authors could observe no evidence of the formation of atomic oxygen. It has been found, however, that various catalyzers act as oxygen carriers in the presence of hydrogen peroxid, and that with the exception of catalase all substances which break down hydrogen peroxid act as oxygen carriers. It is believed that the physiological function of catalase is not to effect the decomposition of hydrogen peroxid as a means of protecting the cell against the toxic action of this substance, but rather that catalase is a substance or mixture of substances having a tendency to combine with hydrogen peroxid to form a very unstable holoxid derivative which immediately decomposes with the evolution of molecular oxygen. The authors are inclined to look upon catalase as a reducing substance, which may under some conditions combine with atmospheric oxygen to form an oxidase.

METEOROLOGY—CLIMATOLOGY.

Meteorology at the British Association, A. L. Rotch (*Science, n. ser., 18 (1903), No. 464, pp. 657–661*).—The author reports that meteorology received much attention at the Southport meeting of the association. This was largely due to the fact that the International Meteorological Committee met with the association, and thus brought together prominent meteorologists from different parts of the world. Meteorology also predominated in the Physical Section of the association, which was divided into two subsections, one of which recognized meteorology as a distinct branch of physics. A commission was appointed to study the relations of solar physics to meteorology; the continuation of exploration of the upper atmosphere by means of kites was recommended; and the author's project to study the atmosphere over tropical oceans by means of kites flown from steamships was indorsed.

"Professor Hildebrandsson announced that the discussion of the cloud observations which had been made simultaneously in various parts of the world indicated the following to be the circulation of the atmosphere at different heights: (1) Above the thermic equator and the equatorial calms there exists throughout the year a current from the east; (2) above the trades an anti-trade blows from the southwest in the northern hemisphere and from the northwest in the southern; (3) this anti-trade does not pass the polar limits of the trades, but deviates more and more to the right in the northern hemisphere and to the left in the southern, so as to become a current from the west over the barometric maximum of the tropics where it descends to increase the trade; (4) the regions situated at the equatorial limit of the trade join sometimes that of the trade, sometimes that of the equatorial calms, according to the season; (5) the pressure of the air diminishes gradually toward the poles, at least beyond the polar circles; (6) the upper layer of air in the temperate zones flows over the high pressures of the tropics and descends there; (7) the irregularities found at the surface of the earth, especially in the regions of the Asiatic monsoons, generally disappear at the height of the lower or intermediate clouds; (8) it is necessary to abandon completely the idea of a vertical circulation between tropics and poles, hitherto assumed, according to James Thomson and Ferrel."

The weather and practical methods of forecasting it, E. B. Dunn (*New York: Dodd, Mead & Co., 1902, pp. VIII+356, pls. 7, figs. 21*).—It is stated that in this work "it has been the aim of the author to avoid all mathematics, and scientific and technical terms, and present the subject in the simplest and most popular form. Rules and methods for determining weather changes are given from a personal and practical experience of the author covering nearly 30 years." The topics treated in

different chapters are the atmosphere, instruments, pressure of the air, temperature, winds, evaporation and humidity, condensation and precipitation, optical and electrical phenomena of the atmosphere, atmospheric disturbances, local storms, weather maps, climate, and how to foretell weather changes by the use of the barometer and local atmospheric conditions.

Weather conditions, W. Elliott (*Rpt. Dept. Agr. Northwest Territories, 1902, pp. 5–21*).—The general weather conditions of the Northwest Territories are described and tables are given which include data for rainfall at a large number of places during 1902 and previous years, temperature observations during 1902, and the relation between daily temperature, total precipitation, and crop yields for different districts from 1898–1902.

Report of the meteorological work of the Ploti Agricultural Experiment Station, M. Svolinsky (*Rap. An. Sta. Expt. Agron. Ploty, 8 (1902), pp. 1–23, charts 3*).—Observations on temperature of the air and soil, atmospheric pressure, humidity, precipitation, evaporation, cloudiness, sunshine, solar radiation, wind movement, and miscellaneous phenomena are recorded.

WATER—SOILS.

Colorado irrigation waters and their changes, W. P. Headden (*Colorado Sta. Bul. 82, pp. 77*).—This bulletin discusses the source, character, and conditions affecting the nature of the irrigation waters of Colorado, especially as typified in the waters derived from the Cache la Poudre River. Analyses of the waters of this stream at different points in its course, of the stored water of the stream, and of the ground water, drainage, and return seepage resulting from the use of the water in irrigation, are reported and discussed in detail. Analyses of the waters of a few other Colorado streams are also reported for comparative purposes, and a brief account is given of a study of the suspended matter carried by the Cache la Poudre in times of high water.

The results show that the character of the water of the Cache la Poudre, and of the mountain streams of Colorado in general, changes rapidly as soon as they enter the plains section of their courses. The amount of total solids in Cache la Poudre water was found to increase from 2.9 gr. per imperial gallon as the river leaves the mountains to 10.2 gr. as delivered to the town of Fort Collins less than 8 miles away. From the results of laboratory experiments and from the occurrence of strontium and lithium in the Cache la Poudre water the conclusion is drawn that the mineral matter held in solution by the streams in their mountain courses is due principally to the solvent action of water containing carbon dioxid on feldspar. "The amount of mineral matter which the Poudre carries through its canyon daily, assuming a flow of 300 second-feet, is nearly 26 tons." This is only about one-half as much as was brought into solution by laboratory experiments with fine-ground feldspar and carbonated water, viz, 4.536 gr. per gallon.

"The effect of storage is to increase the mineral matter held in solution. Some of the increase is derived from the ditches through which the water flows and from seepage directly into the reservoirs. A small increase, 0.5 gr. per gallon, is due to evaporation, but by far the largest increase is shown in instances where seepage water is either intentionally stored or flows into the reservoir." The mineral matter held in solution by stored water varies considerably with different reservoirs, and also differs from that of the streams from which it is derived. "The salts predominating in the water of the Poudre while it is a mountain stream are the carbonates, with some chlorids and sulphates, but as stored in Terry Lake and Windsor reservoir the carbonates have almost disappeared and their place has been taken by the sulphates. The amounts of calcium, magnesium, and sodium sulphates which

appear in the stored waters are large." The amount of potash present is not large and comes mainly from seepage water or other sources besides the river water.

"The amount of nitrogen, including all forms, added with the irrigation water, being less than 4 lbs. per acre, is negligible. . . .

"Water used in direct irrigation, that is, water conveyed by means of ditches directly from the river to the land irrigated, suffers less change than when stored, but does not by any means escape altogether."

Observations on the changes which water undergoes when used in irrigation "indicated that water flowing for 600 ft. over the plat experimented with, carried between 800 and 1,000 lbs. more salts in solution per acre-foot than the on-flowing water. The first water that flowed off gave much higher results, but subsequent samples showed a rapid falling off. The water entering the soil caused the solution of not less than 4,400 lbs. of salts per acre-foot, and probably very nearly three times this amount.

"The salts taken into solution by the water entering the soil and becoming ground water, are calcium, magnesium, and sodium sulphates. The salts dissolved in the next largest quantities were sodium chlorid and sodium carbonate. The amount of salts brought into solution in the ground water, due to the application of water to the surface, varies not only in the total amount of salts, but also in the relative quantities of the individual salts. The salt that went into solution the most freely in 1898 . . . was sodium sulphate, for which we found an increase of 1,430 lbs. in each acre-foot of ground water. In 1899, the largest increase was shown by calcium sulphate, an increase of 1,638 lbs. per acre-foot."

Some of the conditions which probably cause the variations in the relative solubility of the different salts are discussed. These include character and amount of water applied, character of soil, and temperature and other climatic conditions. The general conclusion is reached "that the salts in the ground water are essentially the same at all times, and the application of water to the surface, whether it be irrigation water or rainfall, does not change in any material way the salts present. The relative quantities in which they are held in solution in the ground water vary quite widely, while the causes of the variations are not evident."

The results obtained in a study of the relation between the composition of the ground water and drainage water, although not strictly comparable since the samples were not obtained from the same plats, lead to the conclusion that the drain waters at all times differ from the ground water. "They contain a smaller quantity of salts in solution, and are more uniform in this content than the ground waters. The salts present stand in a different order, especially in regard to their relative quantities, sodium sulphate sometimes disappearing entirely. Calcium sulphate is uniformly first in quantity, magnesium second, sodium carbonate third, and sodium chlorid fourth, with sodium sulphate quite irregular, but usually less than the sodium chlorid. The first significance of these facts is that our drains benefit our lands by removing the surplus water, rather than the useless or deleterious salts, from the soils. . . .

"Of the salts removed, the most injurious one, when present in sufficient quantity, is the sodium carbonate. . . . Sodium carbonate does not seem to be retained by the soil, or removed from solution by passing through it, while the sodium sulphate, or white alkali, is retained to a very marked extent." In the analyses reported the amounts of sodium carbonate in the ground water varied from 10 to 28 gr. per gallon, in the drain water from 11 to 23; sodium sulphate in ground water 89 to 105 gr., in the drain water 5 gr. The amounts of sodium chlorid and calcium and magnesium sulphates were also considerably less in the drain water than in the ground water.

"The amount of potash salts removed by the drain water [about 5 lbs. per acre-foot of water] was less than that found in solution in the ground water. . . . The

nitrogen carried by the drain waters is only a little more per acre-foot than the potash, it being 5.8 lbs. . . .

"We find the total solids in the return waters lower than in the ground waters, and having the same range as found for the drain waters. We find them characterized by the same salts, and in the same order in regard to their relative quantities, i. e., calcium sulphate, magnesium sulphate, and sodium carbonate, with sodium sulphate irregular in its quantity, but always subordinate, except in the sample of Arkansas River water taken at Rockyford, April 24, 1903, concerning which some doubts may be entertained, but which is probably correct, because the ground waters of that section are extremely rich in sodium sulphate. . . . The chief difference between the drain waters and the return waters taken from the rivers is in the potash present, which is greater in the return waters than in the drain waters. While some of the drain waters contain almost as much potash as the return waters, the latter are, as a rule, richer in potash than the former. The main features of these two classes of waters are, however, identical."

The amount of suspended matter in the water of the Cache la Poudre with a flood flow of 12,000 second-feet was found to be 2,800 tons per hour. Chemical analyses of this sediment showed it to differ but slightly in composition from the soils from which it was derived, being slightly richer in organic matter.

The underground waters of Arizona—their character and uses, W. W. SKINNER (*Arizona Sta. Bul. 46, pp. 271–296, figs. 2*).—"This bulletin is a compilation and discussion of the results of an examination of the ground waters of the Territory as to their suitability for sanitary, irrigation, and technical uses." The results of analyses of 235 miscellaneous samples of water collected in different parts of the Territory are reported. Some of these analyses are of special interest from sanitary and technical points of view, but there is not a sufficient number from any one point to permit of definite conclusions regarding the character of any local supply.

The purification of water supplies by slow sand filtration (*Jour. Amer. Med. Assoc., 51 (1903), Nos. 14, pp. 850–853; 15, pp. 909–911; 16, pp. 965–967; 17, pp. 1025–1027, figs. 9*).

Report of the chemical laboratory of the Ploti Agricultural Experiment Station, B. M. WELBEL (*Rap. An. Sta. Expt. Agron. Ploty, 8 (1902), pp. 69–116, chart 1*).—The work of this laboratory during 1902 followed substantially the same lines as in previous years (E. S. R., 14, p. 340). The data reported show that the average nitrogen content of the atmospheric precipitation during 3 years, 1900–1902, was 0.924 mg. per liter, or 3.9 kg. per hectare (3.5 lbs. per acre) in 1900, 5.2 kg. (4.6 lbs.) in 1901, and 3.7 kg. (3.3 lbs.) in 1902. The larger proportion of the nitrogen was in the form of ammonia. The ammonia content of different kinds of precipitation was found as an average of 3 years' observations to be as follows: Snow 0.915 mg. per liter, rain 0.964, rain with storms 1.229, early and late frost (*gelée blanche*) 2.7, hail 2.75, hoar frost (*givre*) 4.2, dew 5, and fog 5.57.

A study of the progress of nitrification in the soil under different conditions, by means of lysimeters 50 by 50 cm. in size, showed that from one-fifth to one-fourth of the water received in form of precipitation was recovered in the drainage. Taking only the days during which the temperature to a depth of 10 to 25 cm. did not fall below 5° C., the daily production of nitric nitrogen per hectare is calculated to have been 501 gm. in soil on which summer wheat had been grown and which had received no fertilizer or manure, 821 gm. in manured soil under summer wheat, and 876 gm. in soil bearing alfalfa. The production of nitric nitrogen in black fallow was about the same as in the manured soil.

Assuming that there are 125 days favorable to the production of nitric nitrogen in the soil during the period of growth of winter wheat, the author estimates that the first soil above referred to would furnish for this crop 63 kg. of nitric nitrogen per hectare (56.1 lbs. per acre), the second 103 kg. (91 lbs.), and the third 110 kg. (98 lbs.).

Analyses showed the nitrogen content of the crops in the 3 cases to be 83.5, 109.5, and 106 kg. per hectare (74.4, 97.5, and 94.4 lbs. per acre), a close agreement with the amounts indicated by the lysimeter measurements. The total amount of drainage water obtained from different lysimeters varied from 16.54 to 20.98 liters, yielding from 16.25 to 23.5 gm. of solid residue on evaporation. The relative proportions of the different constituents in the dry residue were as follows: Nitric nitrogen in the surface soil 45 to 46 per cent, in the subsoil 30 to 37 per cent; lime 25 to 32, organic matter 14 to 16, sodium and potassium chlorids 2.6 to 4, magnesia 1.8 to 2.4, sulphuric acid 1.7 to 1.9, silica 1 to 1.8, iron oxid and alumina 1.3 to 1.6. The amounts of some of these constituents per liter of drainage water are given as follows: Ammonia 0.2 to 0.5 mg., albuminoid nitrogen 0.8 mg., nitric acid very slight traces, phosphoric acid 1 to 3 mg.

A comparison of the amounts of nitrogen removed from the soil by different crops and returned in the residues was continued as in previous years. The results show that winter wheat required from 50 kg. of nitrogen per hectare (44.5 lbs. per acre) in seasons of poor yield to 85 to 100 kg. (75.7 to 89.1 lbs.) in seasons of good; winter rye 65 to 76–83 (57.9 to 67.7–73.9 lbs.) respectively. The residues of the former returned from 12 to 20 kg. of nitrogen to the soil, the latter 10 to 15. The previous conclusion that an increase in yield results in a decrease in protein content, especially in the grain, was confirmed.

The chemistry of the soil as related to crop production, M. Whitney and F. K. Cameron (*U. S. Dept. Agr., Bureau of Soils Bul. 22, pp. 71*).—It is stated in this bulletin that the chemical characteristics of soils have been given little recognition in the classification or mapping of soils by the Bureau of Soils "from the fact that the ordinary methods of determining the plant foods which a soil contains have not given results apparently related in any definite way to the yield of crops."

Discarding the various methods more commonly employed for the chemical examination of soils, for reasons which are explained, the water extract was adopted as the most satisfactory measure of the available plant food in soils, and methods for the rapid determination of small amounts of mineral matter in the water extracts have been worked out. After trying various means of getting soil solutions, including the use of a powerful centrifugal machine, "the Bureau finally adopted the convention of taking 100 gm. of the soil sample, stirring it vigorously for 3 minutes with 500 cc. distilled water, allowing it to stand 20 minutes for the coarser soil particles to subside, and decanting the supernatant solution containing more or less suspended clay and other solid matter." This solution was filtered under pressure through a Chamberland-Pasteur unglazed porcelain filter, and examined by methods which are briefly outlined as follows: "The bicarbonates are determined by titrating the filtered aqueous extract of the soil with a dilute acid solution, using methyl orange as an indicator; the chlorids by titrating with a dilute solution of silver nitrate, using carefully prepared potassium chromate as an indicator; the sulphates photometrically, using a modification of a method proposed by Hinds and Jackson; the nitrates by developing the color resulting from the addition of phenol-disulphonic acid, making the solution slightly alkaline with ammonia, and then comparing photometrically with a standard solution of potassium nitrate similarly treated; the phosphoric acid by comparing the color produced by adding molybdic acid to a solution containing phosphates in the presence of nitric acid with the color produced in a standard solution of sodium phosphate treated in a similar manner; the silica by the use of the nitric acid and molybdate solution, after allowing the soil solution to stand at least 1 hour, reading against the phosphate standard and subtracting the previous reading for phosphate; the potassium from the color produced when an excess of potassium iodid is added to a solution of a platinic salt and photometrically compared with a standard similarly treated, and the calcium and magnesium by an adaptation of the well-known Clark soap method, modified by Winkler, Wartha, and others."

The results of field examinations by these methods of the water extracts of several hundred oven-dried samples of 6 typical soils of varying degrees of productiveness from New Jersey, Maryland, and North Carolina are reported. From these results and from those of analyses of air-dried samples of type soils from various parts of the humid region of the United States the conclusion is drawn that "there is no apparent relation between the dissolved salt of the soils, as determined by the methods outlined above and the yield of crops, and that there are no constant differences between the different types of soil, although these types differ widely in their agricultural and crop values."

The extreme variations in the principal constituents of the water extracts of the 6 typical soils to which special attention was given were found to be as follows:

Variations in principal constituents of water extracts of typical soils.

	Number of analyses.	Parts per million of oven-dried soil.			
		Phosphoric acid (PO_4).	Nitric acid (NO_3).	Potassium.	Calcium.
Windsor sand	34	2.65–12.88	0.56–26.62	10.90–46.11	Trace– 47.50
Norfolk sand	98	1.71–16.52	.67–23.76	11.64–44.90	Trace– 46.86
Sassafras loam	80	2.24–21.45	.50–38.40	7.94–46.80	2.84– 62.72
Leonardtown loam	62	2.90–16.50	Trace–62.00	10.08–51.66	2.66– 34.22
Cecil sandy loam	57	.59–27.59	Trace–28.41	7.47–72.70	11.08–100.35
Cecil clay	120	2.40–40.60	Trace–34.12	4.93–83.80	10.70–102.85

The extreme variations found in analyses of air-dried samples of about 50 type soils from different parts of the eastern half of the United States were as follows: Phosphoric acid from 3.5 parts per million in Cecil loam (New Jersey) to 37.8 parts in Allegan gravelly loam (Michigan), nitric acid from 1.4 parts in Orangeburg sandy loam (Alabama) to 210.5 in Conestoga loam (Pennsylvania), potassium from 5.2 parts in Houston black clay (Texas) to 84 in Miami clay loam (Ohio), calicium from 2 parts in Cecil loam (New Jersey) to 213.2 in Orangeburg clay (Alabama).

The average of 147 of the analyses (the basis of selection of which is not stated) is reported as follows: Phosphoric acid 7.64, nitric acid 5.47, calcium 11.67, and potassium 22.74; and the conclusion is drawn that "while these values will undoubtedly vary somewhat as a result of wider investigations, it is believed that they represent closely the average figures for the great majority of cultivable soils as regards these several constituents, which the procedure used in this investigation will show; and so far as the investigations have been carried, it may be stated, no evidence has yet been found, except possibly in occasional samples, where the quantity of any one of these necessary plant foods was below the amount necessary for the support of a medium to good crop."

Results of examinations of the water extracts of soils at different depths are cited to show "that the soil proper does not contain materially more soluble plant food than does the subsoil." Examinations of soil water obtained by means of the Briggs centrifuge showed the soil solutions to be remarkably uniform, although the amounts of water originally present in the soils varied from 10 to 25, and widely divergent soil types were used. Data as to the effect of drying in increasing the solubility of the soil constituents are reported.

The authors state that in view of the results reported "the conclusion seems justified that, although differences in the dissolved salt content, or in the concentration and composition of the soil moisture, may be a factor in the yield as well as quality of a crop, it does not appear to be a major one in determining or controlling the wide variations observed in crop yields on different soils. It appears further that practically all soils contain sufficient plant food for good crop yield, that this supply will be definitely maintained, and that this actual yield of plants adapted to the soil

depends mainly, under favorable climatic conditions, upon the cultural methods and suitable crop rotation, a conclusion strictly in accord with the experience of good farm practice in all countries, and that a chemical analysis of a soil, even by these extremely delicate and sensitive methods, will in itself give no indication of the fertility of the soil or of the probable yield of a crop, and it seems probable that this can only be determined, if at all, by physical methods, as it lies in the domain of soil physics."

The influence of climate, texture of the soil, rotation, and variety of crop on the yield of crops, as well as the rôle of commercial fertilizers, are discussed. It is claimed that in view of the results reported in this bulletin "the rôle of fertilizers requires other explanations than those now generally accepted. There is no question that in certain cases, and in many cases, the application of commercial fertilizers is beneficial to the crop, . . . but whether [the] increase is due to an actual increase of the plant food in the soil, to an early stimulation of the plant to enable it to get its roots out into a sufficient volume of soil, or to some physiological or physical effect is not altogether clear."

The authors conclude "that on the average farm the great controlling factor in the yield of crops is not the amount of plant food in the soil, but is a physical factor the exact nature of which is yet to be determined."

Pineapple culture. I, Soils, H. K. Miller and H. H. Hume (*Florida Sta. Bul. 68, pp. 669–698, pls. 9*).—Chemical and mechanical analyses of 21 samples of soils, with corresponding subsoils, collected in different localities in Florida where pineapples have been successfully grown, are reported in this bulletin, with descriptions of the soils and of the local conditions and characteristic vegetation of the regions from which they were obtained, notes on sampling, and a general discussion of the requisites of a good pineapple soil. Comparing the results of the chemical analyses with the average figures given by Hilgard, it is shown that the pineapple soils are generally deficient in plant food.

"Few of the soils would be able to produce more than two or three crops of pineapples if all the plant food present were available. And when we consider that only a small proportion of this is actually in a condition to be taken up by the plants, we can readily understand why it is impracticable to produce pineapples on such soils without making liberal applications of a complete fertilizer.

"In a general way all our pineapple soils are shown to belong to the same type, a type which is marked by the absence of any appreciable amount of very fine sand, silt, and clay. The capacity of these soils for holding water is not great, inasmuch as the interstitial spaces are relatively large and are not altogether capillary, but are only such near the points of contact of the soil grains."

The sugar-cane soils of Jamaica, H. H. Cousins (*Bul. Dept. Agr. Jamaica, 1 (1903), Nos. 4, pp. 76–93; 5, pp. 97–109*).—Mechanical and chemical analyses of 31 samples of sugar-cane soils and 23 subsoils from different districts of Jamaica are reported, together with the results of fertilizer experiments on some of the soils. The wide variation in the character of the soils successfully used in sugar-cane production is noted. They vary from light gravelly sands to stiff clays and from soils containing almost no lime to those containing 50 per cent of calcium carbonate. All soils on which sugar-cane cultivation is normally successful present, however, on the whole a very high standard of fertility, the proportion of phosphoric acid being particularly high, while potash is the constituent of which there is the smallest available supply.

Reclamation of alkali land at Fresno, Cal., T. H. Means and W. H. Heileman (*U. S. Dept. Agr., Bureau of Soils Circ. 11, pp. 9*).—A brief account is given of experiments in drainage and flooding to remove alkali from a 20-acre tract of land 2½ miles south of Fresno. "Three-inch, 4-in., and 6-in. tile were laid over the tract at an average depth of a little over 3 ft. and 150 ft. apart. . . . The work of ditching

was commenced in December, 1902, and was completed in February, 1903." It was found to be impossible to obtain a gravity outlet for the drainage water, and a chain pump operated by a water wheel was installed to remove the drainage water. The total cost of ditching, tiling, and all incidentals except the cost of the pump and water wheel was $16.50 per acre.

"About the first of March, 1903, irrigation was commenced. The land was divided into 30 checks, the size of each check depending upon the slope of the land. The largest checks, those on the level land, are about 2 acres in extent, while on the steeper slopes they are less than half an acre. The object was to divide the land in such a way that it could all be kept under water to a depth of 4 in., and the reclamation was to be accomplished by maintaining the water at this depth until enough alkali had been washed out of the soil through the drains to enable a crop to be grown."

When the drainage system was installed 18 of the 20 acres contained too much alkali to produce a crop. After 4½ months of the treatment above described all of the land, with the exception of small spots, amounting in the aggregate to less than 2 acres, was considered ready for the sowing of alfalfa. On the basis of this demonstration of the feasibility of reclaiming alkali land by underdraining and flooding, the authors outline a general plan for the reclamation of the Fresno district, at an estimated cost of $10 per acre.

Soil temperatures at Lincoln, Nebr., 1888–1902, G. D. SWEZEY (*Nebraska Sta. Rpt. 1902, pp. 95–129*).—Observations on soil temperature have been made at the station during 15 years beginning with May 1, 1888, with thermometers placed at depths of 1, 3, 6, and 9 in., and 1, 2, and 3 ft. The readings for the years 1888 to 1893 have already been reported (E. S. R., 6, p. 123). A detailed tabular summary of daily readings for the years 1894 to 1902 is given in this article.

During 1891 readings were made 4 times daily during February and August for the purpose of studying the behavior of the diurnal wave of temperature. The data reported show "that the daily fluctuations in the air are nearly coincident in time with those at the surface of the ground and are not very different from them in amount; that the diurnal wave gradually progresses downward and at the same time gradually grows less marked until it finally disappears. In winter the daily maximum is reached in the middle of the afternoon; at depths of 3 to 6 in. the maximum occurs in the evening; at 1 ft. it is delayed till the following morning, below which it is scarcely appreciable, appearing, if at all, during the following day; the minimum temperature, which occurs in the air in the early morning, is propagated downward at about the same rate. In summer the daily range is considerably greater at all depths, the changes are appreciable to a depth of at least 2 ft., and are retarded to about the same extent as in winter."

A study of the monthly normals leads to similar conclusions regarding the progress of the annual temperature wave, that is, "the annual changes of temperature are greater at and near the surface of the ground than in the air itself, and that the annual range, like the diurnal, decreases with great regularity as we go down. The data also show that on the whole the air receives heat from the soil rather than the soil from the air; this follows from the fact that the soil is warmer than the air. . . . The temperature of the soil to the depth of a few inches is higher during every month of the year than is the air which lies upon it, and the deeper soil is warmer on the average than the air. . . . How much of this excess is due to the downflow of solar heat and how much to the upward flow of the internal heat of the earth does not appear from our data; we can only say that more of it comes from above than from below, but how much more we can not say because our observations do not reach deep enough. . . . At the depth of our deepest thermometer the flow of heat is downward rather than upward."

It was found "that the yearly maxima and minima are reached at practically the same time for the air and the upper few inches of soil, and that the annual wave of temperature progresses somewhat regularly downward, although of course somewhat distributed by temporary changes in the weather, requiring about a month to reach the depth of our lowest thermometer."

The movement of the frost line and periodic changes in temperature are briefly discussed.

Uses of peat and its occurrence in New York, H. Ries (*Albany: Univ. State of New York, pp. 36, illus.*).

The study of soils and agronomic charts, H. Lagatu (*L'étude des terres et les cartes agronomiques. Montpelier: Coulet & Son, 1903, pp. 31*).—This article discusses the preparation and use of soil maps or agronomic charts and reports studies of the quarternary diluvium of Vendres and the blue tertiary marls of the Montady basin with suggestions as to the fertilizer requirements and management of these soils.

The frontier of physiography, W. H. Hobbs (*Science, n. ser., 18 (1903), No. 460, pp. 538–540*).—This article explains the province and importance of a study of *epeirogenic physiography*, as distinguished from *orogenic physiography*, in its relation to the architecture of the earth's surface, and refers to investigations made in southwestern New England which indicate "that for a large area the earth's physiognomy is the outward expression of its internal structure." The results of this study in detail are to appear in a monograph of the U. S. Geological Survey.

FERTILIZERS.

Experiments upon the use of potash as a fertilizer, H. J. Patterson (*Maryland Sta. Bul. 89, pp. 165–196*).—This bulletin gives a brief historical account of the use of potash in agriculture; discusses the rôle of potash in plants, the quantity removed from soils by plants, origin and condition of potash in soils, sources and forms of potash fertilizers; and reports experiments begun in 1897 on tenth-acre plats, of medium, stiff, clay loam having fairly good drainage, for the purpose of studying "some of the underlying principles surrounding the use of potash fertilizers as to their time and method of application, their relation to other plant foods and ingredients which enter into the different sources of supply, and to make a general study of the effect of potash on the quality of the crop."

Kainit, muriate of potash, sulphate of potash, sulphate of potash and magnesia (double manure salt) were applied (1) just before planting, (2) for spring crops in the fall and fall crops in the spring. Other potash fertilizers used in the series of tests were carbonate of potash and magnesia, wood ashes, cotton-hull ashes, and silicate of potash. Lime at the rate of 800 lbs. per acre with muriate and sulphate of potash, and muriate of potash, with and without lime, combined with sufficient dissolved rock phosphate to furnish phosphoric acid equal to that in wood ashes were also tested in the series. One plat received barnyard manure at the rate of 5 tons per acre and a number of check plats received no potash.

The fertilizers were applied broadcast just before planting or 3 to 6 months before. The results obtained with 6 crops—corn, late potatoes, cowpeas, wheat, hay, and early potatoes—are reported and "with one exception, all favor applying fertilizers which contain much chlorids, several months before planting the crop, and those having the potash as sulphate at the time of planting the crop. The crop of cowpeas gave results just the reverse. It is a matter of interest to note that the results obtained give about the same figures favoring applying chlorids a considerable time before planting crop, as was obtained favoring the application of sulphates at time of planting the crop; that is, by excluding the cowpea figures, there was in 5 crops 3,527 lbs. more product obtained by applying chlorin potash salts 3 to 6 months

before planting crop, and 3,600 lbs. more by applying sulphates at time of planting crop. . . .

"None of the results show a very marked increase of product as a result of potash fertilization, yet they do point toward muriate as being the most efficient in producing an increase of crop. Sulphate of potash stands second; carbonate of potash and kainit indicate negative results." All of the fertilizers furnishing potash in the form of carbonate were effective in increasing the yield. "Cotton-seed hull ashes proved the most effective. . . . The carbonate of potash and magnesia, which is one of the Stassfurt productions, did not seem quite as active at the start, but with the 6 crops it produced a larger increase than wood ashes. . . . The carbonate of potash and magnesia produced on the 6 crops over double as much increase as was produced by the muriate of potash when compared to their respective nothing plats. . . .

"The use of lime with muriate and sulphate did not prove of any material advantage. . . . The use of lime with sulphate of potash was more effective in increasing yields than wood ashes, while the muriate of potash and lime was less so. Supplementing muriate with phosphoric acid, and with lime and phosphate in combination, gave [inconclusive] results."

The results of these experiments as well as of others made at the station indicate that the soil used is not as deficient in potash as in phosphoric acid. It also lacks organic matter and nitrogen.

No special effect of the potash fertilizers on the quality of the product was observed in the experiments reported in this bulletin, but in other experiments at the station on tobacco "it was shown that high-grade sulphate of potash produced the best tobacco, and carbonate of potash, as furnished by cotton-seed hull ashes, the next best. All potash salts which contained either much chlorin or magnesia produced a tobacco of poor quality, which cured badly and [showed] very poor burning [properties].

"In the tomato experiments, potash had a marked effect in increasing the yield and quality of the tomatoes. Tomatoes fertilized with potash were more solid, yet a little more acid."

Is nitrate nitrogen more effective than that of ammonia salts and is the ratio of 100:90 correct? BACHMANN (*Fühling's Landw. Ztg., 52 (1903), Nos. 4, pp. 132–138; 5, pp. 183–190*).—The results of a number of experiments with different kinds of crops are reported to show that when proper attention is given to the time and manner of applying ammonium salts they are often more effective than nitrates, and that Wagner's ratio of 100:90 is not correct. Early application in the spring seems to be the most important requirement for effective action of the ammonium salts on most crops. There is a considerable after-effect of the ammonium salts not observed in case of nitrates.

The manufacture of superphosphates and other common fertilizing materials, L. SCHUCHT (*Die Fabrikation des Superphosphats mit Berücksichtigung der andern gebräuchlichen Düngermittel. Brunswick: Friedrich Vieweg & Son, 1903, pp. XI+356, pls. 4, figs. 79*).—The manufacture of superphosphates is treated from both theoretical and practical standpoints. The preparation of phosphoric acid, double superphosphates, Thomas slag, bone meal, precipitated phosphate, and other citrate and citric-acid-soluble phosphates, etc., is also discussed. A chapter is devoted to methods of examination of fertilizers and another to means of preventing accidents, and various tables useful in connection with the manufacture and examination of the products are given.

A new adulterant of commercial fertilizers, A. BRUTTINI (*Staz. Sper. Agr. Ital., 36 (1903), No. 7, pp. 584–590*).—It is claimed that the residue from the mother liquor obtained in preparing salt from brines is used in the preparation of fertilizers. Its fertilizing value is shown to be low.

Analysis of commercial fertilizers sold in Maryland, H. B. McDonnell et al. (*Maryland Agr. Col. Quart., 1903, No. 21, pp. 54*).—The results of analyses of 489 samples of fertilizers examined from March to June, 1903, are reported, with notes on valuation, the text of the State fertilizer law, and a brief discussion of proposed amendments of the law.

Complete report on commercial fertilizers for 1902, J. H. Stewart and B. H. Hite (*West Virginia Sta. Bul. 85, pp. 110*).—This report contains a list of the fertilizers registered for sale in the State during the year and the results of analyses, with notes on the operation of the new fertilizer law and the source and value of various fertilizing materials.

Licensed commercial fertilizers, F. W. Woll (*Wisconsin Sta. Bul. 100, pp. 3–13, 18, 19*).—The text of the State fertilizer law is given and analyses of 17 samples of fertilizers licensed in the State during 1903 are reported with a brief general discussion of the subject of fertilizers.

FIELD CROPS.

Report on work at the Ploti Experiment Field in 1901-2 (*Rap. An. Sta. Expt. Agron. Ploty, 8 (1902), pp. 139–142*).—The work has been continued along former lines (E. S. R., 14, p. 340), but has been extended. This season winter wheat after corn yielded 930 kg. of grain and 2,400 kg. of straw, and winter rye after a cereal crop 960 kg. of grain and 480 kg. of straw per hectare less than a crop grown on cultivated fallow. Green manure seemed to increase the yield of winter wheat over cultivated fallow. These results were obtained on the extension of the experiment fields and represent only 1 season.

The results on the older portions of the field showed that the time of cultivating fallow was of great importance in growing winter wheat, and that it affected in a large measure the succeeding summer crop. The bare fallow gave the best yields of winter wheat and summer barley. Fallows cultivated in April and May gave about equal yields, but the quality was much in favor of April cultivation. A field under a 9-year rotation, including crops of leguminous forage plants of long periods of growth, produced much better yields of winter wheat and summer cereals than a field under a 4-year rotation.

Deep plowing produced the larger yields of sugar beets and winter wheat, while shallow plowing gave the larger yields in spring wheat. Shallow cultivation in growing winter wheat and oats by the Owsynski method was unprofitable this season as compared with deep cultivation.

Plats receiving barnyard manure showed an increase of 70, 56, and 28 per cent in the yield of wheat, lentils, and beets, respectively, as compared with the check plats. The addition of phosphates to barnyard manure had effect on the sugar-beet crop only, the increase in yield as compared with the manured land being 68.5 per cent. The results with complete fertilizers containing no calcium carbonate showed an increase of 12 per cent for cereals and 26 per cent for sugar beets over a complete application containing the substance. The use of superphosphate seemed to increase the weight of the grain of winter wheat, oats, barley, and lentils.

Annual Report of the Burdwan Experimental Farm for the year 1901-2, D. N. Mookerji (*Calcutta: Dept. Land Records and Agr., Bengal, 1903, pp. 13*).—A description of the farm is given, and the results of fertilizer, culture, and variety tests are reported. The chemical composition of 2 samples of the surface soil is also shown.

A mixture of bone meal and nitrate of potash, among different fertilizer applications for paddy, gave the best returns. This has been uniformly the case since the beginning of the experiments in 1891. Jute plowed under for green manuring, when

3 ft. high, gave a profitable increase in the paddy crop. Since 1889 cow manure has been the most effective fertilizer for jute. An experiment with sugar cane consisted in testing the relative merits of cow manure, bone meal, a mixture of the two, and a mixture of cow dung and superphosphate applied in quantities furnishing 250 lbs. of nitrogen per acre. All returns showed a small profit. The use of cow manure and bone meal gave the largest yield. Fertilizer tests with potatoes resulted in favor of manure kept in covered pits and moistened with the liquid manure of cattle. The use of *Sesbania aculeata* as a green manure for potatoes proved profitable as compared with unmanured plats.

During the last 4 years sowing paddy at the rate of 60 lbs. per acre has given decidedly better results than sowing one half that amount. The increase in yield this season due to seed selection amounted to 30 per cent. The ordinary method of planting sugar cane in shallow furrows yielded 49,236 lbs. and the method of trench planting 62,351 lbs. of cane per acre. Cuttings from the whole canes gave better results than top cuttings. In potato planting experiments the same weight of tubers as cut seeds gave a larger yield than whole tubers, but for the same number of plants per acre the results favor the whole tubers.

The results of variety tests were in favor of Diamond Harbor paddy, Kajli sugar cane, Amragachi potatoes, and Black Seeded sorghum.

Field experiments with fertilizers, C. E. THORNE (*Ohio Sta. Bul. 141, pp. 69–84, pls. 4*).—The plan of these experiments and a summary of the results up to 1900 have been published in previous bulletins (E. S. R., 13, p. 340). The work is being conducted at the station at Wooster and the branch station at Strongsville. The purpose of the present bulletin is to discuss the questions relating to the economical production of crops by the use of commercial fertilizers. Data thus far obtained at both places, showing the average yield, average increase in its value, cost of fertilizers and profit or loss per acre, and the effects of reducing the nitrogen and potash, the comparison of fertilizers of different percentage composition, and the influence of lime on clover, are given in tables.

The average value of the total increase in the 5-crop rotation at Wooster has been greatest on the plats receiving the largest applications of commercial fertilizers and barnyard manure, and these plats have also gradually outranked the others in net profit per acre. The results at Strongsville indicate that the applications of nitrogen and potash may be safely reduced to the lowest quantities used in this test. They further show that phosphoric acid is the dominant element in producing increase of crop on that soil. In these tests steamed bone meal proved more effective than raw bone meal, believed to be due to its greater fineness.

In 1900 an experiment was begun at the station to test the effect of lime upon clover, on soil poor in clover production. The average yield on plats receiving 1,000 lbs. of lime per acre, either alone or in combination with other fertilizers, was in some instances one-half ton per acre larger than on the corresponding unlimed plats. The author believes these results indicate "that on a soil which has become acid through exhaustive cultivation and the use of incomplete fertilizers, and on which clover refuses to grow, the addition of lime may restore the conditions essential to clover production."

The following conclusions are considered applicable to the kind of soil on which the experiments are being made, which is described as "a thin sheet of glacial drift, lying upon and largely modified by shales and sandstones of the Waverly formation.

"For the soils under test in these experiments phosphorus is the controlling element in producing increase of cereal crops, and neither nitrogen nor potassium will produce a profitable increase except when used in association with phosphorus.

"Except on soils which have been depleted by exhaustive cropping, the quantity of

phosphorus in the fertilizer, as compared with the nitrogen and potassium, should be much greater than that found in barnyard manure.

"While the effect of nitrogen in the fertilizer is secondary to that of phosphorus on these crops grown in rotation with clover, the considerably larger increase produced by fertilizers containing nitrogen, especially in the wheat crop on the worn soil at Wooster, is evidence that this element can not be entirely omitted from a fertilizer for such soils without loss of possible increase.

"Potassium apparently occupies the third place in a fertilizer for these soils, yet it is evident that some carrier of this element is essential to the highest effectiveness of the fertilizer.

"No definite ratio between the different constituents of the fertilizer can be fixed for all soils and crops. Apparently crops immediately succeeding clover or other legumes require less nitrogen in the fertilizer than those more remote, while the ratio between the phosphorus and potassium needed is probably chiefly determined by the geological history of the soil."

Fertilizer formulas for different conditions are suggested.

Infected alfalfa soil, C. G. Hopkins (*Illinois Sta. Circ. 70, pp. 2*).—Brief directions are given for the inoculation of land with infected alfalfa soil furnished by the station.

Experiments with buckwheat, J. H. Stewart and H. Atwood (*West Virginia Sta. Bul. 84, pp. 467–474, pls. 5*).—Fertilizer and variety experiments with buckwheat have been carried on for 5 years at the station and near Reedsville, in Preston Co. At Reedsville in 1898 plats receiving 300 lbs. nitrate of soda, 400 lbs. sulphate of potash, and 400 lbs. acid phosphate yielded 17.5, 21.2, and 43.7 bu. per acre, respectively, as compared with 17.5 bu. on the check plat. The year following the yields on plats fertilized with 188 lbs. nitrate of soda, 90 lbs. sulphate of potash, and 77 lbs. acid phosphate were 10, 17.7, and 31.6 bu. per acre, respectively.

In 1900 acid phosphate exercised a beneficial influence wherever applied, whether alone or in combination, while nitrate of soda and sulphate of potash, either alone or used together, did not materially increase the yield. The plat receiving 400 lbs. acid phosphate ranked first, with a yield of 40 bu., while the plat receiving the same amount of nitrate of soda and sulphate of potash yielded 23.08 and 23.1 bu., respectively. The check plat in this series gave a yield of 22 bu. per acre.

The results of 1901 show that amounts of acid phosphate in excess of 150 lbs. per acre increased the yield but slightly. The plat which received no fertilizer in addition to 30 bu. of stone lime per acre applied in 1899 yielded this season 32.1 bu. per acre as compared with 22.7 bu. on the no-fertilizer plat. The last year of the experiments acid phosphate again showed its superior effect, and nitrate of soda and sulphate of potash gave the best returns when used in connection with each other. In the experiments at the station acid phosphate did not show such marked results, yet its beneficial effect was apparent.

In a variety test the average yields for 3 crops, 1 grown at the station and the others at Reedsville, were 31.3, 19.6, 18.1, and 20.8 bu. per acre for Japanese, Silver Hull, Gray, and Russian buckwheat, respectively. Seed from Ontario, Canada, yielded 3 bu. per acre more than seed grown in West Virginia.

Buckwheat was sown on 8 different dates, from May 5 to July 13, and the best yield was obtained from the sowing May 28, which was closely followed by that made June 6. Suggestions on the culture of the crop are given.

The continuous growth of mangels for 27 years on the same land, Barn Field, Rothamsted, A. D. Hall (*Jour. Roy. Agr. Soc. England, 63 (1902), pp. 27–59, figs. 9*).—An account is given of the experiments in the continuous growth of mangels on the same land, which form a part of the Rothamsted investigations.

After describing the experiment and reporting the results in detail, the author concludes—

"That mangels can be grown continuously on the same land without injuring the tilth of the land or the health of the crop. That a liberal dressing of farmyard manure forms the best basis of the manure for mangels. That the crop will further respond to considerable additions of active nitrogenous manures to the dung, particularly of nitrate of soda. That a free supply of potash salts is essential to the proper development of the mangel, hence a specific potash manuring is desirable even when dung is used in large quantities, and on a strong soil initially rich in potash. When nitrogenous manures are used in addition to dung, the potash salts should be increased pro rata, in order to maintain the health and feeding value of the crop and to bring it to maturity. That, in conjunction with dung, superphosphate or other phosphatic manure is hardly necessary and will give little appreciable return, especially when the crop is grown in rotation. That, as soluble alkaline salts are beneficial to the mangel crop, either as direct foods or as economizers of potash, a dressing of salt should always be included among the manures for the mangel crop."

A variety test of oats, J. H. Stewart and H. Atwood (*West Virginia Sta. Bul. 84, pp. 475–480*).—Of 24 varieties grown in 1900 Extra Swedish, Black Prolific, Silver Mine, White Bonanza, American Banner, Big Four White, Imperial American, and White Russian, given in the order of their productiveness, yielded from 60 to 67.8 bu. per acre. The lowest yield obtained from any variety was 35 bu. In 1901, 5, and in 1902, 7, of these varieties were again among the 8 leading sorts. The influence on the yield of the distribution of rainfall during the growing season is shown.

On the viability of shelled oats, J. A. Andersson (*Landtmannen, 13 (1902), No. 42, pp. 676–678*).—Trials conducted by the author showed that shelled oats are considerably inferior to unshelled oats, not only as regards viability and germinative energy, but also in yield. The latter was 20 to 25 per cent lower in case of the shelled oats, under similar cultural conditions for both kinds of grain.—F. W. WOLL.

The rape plant; its culture, use, and value, J. H. Grisdale (*Canada Cent. Expt. Farm Bul. 42, pp. 6*).—General and brief directions are given for the culture of the rape plant, and the uses of the crop in feeding different kinds of farm animals are noted.

Distance experiments with sugar beets, J. J. Vaňha (*Centbl. Agr. Chem., 32 (1903), No. 8, pp. 538, 539*).—Sugar beets were grown 20, 25, and 30 cm. apart in rows 35, 40, and 45 cm. distant. The distance allowed each plant ranged from 700 to 1,350 sq. cm. The smallest yields were obtained from the 35 cm. rows with the plants at intervals of 30 cm. Planting the beets 30 cm. apart in rows 45 cm. distant gave much the best yields.

Distribution of sugar in the beet, I. Zlobinski (*Vyestnik Sakh. Prom., 1903, No. 21; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 4, p. 499*).—Taking his investigations as a basis, the author describes the portion of the beet richest in sugar to be a narrow zone around the center of the root.—P. FIREMAN.

The effect of removing or injuring the leaves of sugar beets on the development of the plant, H. Claassen (*Centbl. Agr. Chem., 32 (1903), No. 8, pp. 539–541*).—Experiments were made to determine the effect of removing some of the leaves of sugar beets while the plants are still growing. In one row the small inner leaves of the plant were entirely cut away; in another row the larger outer leaves were removed; while from all except the smaller inner leaves of the plants in a third row, one-half of the leaf surface was cut away; and in the fourth row the leaves were mutilated in a manner approximating injuries due to hail.

The smaller inner leaves were soon replaced after their removal by a new growth. The larger leaves were not replaced, but the remaining ones made a good vigorous

growth, so that by the end of the season the ground was again well covered. The injured leaves remained green and fresh, and the smaller inner leaves of these particular plants were induced to make a better growth by this treatment. The results showed that the removal of the leaves and injury to the same had practically no effect on the sugar content, but that it reduced the weight of the beets. Cutting away the inner leaves had the least effect. It is estimated from the data obtained that the removal of entire leaves, or parts of the same, whether by hail or otherwise, may cause a reduction of 30 per cent in the weight of the crop.

Investigations with sugar cane (*Verslag. Proefstat. Suikerriet, West Java, 1903, pp. 85–94*).—Water cultures of sugar cane were successful in development when nitrogen was furnished in the form of nitrate of potash, while plants given nitrogen as ammonium sulphate perished. The plants seemed to absorb the ammonium sulphate, but were incapable of assimilating it. It is concluded from these results that under field conditions cane draws upon the nitrates for its nitrogen supply and that ammonium sulphate can be useful to the plants only after it has undergone nitrification.

The increase in the weight of dry matter was studied by making 200 sections of a leaf in the morning, and the same number at different times during the day from leaves of the same plant and apparently equal in all respects to the one from which the first lot of sections had been made. The dry matter in these sections was determined and the increase noted. It is concluded that under favorable weather conditions an increase in weight of the dry matter of more than 15 per cent in the course of a forenoon indicates good growth, an increase of 10 to 15 per cent, medium, and from 5 to 10 per cent, poor growth, while an increase of only 5 per cent may be regarded as practically a stagnation in growth.

Observations with reference to the transpiration of water by the cane plant showed that the quantity was approximately 5 liters per day. Experiments on the respiration of the plant were made and the daily quantity of carbon dioxid formed and glucose consumed in different varieties is given.

Cuttings of 4 or 5 internodes are recommended for planting.

Experiments in growing tobacco of the Sumatra type under shade, E. H. Jenkins (*Connecticut State Sta. Rpt. 1902, pt. 4, pp. 446, 447*).—It was found that mosquito netting as a covering for the growing crop was as durable as cheese cloth and shaded the plants to a much less extent. The author does not consider shade at all necessary in that latitude, and believes the value of shade to lie in the protection from insects, high winds, hail, and drought, and in providing a higher and more equable temperature and a damper atmosphere.

Owing to an unsatisfactory growth of part of the crop an intended comparison of curing on the stalk and curing the primed leaves became impossible. The pole-cured crop of this season was about 250 lbs. less than the pole-cured crop of 1901 and also inferior to it in quality. The finished crop of 1901 was sold at an average price of $1.59 per pound.

Preliminary report on fertilizer experiments with tobacco at the Deli Experimental Fields in 1902, D. J. Hissink (*Meded. 'S Lands Plantentuin, 1903, No. 62, pt. 3, pp. 68*).—The plan and purpose of the experiments on the different fields are described, and data with reference to planting, cultivating, and harvesting the crop, together with meteorological records, are presented.

Influence of climate and soil on the composition and milling qualities of winter wheat, A. M. Soule and P. O. Vanatter (*Tennessee Sta. Bul. Vol. XVI, No. 4, pp. 51–88, figs. 22*).—The experiment here reported is cooperative between the station and the Bureau of Plant Industry of this Department. Former results of similar work have been previously noted (E. S. R., 13, p. 546).

Of 48 varieties of wheat tested for several years, not more than 6 are considered first class. The results for the 6 leading varieties are summarized in the following table:

Results with varieties of winter wheat.

Name of variety.	Yield per acre, 1903. Grain.	Yield per acre, 1903. Straw.	Average yield of grain for 4 years.	Number of grains per ounce of seed used in 1903.	In crop of 1903: Av. number of grains— Per head.	In crop of 1903: Av. number of grains— Per ounce.	Average weight of grain per bushel for 4 years.	Relative hardness for 3 years.	Protein, average for 4 years.
	Bu.	*Tons.*	*Bu.*				*Lbs.*		*Per ct.*
Poole	48.54	3.77	37.23	776	19.58	965	58.56	72	15.43
Improved Poole	47.60	3.42	37.21	759	21.09	888	58.56	71	15.22
Niger	44.27	3.09	36.77	619	19.01	736	59.00	127	15.20
Imp. Fulcaster	45.21	3.69	36.56	764	20.00	914	59.00	106	16.01
Fulcaster	39.27	3.06	36.25	693	19.02	772	59.76	138	17.06
Mediterranean	42.55	3.18	36.18	715	19.33	821	59.91	124	17.39

These varieties ripened June 10 and 11. Poole is the only variety brought into the State which is recommended for general culture. The yield of straw in 1903 was heavy, and the varieties given above were among the heaviest producers, Poole leading all varieties. The lowest average yield of the varieties tested for 4 years was 24.11 bu. per acre. Some of the reasons given for low yields in the State are disregard of rotation, improper preparation of the seed bed, deficiency of vegetable material in the soil, late seeding, and growing unsuitable varieties.

The number of grains per ounce in the varieties tested varied from 589 for Red Cross to 1,068 for No. 5342, a foreign variety furnished by this Department. The average number of grains per head ranged from 15.58 in Velvet Chaff to 34.86 in Mealey. This last mentioned variety contained 1,016 grains per ounce, and ranked first in relative hardness.

The protein content of the varieties was high, the lowest, 13.19 per cent, being found in Dawson Golden Chaff. The influence of the season on the protein content is shown by the fact that Wood Hybrid, one of many examples, contained 21.92, 13.77, 15.74, and 15 per cent in 1900, 1901, 1902, and 1903, respectively. The protein was highest when the rainfall was somewhat deficient during the ripening period, but it was not materially affected by fertilizer or soil treatment.

The relative values of these varieties of winter wheat for the production of flour and bread were determined and compared with those of standard wheats grown in Kentucky, Ohio, Oklahoma, Minnesota, and Ontario. The percentage of flour was found to be high in Tennessee wheat. Fulcaster ranged in this respect from 70 to 75 per cent and averaged 73.4 per cent. There was considerable variation in the different wheats, but leading varieties from other sections of the country were not reduced in flour content when grown in Tennessee, and some of the varieties regarded as inferior for the State were as high in flour content as the leading varieties.

The ash content of the Tennessee samples, although showing wide differences, did not vary more than in the other samples, and is regarded in general as being very high. The Tennessee wheat also showed a very satisfactory gluten content, being below 10 per cent in only 2 instances, generally over 11 per cent, and in a large number of cases over 13 per cent. Fulcaster and Mediterranean stood high in this particular, as did also Kansas Mortgage Lifter, Blue Straw Fultz, Perfection, Early Ripe, Rice Wheat, and others. The leading Tennessee varieties yielded as much gluten as Turkey Red or the Minnesota hard spring wheats, and much more than the soft wheats, such as Early Genesee Giant and Dawson Golded Chaff. The absorptive capacity of the Tennessee flours was equal or superior to that of standard varieties grown in other sections of the country. In Fulcaster the absorptive capacity ranged from 60 to 62, and in Poole and Mediterranean it also ranked well. The

Tennessee hard wheats, as Fulcaster and Mediterranean, did not class as high in color as early Genesee Giant, Dawson Golden Chaff, Winter King, and Poole, but these softer varieties can be satisfactorily produced in the State. The milling and baking tests were also favorable to the varieties produced in Tennessee, and the number of loaves obtained per barrel of flour equaled or exceeded the number obtained from wheats grown in other States.

The seed selection carried on with Fulcaster, Mediterranean, and Poole is described, and the results obtained with Mediterranean for 3 years are tabulated. Large grains from medium heads gave the best average yield—32.68 bu. per acre. Large grains from large heads stood second, with an average yield of 32.37 bu. It is stated that selections from medium sized heads are most likely to give satisfactory results. The large grains have always given the best average yields. It is believed that the standard of a variety may be maintained, and that it may be adapted to local conditions, by carefully grading the seed selected from the best type heads in the field. In order to show results selection from type heads should be carried on systematically through a series of years.

The use of commercial fertilizers and barnyard manure on impoverished soil after bare fallow was not profitable. The cost per bushel of increase in 1902 was lowest with barnyard manure, and in this case it amounted to 56 cts. per bushel. In 1903 a mixture of 50 lbs. nitrate of soda, 100 lbs. acid phosphate, and 25 lbs. of muriate of potash per acre produced the most profitable increase, at a cost of 50 cts. per bushel. Lime showed a loss in 1902, but in 1903 gave an economical gain, the cost per bushel of increase being about 11 cts. For the 2 years barnyard manure gave the largest increase of gain at the least cost—55 cts. per bushel. The same fertilizer applications were tested on an impoverished soil after a crop of cowpeas had been turned under. The increase with this treatment varied on an average for the 2 seasons from 5.31 to 11.43 bu. of wheat per acre. The plowing under of cowpeas and the liberal application of phosphates, potash, and lime are recommended for impoverished soils.

Soil treatment for wheat in rotations, with special reference to southern Illinois soils, C. G. Hopkins (*Illinois Sta. Bul. 88, pp. 113–143, figs. 8*).—Cooperative rotation experiments have been in progress for 2 years at Vienna, Odin, Cutler, and Mascoutah, in southern Illinois, and the results thus far obtained are reported. The plan of the experiment is as follows: First year, corn or wheat with a leguminous catch crop on certain plats; second year, oats with a leguminous catch crop on the same plats as in the first year; third year, clover, cowpeas, or some other leguminous crop.

All leguminous catch crops are plowed under for the benefit of the land. The quantity of lime applied is governed by the need of the soil, as indicated by a determination of its acidity. Phosphoric acid is given in applications of 400 lbs. of fine-ground steamed bone per acre the first year, and of 200 lbs. each year thereafter, and potash in applications of 200 lbs. per acre of potassium chlorid or potassium sulphate the first year and afterwards 100 lbs. annually. The fertilizers are not applied uniformly to all plats, but only to certain ones. Barnyard manure is used alone and in combination on some plats, and is applied only once in a rotation at the rate of 2 tons per acre.

The results obtained on each experimental field are shown in tables and discussed. Owing to the very uniform soil on the Cutler experiment field, the results there obtained are taken as the basis for a general discussion of the effects of the soil treatment.

Making allowance for the value of the fertilizing materials removed by the wheat crop, a plat on which leguminous crops were plowed under gave a net return of $1.42 per acre of wheat, while the check plat gave $0.88. The results of 2 other plats indicated that the omission of this treatment with luguminous crops had reduced

the profits by $1.73, even after allowing $1 for the expense of growing and turning under a leguminous crop and disregarding its residual effect. The plat receiving barnyard manure gave a return of $3.57, against $0.88 with no fertilizer of any kind. Moderate applications of ground limestone to acid soils gave a marked improvement in the growth of leguminous crops, but the full extent of this improvement has not yet been determined. The application of phosphoric acid proved a very profitable treatment for this soil. Lime and a leguminous crop turned under gave a return of $2.73, and the addition of phosphoric acid apparently increased this return to $7.30 per acre; and the returns with manure ($3.39) were apparently increased to $8.30 by the addition of phosphates. Potash also proved profitable, especially when used with a leguminous crop and phosphoric acid, the profit of $7.30 an acre noted above being brought up to $11.88 where potash was added. The use of potash without phosphoric acid is considered unprofitable on nearly all Illinois soils, the swampy soils excepted, since with the exception of swampy and sandy lands, the subsoils contain large supplies of potash, and attention is called to the probability of making these stores more available to growing crops by tile drainage.

The effect of tile drainage was observed on the Odin experiment field. In 1902 2 plats, one of which was tile-drained, were treated with a leguminous crop, lime, and phosphoric acid. The yield of oats on the tile-drained plat was 19.2 bu. per acre, and on the other, 16.7 bu. In 1903 the tiled plat yielded 13.4 bu. of wheat per acre, and the untiled plat 5.8 bu. An untiled plat treated in all respects the same as the foregoing, and receiving in addition an application of potash, yielded 14 bu. of wheat per acre, while on the tiled land the increase in favor of the potash plat was only from 13.4 to 15.2 bu. Comparing 2 plats on the tiled land, the use of potash appears to have reduced the yield of oats by 1.5 bu. The beneficial effect of mulching land with wheat straw, which was incidentally observed, is briefly noted.

The structure and color of wheat kernels, W. von Gromann and F. Schindler (*Fühling's Landw. Ztg., 52 (1903), No. 4, pp. 117-121*).—Microscopical examinations were made to determine the possibility of differentiating varieties of wheat by the internal structure of the kernel, and to determine whether widely different climatic conditions influenced the color and thickness of the pericarp, and whether the color of the grain is due to any extent to the outer layer.

No regular and well-defined differences in the internal structure of the kernel of wheat varieties was discernible. The pericarp of *Triticum spelta*, *T. dicoccum*, and *T. monococcum* differentiated itself from the pericarp of the naked wheats by its weaker development. Wheats from various countries were also studied, but no regular structural differences were observed which might be attributed to climatic conditions. The authors believe, however, that the climate may effect the structure of the pericarp and that, to demonstrate this point definitely, kernels varying practically only with reference to the climatic conditions under which they were produced should be obtained.

It was found that the color of the pericarp of different varieties of wheat is uniform and the conclusion is drawn that for this reason the difference in color of wheats must be due to the color of the seed coat. The outer layer of the seed coat is colorless, while the color of the inner layer accords with the color of the grain.

Reports on the investigation of Russian wheat, I. D. Kolesnikov, A. I. Kovenko, and P. B. Budrin (*Trudi Syez. Dyeyat. Selsk. Khoz. Opuitn. Dyela, 1901, pp. 109-124; abs. in Zhur. Opuitn. Agron. [Jour. Expt. Landw.], 4 (1903), No. 4, pp. 486, 487*).—Attention is called to the fact that the varieties of Russian wheat on the market are little known, and that there is neither a correct botanical description of them nor an established nomenclature. The establishment of at least one special station in Russia for the investigation of agricultural plants is recommended.—P. FIREMAN.

HORTICULTURE.

The relation between hybrid characters and those of their parents, H. De Vries (*Rev. Gén. Bot., 15 (1903), No. 174, pp. 241–252*).—The laws governing the production of hybrids are stated by the author as follows: (1) Crosses between forms corresponding to elementary or progressive species give constant hybrids. Some common examples are *Ægilops speltæformis* (*Æ. ovata* X *Triticum vulgare*) and *Medicago media* (*M. falcata* X *sativa*). (2) Crosses between forms corresponding to properly called varieties, retrogressive or "degressive," give hybrids whose offspring separate according to the law discovered by Mendel for peas. (3) When the difference between the 2 parents of a hybrid is in part of a progressive nature and for the other characters of a retrogressive or "degressive" nature, the offspring of the hybrid does not change for the first, but separates according to the latter.

The author states that the first 2 cases are simple, but relatively rare. The third is the ordinary case for the large majority of crosses made by different investigators. A number of examples are cited under the different laws.

As explanatory of the words "progressive" and "retrogressive," the author notes that when new characters are being acquired by an individual this constitutes a "progressive" mutation. Once acquired, however, a character may not always remain visible in the development of an individual. While not apparent it may be present in a latent state. This the author calls a "retrogressive" mutation.

The forward movement in plant breeding, L. H. Bailey (*Proc. Amer. Phil. Soc., 42 (1903), No. 172, pp. 54–68*).—This is a comprehensive review of the work in plant breeding now being carried on in America. It deals with the methods, ideals sought for, and results obtained. The work with corn in Illinois and wheat in Minnesota is noted in considerable detail.

Forcing rhubarb in the dark, V. H. Davis (*Jour. Columbus Hort. Soc., 18 (1903), No. 3, pp. 86–91, figs. 3*).—The details and results secured in winter forcing seedling rhubarb roots are recorded. Usually only crowns from 3 to 5 years old are used for winter forcing. In the present experiment seedlings obtained by sowing seed in April in drills 24 in. apart were used. The seedlings made a remarkably good growth during the summer, many leaves attaining a foot across, with stalks 15 to 20 in. long and an inch thick.

After the ground had been frozen and thawed out once in the fall the roots were plowed out and placed in a dark cellar. They were packed closely together, with the crowns up and soil sifted between until the roots were covered 2 or 3 in. deep. They were then thoroughly soaked with water and the room made perfectly dark. The stalks pushed rapidly into growth, and within 4 weeks an excellent growth of rhubarb was secured. These seedling roots furnished 2 pullings of first-class stalks, 2 more of fair stalks, and 2 or 3 more small pullings of rather small and spindly stalks.

In all, the one crop lasted about 4 weeks. The exhausted roots were then removed and a new supply grown in like manner. It is stated that in this work the temperature should never be allowed to go above 60° F., unless quick results are wanted at the expense of quality and quantity. The crop grown in this experiment sold for from 60 to 75 cts. per dozen bunches, and there were from 4 to 6 stalks in each bunch. From an area of 870 sq. ft. of cellar space rhubarb to the amount of $35.55 was sold, and it is believed that the yield obtained in this experiment can be materially increased when more attention is given to the growing of the seedlings.

Special mention is made of the desirability of growing the roots in absolute darkness, since by this method the strength of the root is directed into the stem of the rhubarb rather than into the production of foliage. "By planting the seed on

heavily manured loam soil and thinning the plants to a distance of 1 ft. in the rows, with proper cultivation and mulching if need be, we believe roots can be grown in a single season which will give twice the yield received from our experiment. If it can be done with certainty from year to year the question of obtaining crowns for forcing purposes will be solved."

Storing and forcing of chicory, H. W. WARD (*Gard. Chron., 3. ser., 34 (1903), No. 879, pp. 299, 300*).—In blanching chicory the author states that as soon as the plants die down in the fall he finds it advisable to sprinkle a small quantity of wood-ashes around and over them. Troughs about 10 in. deep, 9 in. wide, and 8 ft. long are placed over the rows and covered with a quantity of clean, and slightly fermenting leaves to a depth of 2 ft. When thus handled it is claimed that well-blanched chicory may be cut within 2 or 3 weeks. It has been found desirable to blanch contiguous parts of 6 or more rows at one time, as a better and more even degree of heat is secured from the leaf bed by this method. As the season advances and the weather becomes warmer the depth of the leaf bed should be reduced.

Where this method cannot be followed, successive batches of roots may be taken up and placed 3 or 4 in. apart in shallow boxes or pots, with light mold packed moderately firm about them, and placed in a dark frost-proof cellar, cave, or shed. When thus forced in boxes they should also be covered over with boxes at least 8 in. deep.

Results of variety tests of vegetables during the last 5 years, E. JUNGE (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1902, pp. 125, 126*).—The best varieties grown in the gardens of the horticultural school at Geisenheim for 5 years are enumerated for a large number of different kinds of vegetables.

The white truffle mycelium, E. BOULANGER (*Les mycelium truffiers blancs. Paris: Oberthur, 1903, pp. 23, pls. 3*).—A technical botanical description is given of truffle mycelium, with microscopic drawings showing the development of different stages of the mycelium. The gist of this paper has been noted from another source (E. S. R., 15, p. 253), as has also a paper on the artificial culture of truffles, by L. Matruchot (E. S. R., 15, p. 253), which is included in the article.

Systematic pomology, F. A. WAUGH (*New York: Orange Judd Co., 1903, pp. 288, figs. 35*).—This is a text-book on systematic pomology. It treats of the description, nomenclature, and classification of fruits, including the usual orchard fruits, small fruits, and grapes. The blank forms used in describing and classifying fruits at a number of agricultural colleges and experiment stations and at this Department are reproduced.

The book contains exercises in fruit nomenclature, classification, and description, as well as others in judging fruits. Blank score cards are given for judging all the more usual fruits seen at fairs and horticultural exhibitions. The book concludes with a glossary of the terms used in systematic pomology, and an index. The work as a whole deals with methods and principles, and therein differs from the books on systematic pomology thus far published in the United States, which confine themselves more closely to detailed descriptions of varieties, etc. It will, undoubtedly, prove of much usefulness as a text-book in agricultural schools and colleges, and as a guide to judges at fruit fairs and exhibitions.

The fruit census of Connecticut, E. H. JENKINS, W. E. BRITTON, and B. H. WALDEN (*Connecticut State Sta. Rpt. 1902, pt. 4, pp. 432-443*).—The statistics secured in a careful canvass of the State by agents and through a circular request for information are tabulated for orchard and small fruits grown in each of the different counties of the State. Apples are the leading fruit, the total acreage being 4,717.25. Peaches follow, with 3,616 acres; and then strawberries, with 445.67 acres. Next in importance stand Japanese plums, with a total of 262.8 acres. Commercial peach growing is shown to have developed rapidly during the past 10 years, the total area

devoted to peaches in 1892 being 730 acres with a yield of 40,603 bu., as compared with an area of 3,616 acres and a yield of 312,174 bu. in 1902.

Report of the fruit experiment stations of Ontario, L. WOLVERTON ET AL. (*Ontario Fruit Expt. Stas. Rpt. 1902, pp. 104, map 1, figs. 36*).—A further report is given on the success or failure of the orchard and small fruits grown at each of the 15 experiment fruit farms in Ontario. Descriptions and full-sized illustrations are given for purpose of identification of several varieties of apples, blackberries, cherries, grapes, peaches, pears, plums, and strawberries. The report also contains a catalogue which shows in tabular form the values of the different varieties of orchard and small fruits grown in Ontario, and their adaptability to the various parts of the Province. The plan of the report is similar to those previously noted (E. S. R., 14, p. 41). Japanese plums have proved very successful as far north as Georgian Bay.

Special methods of cultivation for special conditions, W. T. MACOUN (*Ontario Fruit Growers' Assoc. Rpt. 1902, pp. 56–59*).—Notes are given on the good results secured in the vicinity of Montreal by growing orchards in sod. This practice is considered very desirable in young bearing orchards in that vicinity, where winter-killing of the roots is extremely likely unless protected by grass, sod, or some clover crop. Some data are given on the yields and profits obtained in planting Wealthy apple trees 10 ft. apart each way. For the 4 years, 1899 to 1902, the total receipts per acre were $940.15 and the expenses $454.62, leaving a net profit of $485.53, or an average profit of $121.38 per year from this method of growing Wealthy trees.

An experiment in planting fruit trees too deep (*Ber. K. Lehranst. Wien, Obst u. Gartenbau, Geisenheim, 1902, pp. 83–88, figs. 3*).—A number of different kinds of fruit trees were set out to a normal depth; others were planted 10, 15, 20, 30, and 40 cm. deeper than the normal, to see what effect this would have on the root development of the trees. In general the size of the tree and the extent of the root development decreased with every increase in depth of planting beyond the normal.

Apples and apple growing in Minnesota, S. B. GREEN (*Minnesota Sta. Bul. 83, pp. 31, pls. 49, figs. 7*).—Popular directions are given for the culture of apples in Minnesota, including details as to methods of planting, protection of the trees from sun scald, manuring, cultivation, and selection of hardy stocks, and descriptions of 67 varieties grown in the State. Half-tone illustrations are given of the whole and halved apples of 55 varieties.

The most successful varieties grown in Minnesota consist of a few Russian varieties and seedlings of local origin. Some of the varieties recommended for planting are as follows: Of the first degree of hardiness—Duchess, Hibernal, Charlamoff, and Patten Greening, and of the second degree—Wealthy, Longfield, Tetofsky, Malinda, Okabena, and Peerless. The crabs and hybrids recommended for general cultivation are Virginia, Martha, Whitney, Early Strawberry, Minnesota, Sweet Russet, Gideon No. 6, Briar Sweet, Florence, and Transcendent.

While seedlings of *Pyrus baccata* have proved most resistant to root killing they are not entirely adapted to all varieties of cultivated apples. Hybrid crabs at present form the most promising source for hardy stock. For the severest locations in Minnesota and Manitoba it is believed to be a good plan to grow only hybrid crabs and have them grafted on pure *Pyrus baccata*. Root-grafted trees are believed to be more hardy than top-grafted.

In light, dry soils it is recommended that the trees be planted 12 in. deeper than they naturally grow in the nursery. On steep hillsides they should be planted deeper yet, in some instances being set as deep as 20 in. or more, for the purpose of affording

protection to the roots. The author recommends that the orchard be plowed late in the autumn to act as a winter mulch. On steep hillsides where cultivation is not possible the orchard should be mowed and the grass piled around the trunks. When the snow is not over 6 in. deep it is recommended that in addition to late plowing the trees be mulched with coarse manure or litter for a distance of 3 to 6 ft. from the trunk.

Thinning apples, S. A. BEACH (*New York State Sta. Bul. 239, pp. 197–224, pls. 2*).—Experiments were made by the author covering a period of 4 years in thinning apples, to determine the effect of thinning on size, color, quality, and yield of fruit; the amount of the different grades of fruit; the influence of thinning in promoting regular annual bearing; and finally the cost and profitableness of thinning apples.

The varieties of apples under observation were Baldwin, Hubbardston, Nonesuch, and Rhode Island Greening. Three methods of thinning were practiced. By the first method all wormy, knotty, or otherwise undesirable fruits were removed and each cluster thinned to 1 fruit. The second and third methods were similar to the first, except that the fruits were thinned to not less than 4 and 6 in. apart respectively. The data obtained in the experiments are given quite fully in tabular form and discussed.

In seasons of heavy crops, thinning was found to heighten the color of both yellow and red fruits and to increase the size of the fruit. When only a small crop was set thinning had no appreciable influence on either color or size. With Rhode Island Greening, which has a tendency to bear more regularly and produce smaller crops, the effect of thinning was less noticeable than with Baldwin and Hubbardston. As to the influence of thinning on the regularity of bearing, the experiments with all 3 varieties are fairly uniform in showing no material change in either the amount of fruit grown or the regularity of its production by thinning.

Data sufficient to furnish a basis for specific directions as to distances apart to thin apples were not obtained in this experiment. This is a matter that depends upon the amount of fruit that sets, its distribution on the tree, and the ability of the individual tree to bring fruit to perfection. Supplementary evidence covering a period of 10 years and tending to show the variability in productiveness of trees of the same variety from year to year are given for several Rhode Island Greening trees. The data bring out the fact that some trees regularly produce year after year heavier crops than others.

Where thinning is practiced the author advises that the work be begun within 3 or 4 weeks after the fruit sets, even if the June drop is not yet over. In these experiments the time required for thinning and harvesting the apples on the thinned trees was about twice as great as the time required for harvesting the fruit from the unthinned trees. It is believed that the cost of thinning a well-loaded apple tree should not exceed 50 cts.

As to the market value and profitableness of thinning, the experiments show that the thinned trees bear a larger percentage of first-grade fruit than unthinned trees, and that the fruit is much better adapted for making fancy grades. When this fancy fruit can be marketed in boxes or barrels in quantity buyers are likely to give a higher price for it. The opinion of a practical grower, in whose orchard the experiments were conducted, is to the effect that when there is a heavy set of apples and the likelihood of a large crop of small fruit general, it will pay to thin to such an extent as to insure good-sized fruit; otherwise not, except as a protection to the tree.

Should apples be thinned? F. H. HALL and S. A. BEACH (*New York State Sta. Bul. 239, popular ed., pp. 10*).—A popular summary of the above bulletin.

The effect of grass on [apple] trees, DUKE OF BEDFORD and S. U. PICKERING (*Woburn Expt. Fruit Farm Rpt. 1903, pp. 56, pls. 3*).—Some data showing the injurious effects of grass on the growth of fruit trees were reported by the authors 3 years

ago (E. S. R., 12, p. 749). The present pamphlet gives the details of investigations made to determine why grass has such a serious effect on the development of apple trees.

Experiments have been made with both dwarf and standard trees. The details of the experiments reported by the authors clearly indicate that the injurious action of grass is not due to its harmful effects in absorbing or evaporating the moisture of the soil about the trees, nor of removing the plant food from the soil, nor of interfering with the air supply in the soil. On the other hand, it is thought probable that it may be attributed to the action of some product, direct or indirect, of grass growth which exercises an actively poisonous effect on the roots of the trees.

Data are given which show that the temperature of the soil on bright days in summer, 6 in. below the surface in land covered with grass, is quite uniformly about 3 degrees lower than in cultivated soils. This, however, is not considered an item of importance, since the average soil temperatue of one summer often differs by more than this from that of another without producing any of the injurious effects caused by grass on trees.

Orchards in grass not only made a very much smaller growth, but also blossomed earlier in the spring and the leaves yellowed up and dropped much earlier in the autumn than with cultivated trees. Calculating the growth of trees in cultivated ground as 100, trees in grass have made a growth in the case of Bramley of 50 per cent, Cox 33 per cent, and Potts 41 per cent. When weeds have been allowed to grow Bramley made an average growth of 66 per cent, Cox 52 per cent, and Potts 73 per cent. It is thus seen that weeds are not nearly as harmful in orchards as grass.

Cold storage of apples, H. C. Price (*Iowa Sta. Bul. 72, pp. 31–44, dgms. 2*).—This bulletin contains a discussion of the present status of apple growing in Iowa, the importance of cold storage of apples to the State, directions for handling the apple crop, and the results of a test of the keeping qualities of 15 standard varieties of apples grown in the State.

The author states that but few late varieties do well in the State, consequently the market season of Iowa apples is comparatively short, the bulk of the crop being marketed during November and December. The abundance of apples on the market at this time is a little later followed by a dearth which must be supplied by importation from other States. It is believed that this condition might be changed if the surplus crop harvested in the fall could be kept in cold storage until such time as needed later in the winter.

Experiments were therefore made to test the keeping qualities of some of the varieties commonly grown in the State. A number of barrels of each of 15 varieties were stored in September and October, and examined at intervals of a month during the winter until April 14. The amount of decayed and sound fruit found in the barrels of the different varieties at each inspection is given in tabular form.

The data show that McMahon White, Northern Spy, Pewaukee, Roman Stem, Seek-No-Further, White Pippin, and Wolf River all possess poor keeping qualities and are not considered suitable for storing. On the other hand, such varieties as Ben Davis, Domine or Wells, Janet, Romanite, Willow Twig, Fameuse, and Wealthy kept especially well. Especially satisfactory results were secured with Fameuse and Wealthy, both of which kept well until March. The results with Wealthy and Fameuse are believed to be of great value to the apple growers of the State, since these varieties are hardy throughout the State, productive, and of excellent quality.

Observations on the fertilization of peach orchards, E. H. Jenkins (*Connecticut State Sta. Rpt. 1902, pt. 4, pp. 443–445*).—The data secured in 1902 are added to those reported in previous years (E. S. R., 14, p. 354) on the yields of peaches obtained on plats differently fertilized. Each plat contains 48 trees, which are replaced as

they die. The average number of baskets of peaches secured from each tree on the differently fertilized plats for the years 1899 to 1902 is shown in the subjoined table:

Yield of peaches on plats differently fertilized.

Plats.	Fertilizers applied.	1899.	1900.	1901.	1902.	Average.
		Baskets.	*Baskets.*	*Baskets.*	*Baskets.*	*Baskets.*
A	65 lbs. muriate of potash, 160 lbs. acid phosphate	3.2	5.6	3.3	1.6	3.4
B	65 lbs. muriate of potash, 160 lbs. acid phosphate, and 170 lbs. cotton-seed meal.	3.8	6.3	3.3	3.6	4.3
C	65 lbs. muriate of potash, 160 lbs. acid phosphate	3.5	5.2	2.8	2.1	3.4
D	130 lbs. muriate of potash, 160 lbs. acid phosphate	4.1	5.8	3.6	2.2	3.9

Peach-bud dropping, G. Abbey, Jr. (*Gard. Chron., 3. ser., 34 (1903), No. 879, pp. 307, 308*).—The author calls attention to the statement in The Book of the Peach (E. S. R., 15, p. 363) that peach-bud dropping is due primarily to looseness of soil, absence of lime, and want of water at the roots, and gives the results of some personal experiments in which peach-bud dropping was found to be due to "the premature development of the buds, caused by the necessary closing of the ventilators on account of plants being put in when the peach house should have been kept cool and open."

Reports of experimental shipments of pears and peaches (*Canad. Hort., 26 (1903), No. 11, pp. 453–455*).—An account is given of a shipment of a carload of Bartlett pears from Grimsby, Canada, to Glasgow, Scotland. The pears were picked perfectly green and packed without wrapping in half cases with excelsior padding. They were carried across the ocean at a temperature of 44 to 46° F., as a result of which 71 cases arrived over-ripe and had to be thrown out. The remaining pears sold for from 30 cts. for 20 lbs. to $3.47 for a 40-lb. box, and averaged for the whole lot about $1 net per box. Fifteen half boxes of peaches shipped at the same time under like conditions were wholly decayed upon arrival. With suitable ocean storage it is believed this trade could be made very profitable.

Plum culture and district lists of plums suitable for Ontario and Quebec, with descriptions of varieties, W. T. Macoun (*Canada Cent. Expt. Farm Bul. 43, pp. 54, pls. 2, figs. 4*).—This is a popular bulletin on plum culture, dealing with methods of propagation, preparation of the soil, and particulars as to planting and subsequent care of the trees. Lists are given of varieties most suitable for the different fruit districts in the provinces of Ontario and Quebec, and descriptions given of 38 American, 34 European, and 4 Japanese sorts.

A popular paper on Fertilizers for the Plum Orchard, by F. T. Shutt, is included in the bulletin, and another of like nature on Plum Insects, by J. Fletcher. Notes are also given on canning and preserving American plums, and a number of the formulas that have been found useful in station experience are given. With American varieties of plums it has been found desirable in nearly every case to peel the fruit before preserving. The Bixby variety was the best of those tested cooked with the skin on. The usual diseases affecting plums are described and remedies suggested.

The truth about the strawberry-raspberry (*Rubus illecebrosus*), A. Rehder (*Amer. Gard., 24 (1903), No. 457, p. 603, fig. 1*).—According to the author this plant was introduced into America from Japan about 1895, and probably takes its name from the shape of the fruit. It is not a cross between the strawberry and raspberry. It differs from the Indian raspberry (*Rubus rosæfolius*), by which name it has been

sometimes called, in a number of details. The fruit is very attractive in appearance, and while rather insipid is considered by the author very agreeable when made into jam or preserves. It grows readily in most any soil in the Northern States, and is not easily eradicated. The article contains a botanical description of the fruit.

Cranberries in West Virginia, L. C. CORBETT (*West Virginia Sta. Bul. 86, pp. 115–126, pls. 4*).—This bulletin contains directions for the propagation and culture of cranberries, with an account of successful experiments inaugurated by the author in cranberry growing in some of the mountain glade lands of West Virginia.

The experiments were begun in 1894. At the present time a number of plats have been thoroughly established. The berries produced are of large size and superior color. The yields obtained varied from 84 to 160 bu. per acre. Six varieties are described, including the native sorts. The experiments thus far have taught the necessity of stripping all sod and vegetation from the area to be planted and putting on a coating of at least 4 to 6 in. of sand free from clay or the seeds of persistent weeds. Flooding does not appear to be necessary on the plats under observation.

Report of the experimental vineyard at the Ploti Experiment Station (*Rap. An. Sta. Expt. Agron. Ploty, 8 (1902), pp. 126–133*).—An account is given of the yield, sugar, and acid content of grapes when fertilized with a number of different fertilizers. Phenological notes are included on a number of varieties of European grapes.

Fertilizing grapes with nitrate of soda (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1902, pp. 15, 16*).—In an experiment in which about 160 lbs. of nitrate of soda was used per acre in 3 separate applications, it was observed that the wood growth was much heavier than where the nitrate of soda was omitted, and the development and yield of grapes was most satisfactory. The nitrate of soda was most effective with the variety Elbling, followed by Sylvaner. It was least effective with the Reisling variety, the effect on this variety being only about one-third as great as with the Elbling.

Influence of the method of storing grape cuttings in winter on the rooting of the same, GOETHE and ZEISSIG (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1902, pp. 56–58, fig. 1*).—In this experiment 4 bundles of grape cuttings were used. One bundle was placed, immediately after being made, in dust, another in sand, a third half in sand, and a fourth was left standing free. All were kept in a cellar. The following spring they were planted out in a nursery. The strongest growth was made by the cuttings preserved in the dust, followed by those wholly in sand, and then by those half in sand. Those left standing in the open in the cellar gave the poorest results of all, only about a fifth as much growth being obtained as where the cuttings were preserved in dust.

Investigations on the process of ripening of one-year-old grape wood, ZEISSIG (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1902, pp. 59–64, fig. 1*).—The changes in the physical structure which occur in the ripening of one-year-old grape wood were investigated. The wood was examined at intervals between August 16 and November 3. It was observed that with the increase in maturity of the wood there was an increase in the size of the starch grains and in the total quantity of starch stored up, particularly in the bast. The fibrovascular tissue was further developed, the secondary bast fiber and sieve tubes developed in the bast portion, and finally the whole external bark shrank and became separated from the inner tissues by the formation of a periderm.

An examination of a number of shoots, the upper portion of which were more or less unripe, showed that there was a considerable increase in the pith from the ripe portion of the shoots upward, and a corresponding decrease in the wood and bast tissue in which the reserve material is stored up. This fact is believed to account for the greater suitability of ripe shoots for cuttings over immature shoots.

15293—No. 5—04——5

The periderm often failed to develop in the unripe portion of the shoots. The periderm was found essential to the protection of the shoots over winter. Whenever it failed the shoots died, whether they contained starch or not. Poorly ripened wood having an imperfect periderm may withstand mild winters, but not a rigorous one. The secondary bast tissue appeared to play no important rôle in the wood-ripening process. Starch, on the other hand, appeared as the factor of importance in determining the quality of the ripe wood. The periderm was found to develop earlier with grapes grown on a south wall than on a west wall or on the north side of a large post.

The specific gravity of one-year grape shoots and its relation to the ripeness of the wood, ZEISSIG (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1902, pp. 64–68, fig. 1*).—A review is given of the work of Gouin and Andouard, in which it is shown that they found the specific gravity of ripe grape wood lighter than unripe wood. Ravaz and Bonnet, on the other hand, by first eliminating the air from the wood by soaking in water or alcohol, found the ripe wood the heavier.

In the author's investigations along the same lines he found that the specific gravity of grape shoots decreased from the ripe into the unripe wood toward the end of the shoots. This was true, however, only when the whole round cutting was taken. When the shoot was split and the pith removed, then there was but little difference in the specific gravity of the ripe and unripe wood.

Sportiveness of grapevines, J. C. TALLACK (*Gard. Chron., 3. ser., 34 (1903), No. 880, p. 325*).—The author states that of 2 stems taken from a single Muscat of Alexandria vine one stem produced normal Muscat of Alexandria grapes with typical berries, while "the other stem developed into Canon Hall Muscat, with all that variety's characteristics as regards bad setting, form of bunch, and of berry." In another instance a vine of Black Hamburgh produced a bunch with berries double the normal size, and different in form to all the rest of the vine. "The spur which produced this carried 2 laterals, each of which bore a bunch, one being absolutely normal."

Cross-fertilizing experiment with grapes (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1902, pp. 58, 59*).—In some cross-fertilizing experiments with grapes it was found that pollen of several varieties was capable of germinating and fertilizing grape blossoms after being preserved a year. It is noted, however, that the berries obtained from blossoms fertilized with this pollen were poorly developed. Very satisfactory results were secured when the pollen was preserved only a month or so.

Concentrated must from frozen grapes (*Ber. K. Lehranst. Wein, Obst u. Gartenbau, Geisenheim, 1902, pp. 148, 149*).—It is noted that in the season of 1902 a portion of grapes late in the season were frozen on the vines. These were gathered in the morning and quickly pressed before they thawed out; as a result a concentrated must was secured. Analyses are given of this must and of must obtained from the grapes after they had thawed out, a mixture of the 2 musts, and of the must obtained from the second pressing, i. e., after the frozen grapes had been once pressed and then allowed to thaw out and pressed again.

Tea cultivation and curing in India, E. E. OSGOOD (*U. S. Consular Rpts., 73 (1903), No. 278, pp. 554–558*).—This article discusses briefly the methods observed in India in planting, pruning, plucking, withering, rolling, fermenting, sorting, and packing tea.

Report on the cultivation of rubber, cacao, and other agricultural products in Ceylon, W. H. JOHNSON (*London: Waterlow & Sons, Ltd., 1903, pp. 9*).—The author states that Para rubber grows most successfully in Ceylon at about 100 ft. above sea level, where the annual average rainfall is over 100 in. Para trees in Ceylon are ready for tapping after the seventh year from seed. About 1 lb. of rubber is obtained per tree annually.

The trees are tapped by a row of V-shaped incisions made 3 or 4 in. apart and beginning about 6 ft. from the ground. The size of the V's are about 5 or 6 in. long and the open end about 4 in. across. The latex is caught in a small round tin cup, 3 or 4 in. in diameter and about 4 in. deep, and is fixed to the tree by pressing the thin edge of the cup into the bark. The tree is tapped every day until the base is reached, when a second series of similar incisions is begun inside the first series, commencing with the top row. A third, and sometimes a fourth series of inner V's is made, the number depending upon the size of the first incision and the size and age of the tree. Tapping is performed during the early morning and late in the afternoon.

The latex is cured when brought in from the field by pouring into enameled iron saucers about 1 ft. in diameter and 2 in. deep, and left until the rubber coagulates, which usually happens by the following day. If desired it may be hastened by the addition of a few drops of acetic acid; but rubber thus treated is rated at a lower value in the market. The coagulated rubber is pressed out by rolling, after which it is drained and usually submitted to a little artificial heat to hasten drying, and it is then spread out to dry in a well aired room.

Cacao flourishes in Ceylon at all elevations up to 3,000 ft. wherever soil and rainfall are suitable. The 2 varieties of cacao, Forastero and Caracas, which were originally distinct varieties, have become so intermingled by cross fertilization that practically nothing but the hybrid type is now grown. The 2 most serious obstacles to cacao culture in Ceylon are a fungus disease (*Nectria ditissima*) and an insect pest (Helopeltis). The better equipped cacao plantations all have a well equipped drying house fitted with artificial heating apparatus for drying the cacao during wet weather. The drying room is maintained as nearly as possible at a temperature of 110° F. The cacao dried in houses is usually inferior in color to that dried in the sun. The yield per acre was found to vary between 1½ to 4 cwt.

The culture of cocoanuts is steadily increasing, and flourishes up to elevations of nearly 2,000 ft. Specially good results were found to be obtained on one estate by regularly burying all fallen leaves and husks of the nuts around the roots of the trees. In addition, artificial manures were applied at fixed intervals. The trees were planted 26 ft. apart, and the ripe nuts were collected once a month and stacked in heaps in the open air for about a month in order to make them more easy to husk.

Some notes are also given on the culture of cardamoms in Ceylon, and on the Ceylon Botanical Department. The author recommends that the government introduce and cultivate Para rubber in the Gold Coast.

Rubber-tapping experiments at the Botanic Gardens, Singapore (*Queensland Agr. Jour., 13 (1903), No. 3, pp. 269–271*).—An account is given of tapping a number of rubber trees in the Singapore Botanic Gardens, according to the Amazon method. By this method the trees are tapped as high up as a man can reach. A single cut is made with a small axe, the edge of which is an inch or an inch and a half long. A cut is made each day for every 4 in. in diameter of the tree. Thus if the tree is 12 in. in diameter 3 cuts will be made in a day. Every day a fresh cut is made 4 fingers below the cuts of the previous day.

The axe described was found more satisfactory in these experiments than tapping with a chisel and mallet. When the trees were lightly beaten with the mallet in the vicinity of the cut there appeared to be a distinct increase in the flow of the latex. Some data obtained in tapping 100 trees are tabulated which show that the amount of latex obtained from 40 trees with 5 incisions each gave as much latex as 20 trees with 10 incisions or 100 trees with 2 incisions, which shows that each cut gives approximately the same amount and that the return, therefore, depends more on the number of incisions than on the size of the tree.

Sometimes trees which produced but little rubber when first tapped became very

productive after being cut 10 days in succession. After long, dry, hot periods when rains had commenced old wounds which had long ceased to flow frequently broke out again and produced long tears of rubber.

Greenhouses, L. C. Corbett (*West Virginia Sta. Bul. 87, pp. 115–139, pls. 3, figs. 2*).—Notes are given on the comparative durability of greenhouse walls as indicated by station experience, and suggestions given on building greenhouses.

For practical purposes in West Virginia the author considers a 9-in. wall, constructed of brick laid in double courses with about ½ in. air space between the 2 layers, the most satisfactory. The desirability of having space left at the back of benches so that warm air can pass up from below is pointed out. The author's experience with various kinds of metal benches indicates that over a series of years these may be as cheap as wood benches, and are much more satisfactory as regards subirrigation. A 7-ft. bench in the center of the greenhouse was found much more efficient for rose growing when divided into 2 benches each 3 ft. 4 in. wide, with a 4-in. space between the 2 sections. The current of warm air passing up between the benches was very beneficial.

In the author's opinion an ideal ventilator should consist of "two narrow lines of sash, one on either side of the comb and hinged at the bottom of the sash so as to make a broad flue or opening in the top of the house when the ventilators are open." A description is given of a device for fumigating the greenhouse with sulphur. The author discusses the use of large-sized glass and of sash bars in greenhouse construction, and suggests that where 16 by 20 in. or 16 by 24 in. glass is used the sash bars should be 1½ by 3 in., while for glass 14 by 20 in. or less sash bars may be 2¼ by 1½ in., and for 12 by 14 in. glass with bars 12 in. apart a bar 1 by 1¾ in. is considered satisfactory with proper purline supports. Directions are given for laying lapped glass roofs much more rapidly than by the usual methods observed.

FORESTRY.

Sylviculture, A. Fron (*Sylviculture. Paris: J. B. Baillière & Sons, 1903, pp. XII + 563, figs. 55*).—This volume, which is one of a series issued as an agricultural encyclopedia, is designed not only as a handbook on forest culture, but as a source of information on all branches of forestry. The principles of tree growth are discussed, after which the tree as a factor in forestry is considered, and the principal species of forest trees are described, their distribution, habits, and uses being shown.

In practical sylviculture reforestation is discussed at length, various cultural practices being described. The principal types of forests are mentioned, their uses and advantages being pointed out. The concluding portion of the book relates to forests as business enterprises and gives directions for their management, exploitation, estimation of standing timber, valuation tables, etc.

Courses in forestry at agricultural colleges, S. B. Green (*Forestry and Irrig., 9 (1903), No. 11, pp. 552–554*).—The author briefly reviews some of the courses of instruction that should be embraced in or collateral to courses in forestry in agricultural schools.

Second annual report of the forester, W. Mulford (*Connecticut State Sta. Rpt. 1902, pt. 4, pp. 468–470, pls. 2*).—In his work on the development of the farm wood lot, the forester reports the experimental work carried on by the station in which 64 experimental plantations are described, as well as cooperative plantings made by 2 private parties and by the city of Middletown on its waterworks property. The treatment of the forest is described and an outline given for the future plantings of this tract.

As State forester, the author reports upon the purchase of 698.5 acres as a site for a State forest, at a cost of $1,110.12. This area has been surveyed and marked, and preliminary investigations begun for its reforestation. The forestry act under which

this work was undertaken has been amended so that the State forester is authorized to make whatever thinnings or changes that are thought necessary in the woodland, and to sell the timber and devote the proceeds to the maintenance and care of the forest.

The Minnesota National Forest Reserve, E. S. Bruce (*Forestry and Irrig., 9 (1903), No. 10, pp. 489–496, figs. 5*).—An account is given of the work done by the Bureau of Forestry in the Minnesota National Forest Reserve, which was established by act of Congress in 1902. Under the conditions of the law establishing this reserve, a tract of land embraced in the northern portion of Minnesota was set aside under conditions of selection and cutting which should be determined by the Bureau of Forestry of this Department.

The Luquillo Forest Reserve, Porto Rico, J. Gifford (*Forestry and Irrig., 9 (1903), No. 11, pp. 537–541, figs. 5*).—A brief report is given by the author of the forest reserve which was established in Porto Rico by presidential proclamation on January 17, 1903. The principal timber trees are enumerated and described and the forest conditions are shown. The object of this reservation is not so much a source of timber as to protect the headwaters of streams that rise in this region.

An ecological study of the Big Spring Prairie, Wyandot County, Ohio, T. A. Bonser (*Ohio State Acad. Sci., Spec. Paper 7, pp. 96, figs. 20, map 1*).—The region included in this study embraces a tract of about 10 square miles, and is located in Wyandot, Seneca, and Hancock counties, Ohio. The various factors which influence the distribution of plants in this region are considered in detail and the various plant associations are described. The investigations included the study of the climatic, physiographic, historical, and ecological factors. The water content and low temperature of the soil is said to account for the distribution of plants, and artificial drainage, where it has been introduced, has shown that by reducing the water level the plant growth is greatly facilitated.

The absence of trees in this region is attributed to the fact that the dense sod tends to prevent the establishment of tree seedlings, and the frequent burnings have caused various reversions in the plant societies. The loose character of the soil does not offer a firm support for tree roots and on considerable areas forest vegetation is entirely lacking. The author believes that by constructing preliminary ditches at intervals of 4 rods, the entire area can be successfully drained and, as shown by limited experiments, this area is well adapted to the successful cultivation of crops.

Forestry at Biltmore, C. A. Schenck (*Forestry and Irrig., 9 (1903), No. 11, pp. 543–547, figs. 2*).—A description is given of the forestry operations which are being carried on upon the Vanderbilt estate at Biltmore, N. C. The forest embraces 125,000 acres in an almost continuous body, and the plans upon which it is being managed are described. It is hoped that the forest will become remunerative within 20 years from the beginning of management, which was in 1896.

An interesting phase of German forestry, A. Cary (*Forestry and Irrig., 9 (1903), No. 11, pp. 554, 555*).—An account is given of the management of the Sulzburg forest of about 5,300 acres. The system under which this is managed will require about 15 years for its development, and at present about 160 cu. ft. per acre are being cut in the forest. The natural regeneration of fir, beech, and oak is taking place rapidly, the fir reproducing very freely.

An average net revenue of $8 an acre has been derived from the forest during the past 5 years, and each adult male inhabitant and each widow receives yearly about $17 in forest revenue, which as a rule more than pays their local taxes. In addition, the town has built various public works, all of which were either paid for outright or were contingent on the income derived from the forest.

Private forestry and taxation, E. Bruncken (*Forestry and Irrig., 9 (1903), No. 10, pp. 509–512*).—The author reviews the present condition of taxation of forest lands, and offers some suggestions which he believes would help forest development.

Possibilities of reforestation in the white pine belt, F. ROTH (*Forestry and Irrig., 9 (1903), No. 10, pp. 505–509, figs. 2*).—A review is given of the condition of portions of the white pine belt of the United States, and suggestions made for its restocking. The author suggests that the States should retain or buy up the lands and make them as productive as possible. Much of the land has no agricultural value and is adapted to forest growth only. In many places simply protecting the growing saplings from fire is all that is necessary to secure restocking. In other cases considerable replanting will be required. Where planting is contemplated it is believed that nurseries should be established on the spot. From these, coniferous plants should be set out at the age of 2 or 3 years. The species recommended for trial include the white, Norway, and jack pines.

Plantations of poplars, P. MOUILLEFERT (*Jour. Agr. Prat., n. ser., 6 (1903), No. 43, pp. 541–543*).—Attention is called to the relative merits of different species of poplar for planting, and a description is given of the Canada poplar (*Populus monilifera*), the Carolina poplar, a form of the Italian poplar known as black poplar or *P. nigra*, the white poplar, quaking aspen, etc. In the selection of these trees for planting, if the plantation is small, the author recommends the choice of trees that have attained a height of about 3 meters. If an extensive plantation is to be made smaller trees should be used, or if proper precautions are taken many of the species will grow readily from cuttings.

The culture of Eucalypts, T. R. SIM (*Agr. Jour. and Min. Rec. [Natal], 6 (1903), No. 14, pp. 505–509*).—Notes are given on the collection and care of Eucalyptus seed and directions for the preparation of the seed bed, the sowing of the seed, care and transplanting of the seedlings, and for the final planting out of the trees. The distance of planting varies with the different varieties and the object for which the plantation is being cultivated, whether for timber, ornament, or other purposes. Notes are given on a few of the more valuable varieties, and their adaptability to South African conditions, their value as timber trees being pointed out.

The timber industry, A. O. GREEN (*Papers and Proc. Roy. Soc. Tasmania, 1902, pp. 35–76, pls. 7*).—A description is given of the timber resources of Tasmania, and an account of the methods of lumbering. The principal species of timber trees which are cut for export, as well as the smaller ones which are used locally, are described. Experiments made to test the transverse strength, deflection, and elasticity of the timber of a number of species of Tasmanian forest trees are reported, and the effect of seasoning and shrinking as shown by different methods of cutting are noted. The report concludes with a list of prices of different forest products and a tabular statement giving the local names, and the botanical and physical characteristics of different trees, together with general remarks as to their use.

SEEDS—WEEDS.

Tests of the vitality of vegetable seeds, E. H. JENKINS (*Connecticut State Sta. Rpt. 1902, pt. 4, pp. 424–431*).—In continuation of the tests of the vitality of vegetable seeds a report is given of 199 samples of field and garden seeds which were tested during 1902 at the station. The methods adopted are those hitherto described (E. S. R., 14, p. 364), and the results of the different tests are shown in tabular form.

The investigations begun in 1896 on the effect of the age of seed on the vitality of any seed have been continued, and comparisons made between the vitality of Connecticut and California grown seed. Comparisons are also given of the vitality of onion seed from the crops of 1894 to date, the average for 9 consecutive years being 79.7 per cent. Tests of the sprouting capacity of different varieties have been continued, indicating, as previously reported, the White Portugal to be distinctly inferior in vitality to a number of other varieties.

A botanical study of sugar-beet seed, F. TODARO (*Staz. Sper. Agr. Ital., 36 (1903), No. 6, pp. 449–496*).—Studies are reported on beet sampling for improvement of quality, several methods being described. The influence of size and weight of seed on its vitality; the effect of temperature, moisture, etc., on germination; the stimulating effect of various substances in which the seeds were rolled, and the duration of vitality of beet seed are all reported upon at considerable length.

Report of seed testing at Modena for the year ending December, 1901, F. TODARO (*Staz. Sper. Agr. Ital., 36 (1903), No. 6, pp. 497–512*).—A report is given of the seed testing carried on at the Royal Agricultural Seed Testing Station at Modena in which 2,097 tests are enumerated. These tests were made on 975 different kinds of seed, of which 813 were leguminous forage plants, 37 grasses, 71 cereals, 10 sugar beets, and 31 hemp. The maximum, minimum, and average percentages of germination, purity, and intrinsic worth are given in tabular form, together with the percentage of dodder seed present in the samples. The weed seed found in samples of forage-plant seed and some of the more important species, together with the percentages present, are described.

Report of the seed-control station at Vienna for 1901 (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 3, pp. 338–394*).—A report is given of the routine work carried on at the seed-control station at Vienna, together with investigations at the various substations connected with this institution, for the year ending December, 1901.

During the period covered by this report 26,629 samples of seed and their products were analyzed, and 12,584 lots of seed certified to. Of these, clover, alfalfa, and timothy formed the greater portion. The maximum, minimum, and average germinations of all the different lots of seed tested are reported, comparisons being made with the same factors for the previous year's report. Detailed statements are given regarding the purity, germinative ability, presence of dodder, and special examinations of beet seed, cereals, etc.

Noxious weeds and how to kill them, L. R. WALDRON (*North Dakota Sta. Bul. 56, pp. 201–243, pls. 5, figs. 10*).—This bulletin aims to present in a simple manner information regarding the noxious weeds of North Dakota, and to give suggestions for their eradication. After discussing the effect of weeds in agriculture, the author calls attention to the necessity of being able to recognize the more troublesome species. Methods of eradication are discussed, particular attention being paid to the Russian thistle and the tumbling mustard. Other species of weeds are described, those of special interest being pigeon grass, wild oats, quack grass, wild buckwheat, Russian thistle, tumbling mustard, yellow mustard, French weed, and Canada thistle.

Under the discussion of the Canada thistle a brief account is given of an experiment to test the efficiency of frequent cutting as a means of eradicating this plant. A plat of about 5 sq. rods was cut over at intervals of 4 to 7 days during the season of 1903, and the number of plants counted. During the time covered by the experiment 23 cuttings were made and the number of plants decreased from a maximum of 2,000 to a minimum of 15. Other methods of eradication are discussed.

Some common Ontario weeds, F. C. HARRISON and W. LOCHHEAD (*Ontario Agr. Col. and Expt. Farm Bul. 128, pp. 96, figs. 43*).—An increasing demand for information regarding the weeds of Ontario has led to the preparation of this bulletin to supplant that issued in 1899 (E. S. R., 12, p. 1052). A number of additional weeds are described, and the methods of eradication are in many instances given in greater detail. More than 60 species of weeds are described, some of them being figured. In addition to describing the weeds, information is given concerning weed seeds, and a number of the more common found mixed with clover and grass seeds are figured and described.

Chrysanthemum leucanthemum and the American white weed, M. L. FERNALD (*Rhodora, 5 (1903), pp. 178–181, figs. 2; abs. in Bot. Centbl., 93 (1903), No. 37, pp. 259, 260*).—According to the author the American white weed, or ox-eye daisy, which is quite common throughout the eastern part of the United States, is not the typical *Chrysanthemum leucanthemum*, but is a form which has long been recognized and for which the name *C. leucanthemum subpinnatifidum* is given.

Poisonous weeds, C. E. BESSEY (*Nebraska Sta. Rpt. 1902, pp. 14–62, figs. 14*).—A special investigation has been inaugurated in the study of the poisonous weeds in Nebraska, the investigation being made possible by an appropriation of the State legislature for the study of poisonous weeds and the causes of disease in horses and cattle. Notes are given on the distribution of the poisonous weeds in general and their classification. The different poisonous or suspected plants are grouped according to the physical characteristics of the localities in which they are usually found, as well as by geographic distribution, following which an annotated list is given of the stock poisoning and suspected plants which have been commonly met with during the progress of the investigation. The list includes only those plants which are known to be poisonous to stock or are strongly suspected of being so.

DISEASES OF PLANTS.

A disease of clover and alfalfa seed, V. PEGLION (*Staz. Sper. Agr. Ital., 36 (1903), No. 3, pp. 198–204*).—A preliminary note is given of a diseased condition of alfalfa and clover seed. The seed appeared to be of an unusual brownish color, and when examined was found deficient either in germination or the subsequent growth of the seedlings. The cause is apparently due to some fungus, although the parasite was not determined. The affected seed can be readily distinguished and the author condemns the use of such seed.

Studies of a root rot of carrots with special reference to its distribution, J. ERIKSSON (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), Nos. 22–23, pp. 721–738; 24–25, pp. 766–775, pl. 1, figs. 4*).—In the autumn of 1897, on the experimental grounds of the Royal Swedish Agricultural Academy, an apparently new root rot of carrots was noticed. At the time of harvest many of the roots were more or less covered with a mycelium of a reddish violet color. This occurred in felt-like mats, usually present in zonal areas on the roots, the disease sometimes being confined to the upper portions, while at other times only the middle or lower parts of the roots were affected.

A study of the organisms showed that it was *Rhizoctonia violacea* and every variety of carrot examined seemed liable to attack. On the different varieties studied specialized forms of the fungus were discovered and these were found capable of affecting other plants besides carrots. Thus far it has been found possible to inoculate fodder and sugar beets, alfalfa, potatoes, and many weeds, but not red clover nor parsnips. The different plants are affected with varying severity, but beets seem especially subject to injury. The second generation of the fungus grown on beets is much more destructive to beets than the first generation, but the organism seems less able to withstand unfavorable climatic conditions.

Experiments carried on during 1899 and 1900 showed that slaked lime, even when used in considerable quantity, was of little use in combating this fungus. A combination of carbolized lime and "petroleum water" in small quantities proved in some experiments to be valuable in destroying the fungus.

Culture experiments with some rusts of Leguminosæ, E. JORDI (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 24–25, pp. 777–779*).—A preliminary note is given on culture experiments with *Uromyces faba*, *U. ervi*, *U. anthyllidis*, *U. hedysari obscuri*, and *U. astragali*. The experiments showed that these different fungi were specialized upon certain species of plants and could not be inoculated upon others that were more or less distantly related to them.

Some culture experiments with rust fungi on Umbelliferæ, O. Semadeni (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 16–17, pp. 522–524*).—The results of studies of several species of fungi which normally occur in umbelliferous plants are reported. The author found that *Puccinia pimpinellæ*, *P. chærophylli*, and *P. petroselini* were autœcious, while *Æcidium mei*, *P. caribistortæ* and *P. polygoni vivipari* were heterœcious, one phase occurring on species of umbelliferous plants and the other on species of Polygonum.

Club root of cabbages (*Gard. Chron., 3. ser., 34 (1903), No. 878, p. 293*).—According to the writer's observations the club-root fungus remains alive in the soil for a much longer period than has been previously supposed. An account is given of a crop of crucifers on soil that had not carried a similar crop for at least 20 years, having been planted continuously in dahlias, chrysanthemums, and potatoes. The resultant crop was badly infested with club root. Experiments with lime are reported, showing it to be a specific for the prevention of this disease.

Club root of cabbages (*Gard. Chron., 3. ser., 34 (1903), No. 870, p. 163*).—In a brief note the successful use of gas lime for the prevention of club root of cabbages is reported.

A new cucumber disease, M. C. Cooke (*Gard. Chron., 3. ser., 34 (1903), Nos. 867, p. 100; 871, p. 172, fig. 1*).—The author describes a disease of recent appearance on cucumber fruits, in which the fungus forms on the surface of the fruit dark depressed spots, which gradually enlarge and become quite black, cracking either across or around and exposing the paler tissues underneath. The organism has not been definitely determined, but it has been provisionally called *Cladosporium scabies*.

In a subsequent note the author states that the mycelium evidently permeates the entire fruit, and that every fragment of the infected cucumbers should be collected and burned. If spraying should be undertaken, the author believes that Condy's fluid, diluted, would be less liable to injure the fruits than copper fungicides.

A cucumber leaf disease (*Jour. Bd. Agr. [London], 10 (1903), No. 2, pp. 166–170, pl. 1*).—A report is given of the recent observation of a leaf disease of cucumbers, which in general appearances resembles the ordinary leaf spot of that plant. An examination of diseased material showed, however, that it was caused by an entirely different fungus (*Dendryphium comosum*).

This disease which, according to the account, is confined to cucumbers grown under glass, appears early in March and attacks the plants while quite young, destroying the tissues of the leaf, and in bad cases also infecting the growing points of the shoots. The fungus is usually recognized as a saprophyte and was probably introduced into the cucumber houses by the manure that was used. So far only the conidial phase has been discovered, but the fungus is still under observation.

The writer believes that by ventilating the houses and securing a drier atmosphere the disease can be greatly restricted, and if necessary spraying the plants with a weak solution of potassium sulphide would prove advantageous.

Cucumber leaf spot, G. Massee (*Gard. Chron., 3. ser., 34 (1903), No. 871, p. 184*).—In reply to a correspondent the author gives a description of leaf spot of cucumbers which is caused by *Cercospora melonis*. For the eradication of the disease it is recommended that the soil in the cucumber house should be disinfected by spraying with fungicides and care should be exercised to prevent too soft a growth of the foliage and the introduction of the fungus from without the greenhouse.

A mildew of rhubarb, A. Osterwalder (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 24–25, pp. 775–777, figs. 3*).—The author reports the presence of a species of Peronospora on the variety of rhubarb *Rheum undulatum*. This mildew appears upon the leaves early in the spring, producing small reddish spots, which are more or less limited by the veins. Later the spots increase in size and coalesce, destroying the leaf tissues.

The author has compared the species with *P. rumicis*, which has been previously

reported on species of Rheum, and with *P. polygoni*, and is led to believe that the fungus causing this disease is possibly identical with the latter species.

Brown rot of fruit (*Gard. Chron., 3. ser., 34 (1903), No. 864, p. 36*).—A brief account is given of the brown rot of fruit caused by attacks of *Sclerotinia fructigena* on apples, pears, plums, cherries, and peaches, as well as various wild fruits belonging to the same family of plants. The effect of the fungus on the foliage and fruit is described at considerable length.

For the prevention of the disease it is recommended that all dead twigs and shriveled fruits should be collected and burned, and the trees and ground about them thoroughly sprayed with a solution of sulphate of iron 25 lbs., sulphuric acid 1 pt., and water 50 gal. The application should be made in January or February before the leaf buds begin to swell. After the expansion of the leaves the trees should be sprayed at intervals with a weak solution of Bordeaux mixture.

Ripe rot or bitter rot of fruits, N. A. COBB (*Agr. Gaz. New South Wales, 14 (1903), No. 7, pp. 627–652, pls. 2, figs. 44*).—A report is given of the ripe rot or bitter rot of fruits, in which attention is called to a previous publication by the author stating that he was able to cause the disease in peach, plum, nectarine, pear, cherry, grape, and mango after 5 days by inoculating with the ripe rot of the apple (*Glœosporium fructigenum*).

A review is given of the work previously published by the New Jersey Stations (E. S. R., 5, p. 401) on the cross inoculation of different plants with this fungus, and a discussion is given of various inoculation experiments recently performed by the author. These inoculations included passion fruit, lemon, banana, grape, pear, date, plum, quince, apple, peach, hawthorn, guava, and tomato. Reciprocal inoculations were made between these different hosts, and the disease was produced in nearly every instance. The author is led to believe, as a result of these investigations, that there are in reality fewer forms of the fungus than have been hitherto described.

Experiments on combating downy and powdery mildew of grapes in 1902, H. KASERER (*Ztschr. Landw. Versuchsw. Oesterr., 6 (1903), No. 3, pp. 205–209*).—Experiments are reported on the efficiency of a number of fungicides for the prevention of the downy and powdery mildews of grapes. In one series of experiments antimony salts were tested, solutions of antimony sulphate and sodium sulphoantimoniate being employed. The solutions were rendered slightly alkaline by the addition of milk of lime and then sprayed on the grape foliage. Beginning at the same time the principal part of the vineyard was given 3 applications of Bordeaux mixture. At the end of the season no downy mildew was noticeable on the vines treated with Bordeaux mixture, while those sprayed with the antimony solutions showed evidence of Peronospora attack early in August.

A compound of copper called "resin-acid copper" in combination with sulphur was tested as a combined treatment for the downy and powdery mildew without effect. The best results were obtained from the simultaneous treatment of the 2 diseases when vines were sprayed with an alkaline Bordeaux mixture, to each kiloliter of which was added 300 gm. of sodium thiosulphate. Vines so treated did not show the slightest trace of downy mildew and powdery mildew was held in check, although especially troublesome on the adjacent unsprayed vines.

A "red scald" of grapes, H. MÜLLER-THURGAU (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), Nos. 1, pp. 8–17; 2, pp. 48–61; 3, pp. 81–88; 4, pp. 113–121, pls. 5*).—A description is given of a disease of grapes in which the foliage is severely attacked. This disease has been known for a number of years, and is quite widely distributed in Switzerland, and possibly elsewhere. It is known by a number of common names, such as red scald, singe, leaf brown, sun burn, and red burn of grape leaves, the author preferring the latter designation. Both red and white grapes are subject to infection, although some variation of susceptibility of different varieties is known.

The occurrence of the disease is indicated by the appearance on the leaves of intensely red spots of varying size. These increase, destroying the chlorophyll activity of the affected portions of the leaves, and ultimately destroy the whole leaf blade. Somewhat similar appearances are said to be produced by a number of agencies, and the different causes are pointed out for each disease.

The cause of the red scald or red burn of the leaves is a fungus (*Pseudopeziza tracheiphila* n. sp.), which attacks the veins of the leaf, filling the conductive tissues with its hyphæ. The organism has been isolated and cultivated, and a diagnosis of its principal characters is given. Unfavorable soil and climatic conditions for grapes favor the rapid spread of the disease, and draining is recommended to prevent too much soil moisture. Spraying with Bordeaux mixture has given good results in the protection of plants from this disease.

Resistance to chlorosis, J. M. GUILLON and O. BRUNAUD (*Rev. Vit., 20 (1903), Nos. 513, pp. 437–441; 516, pp. 532–535, pl. 1*).—The results are given of a study of different varieties of grapes, in which the relative resistance to chlorosis was determined. The authors adopted a scale of resistance and have noted the points of resistance, from 1 to 20, for a large number of species and hybrids, particular attention being given to the hybrids of the cinerea, Arizonica, candicans, cordifolia, and æstivalis grapes.

Among the European species *Vitis vinifera* is one of the most resistant, and among the American introductions *V. berlandieri* is most resistant to this disease. The hybrids between these species are also found to be quite resistant. The rupestris and riparia hybrids are much more subject to attack than the others described.

The bacteriosis of roses, G. SCALIA (*Agr. Calabro Siculo, 1903; abs. in Bot. Centbl., 93 (1903), No. 34, p. 194*).—A preliminary note is given of a tuberculous disease of roses, which has been observed in Catania, attributed to the action of bacteria. The author has isolated a number of organisms, one of which seemed to be quite constant in its occurrence and character, and for this the provisional name *Bacillus rosarum* is given. It is proposed to study the subject further.

A bacterial disease of sugar beets, G. G. HEDGCOCK and H. METCALF (*Ztschr. Pflanzenkrank, 12 (1902), No. 6, pp. 321–324*).—In the abstract of this article (E. S. R., 14, p. 1085) the bacterium should have been described as not growing upon dextrose gelatin and only slightly, if at all, upon potato, and as producing no color or gas, in contradiction to the organism described by Kramer.

Diseases of chrysanthemums, G. E. STONE (*Amer. Florist, 21 (1903), No. 806, pp. 583, 584*).—The effect of heat, moisture, light, and the circulation of air as factors in diseases of plants grown under glass are discussed, after which special attention is given to the diseases of chrysanthemums. The powdery mildew, rust, and stem rot are described, the rust and stem rot being reported as the most troublesome. Anthracnose of chrysanthemums and 2 forms of leaf spot are briefly mentioned, and in conclusion the author states that cultural methods rather than remedial treatments should be adopted in combating plant diseases in greenhouses.

The chrysanthemum rust, E. JACKY (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 12, pp. 369–381, figs. 8*).—In the author's previous report of studies on the rust of chrysanthemums (E. S. R., 13, p. 153) the identity of the fungus *Puccinia chrysanthemi* and other forms was discussed, and this species was considered different from *P. tanaceti* in its morphological and physiological characters.

The form occurring in Japan and lately described as *P. chrysanthemi chinensis* is reported upon in the present paper. Inoculation experiments with Japanese material showed that the rust is a Hemipuccinia and is capable of invading *Chrysanthemum indicum*, as well as its usual host, *C. chinense;* and it appears to differ from the usual form of *P. chrysanthemi* mainly in the character of its teleutospores.

The author has investigated the question of varietal predisposition to rusts, and so

far as his experiments go could find no evidence of such variation, and believes the resistance of certain varieties to disease is not as common as previously claimed. Infection takes place, so far as *P. chrysanthemi* is concerned, almost entirely through the uredospores. The paper concludes with an account of the morphological and physiological characters of the different species and varieties of chrysanthemum rusts.

Remarks on the biology of chrysanthemum rusts, P. MAGNUS (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), No. 18–19, pp. 575–577*).—Attention is called to the investigations of Jacky, in which the possible identity of species of chrysanthemum rust is suggested and the fact pointed out that the Puccinia produces teleutospores in Japan but only uredospores in Europe. Other examples are cited of somewhat similar phenomena among related fungi.

The cause and prevention of a tulip disease, J. RITZEMA BOS (*Centbl. Bakt. u. Par., 2. Abt., 10 (1903), Nos. 1, pp. 18–26; 3, pp. 84–94*).—A description is given of a disease of tulips and some other bulbous plants, which is due to attacks of *Botrytis parasitica*. This article is essentially the same as one by the author noted from another source (E. S. R., 15, p. 273).

Standard fungicides (*Gard. Chron., 3. ser., 34 (1903), No. 864, pp. 40, 41*).—A detailed note describing the use of fungicides, and giving quotations from a number of publications relative to the preparation and use of Bordeaux mixture, ammoniacal-copper carbonate, etc.

On the adherence of copper fungicides, M. FRÉMONT (*Prog. Agr. et Vit. (Éd. L'Est), 24 (1903), No. 38, pp. 351–353*).—The results of a study of a number of fungicides to test their adhesiveness are given.

The author tested 4 fungicides, each of which contained copper sulphate and carbonate of soda in about the same proportion, to which was added soap, permanganate of potash, and a commercial product known as alkaline polysulphate. These different fungicides were prepared and carefully sprayed in order to distinguish the rapidity of their drying, as well as the duration of their adhesiveness when exposed to ordinary weather conditions.

All of the fungicides adhered very well to the foliage. The mixture containing the polysulphate dried most rapidly, being thoroughly adhesive in 10 to 15 minutes. Next in adhesiveness was the mixture containing soap solution, followed by that containing the potassium permanganate. The simple solution of sulphate of copper, carbonate of soda, and water required the longest time to dry and was less adherent than the other forms.

ENTOMOLOGY.

Observations made by the entomological service of the agricultural institute in 1902, POSKIN (*Bul. Agr. [Brussels], 19 (1903), No. 2, pp. 181–199*).—*Bibio hortulanus* is reported as injurious to various garden crops. In combating this insect it is recommended that the base of the plants and the adjoining soil be sprayed with tobacco decoction. Pears are said to suffer considerable injury from the attacks of *Cecidomyia nigra*. This insect may be controlled to some extent by the collection and destruction of infested pears.

Extensive injuries are reported from the attacks of the codling moth, and a number of experiments are reported in the control of this insect. It is recommended that infested apples be destroyed and that the insects be destroyed in their hiding places by spraying with tobacco decoction, or some other contact insecticide. The larvæ may be controlled by spraying with a Paris green solution to which small quantities of lime are added. Notes are also given on the injuries caused by field mice and on inoculation and other methods for combating this pest.

The leaf hopper of the sugar cane, R. C. L. PERKINS (*Hawaii Bd. Comrs. Agr. and For., Div. Ent. Bul. 1, pp. 38*).—A leaf hopper injurious to sugar cane is described

as new under the name *Perkinsiella saccharicida*. This insect was first observed in 1900 and has since become much more numerous and injurious. The species is native to Hawaii and differs from related species in Australia and other tropical countries. Detailed notes are given on the appearance, habits, and life history of this insect. When the leaf hopper was present in large numbers the midrib and sheath of the leaf became red in spots or almost uniformly, and since the insect secretes honeydew this substance becomes covered with a fungus which gives a peculiar appearance to the affected canes. Certain varieties of cane appear to be more resistant than others.

A large number of natural enemies of this pest are noted, including parasitic and predaceous insects, spiders, and fungi. The author believes that the repression of this pest must be brought about by encouraging its natural enemies and introducing other beneficial species from foreign countries. The successful use of artificial insecticides is believed to be impracticable. Experiments were made by C. F. Eckart, during which the effect of corrosive sublimate, hydrocyanic-acid gas, and carbolic acid upon the cane-leaf hopper were tested. The immersion of infested sections of sugar cane in solutions of corrosive sublimate and carbolic acid, varying from 1 to 2 per cent, and for periods ranging from 3 to 6 hours, showed that the solutions of carbolic acid were ineffective in destroying the eggs of the insect, while corrosive sublimate solutions exhibited considerable effectiveness.

Fumigation with hydrocyanic-acid gas was sufficient to destroy the eggs when infested cane sections were treated for a period of 6 hours or more. The treatment with this gas had a marked effect on the vitality of the cane, while corrosive sublimate apparently had no injurious influence except when used in strong solutions.

The Mexican cotton-boll weevil, L. O. HOWARD (*Science, n. ser., 18 (1903), No. 465, p. 693*).—Notes are given on the investigation of this insect which was begun by the Division of Entomology in 1894, and which has led to the discovery of a method by which a fair crop of cotton can be raised under conditions of infestation by this insect.

Cutworms, J. R. ANDERSON (*Dept. Agr. British Columbia, Bul. 9, pp. 8*).—Descriptive, economic, and biological notes on *Peridroma saucia*. In combating this insect the use of poisoned bait is recommended. The cutworms may be prevented from climbing into fruit trees by the use of mechanical obstructions.

The codling moth regulations, G. QUINN (*Jour. Agr. and Ind. South Australia, 7 (1903), No. 2, pp. 89–92*).—Circulars of information relating to the best methods of controlling and eradicating codling moth have been distributed to various apple growers throughout South Australia and requests were made for information concerning the results obtained by the application of these methods. A large percentage of apple growers were found to be opposed to compulsory spraying, in favor of banding, and opposed to unrestricted sale of infested fruit.

The moth book, W. J. HOLLAND (*New York: Doubleday, Page & Co., 1903, pp. XXIV+479, pls. 48, figs. 263*).—This volume is a companion to the author's butterfly book and is intended to cover the subject of moths in the same manner. No attempt is made to list all of the species of moths occurring in North America, but the common representatives of the more important genera are briefly described and notes are given on their habits and life history. The identification of the species mentioned in the volume is facilitated by the numerous illustrations. Special chapters are presented on the life history and anatomy of moths; capture, preparation, and preservation of specimens; classification of moths; and books relating to moths of North America.

Aquatic insects in New York, J. G. NEEDHAM ET AL. (*New York State Mus. Bul. 68, pp. 197–517, pls. 52, figs. 26*).—This bulletin constitutes a compendium of the general study of aquatic insects in New York, conducted under the direction of E. P. Felt. The subjects discussed in the bulletin include an account of the station

work for the summer of 1901 (pp. 200–204), the food of the brook trout (pp. 204–217), life histories of dragon flies (pp. 218–279), and life histories of Diptera (pp. 279–287); these 4 articles being prepared by J. G. Needham.

The bulletin also contains a discussion of aquatic Chrysomelidæ, by A. D. MacGillivray (pp. 288–327); aquatic nematocerous Diptera, by O. A. Johannsen (pp. 328–441); and the Sialididæ of North and South America, by K. C. Davis (pp. 442–486). It is well illustrated, and is intended as a basis for the study of the economic relations of aquatic insects and food fishes, and for the stimulation of similar lines of investigation by students in entomology and economic zoology.

Remedies for insects, C. W. Woodworth (*California Sta. Circ. 7, pp. 19*).—This is a second revision of Bulletin 115 of the same station (E. S. R., 9, pp. 157, 158).

Fumigation, W. J. Allen (*Agr. Gaz. New South Wales, 14 (1903), No. 7, pp. 597–606, pl. 1, figs. 3*).—The chief causes of failure in fumigation are believed by the author to be carelessness in estimating the size of the tree, fumigating at the wrong time, and carelessness in weighing cyanid. Attention is called to the necessity of exercising care in estimating the volume of the tent, in keeping all holes in the tent closed, and in weighing the cyanid and sulphuric acid. The best time for fumigating in New South Wales is believed to be in June and February, and it is recommended that the work be done at night. Extensive tables are presented showing the amount of chemicals to be used for trees of various sizes.

Sarcopsylla gallinacea in Europe, C. Tiraboschi (*Arch. Parasit., 7 (1903), No. 1, pp. 124–132*).—Notes are given on the habits and life history of the hen flea as observed in various parts of Europe. This insect is also reported as occurring quite commonly on various species of rats, and these animals may therefore be held responsible to some extent for distributing the fleas.

Observations on the Culicidæ, L. Dyé (*Arch. Parasit., 6 (1903), No. 3, pp. 359–376, figs. 5*).—Descriptive notes are given on *Myzorhynchus coustani* and *Stegomyia fasciata*. The habits and life history of these species are mentioned in detail with special reference to the agency of *S. fasciata* in transmitting yellow fever. The literature of the subject is reviewed in connection with a brief bibliography.

Studies on Culex and Anopheles, B. Galli-Valerio and Jeanne Rochaz-De Jongh (*Atti. Soc. Studi Malaria, 4 (1903), pp. 3–48, fig. 1*).—The authors studied the conditions under which mosquitoes might successfully breed and made a number of experiments in testing the effect of various impurities in water in which were found the eggs and larvæ of mosquitoes. During these experiments a test was made of the effect of elevation of temperature of the water upon the eggs of the mosquitoes, and also of the effect of desiccation and various insecticides upon the eggs and larvæ. It was found that a temperature of 40° C. is required for destroying all the larvæ in water. Attention is called to the great importance of draining small pools or ponds or treating them with kerosene oil in order to prevent the undue multiplication of mosquitoes.

The habits of the larvæ of Anopheles in relation to hydraulic engineering, E. Perrone (*Atti. Soc. Studi Malaria, 4 (1903), pp. 49–58*).—The author calls attention to the great multiplication of mosquitoes which may take place in pools of water in excavations for building sites or for other purposes of construction.

Forty years among the bees, C. C. Miller (*Chicago: George W. York & Co., 1903, pp. 327, pp. 111*).—A popular account of the general subject of rearing and managing bees, with notes on the recent methods of feeding and wintering bees, swarming, and care and manipulation of bee products.

The combination of swarms of bees, A. Delépine (*Jour. Agr. Prat., n. ser., 6 (1903), No. 42, p. 510*).—The author describes briefly 2 methods of bringing about the combination of 2 swarms of bees, viz, that in which the 2 hives are placed side by side, and the method of superposition.

Experimental researches on heredity in silkworms, G. Coutagne (*Bul. Sci. France et Belg., 37 (1903), pp. 1–194, pls. 9, figs. 7*).—An extended study was made of the influence of various conditions upon the various races of silkworms with special reference to the transmission of these characters in hybrids or pure-bred descendants of the individual silkworms upon which experiments were made. These experiments were undertaken chiefly from a biological standpoint, and thus far have not led to definite results which can be utilized in practical sericulture.

It was found that the quality and quantity of the silk could be considerably influenced by temperature, moisture, and other conditions under which the silkworms were maintained. In a certain percentage of cases success was had in securing the transmission of especially desirable characters from parents to offspring. It was found that the probability of the transmission of acquired characters to offspring could be stated with some degree of accuracy according to mathematical formulas.

FOODS—NUTRITION.

Roasting of beef, Isabel Bevier and Elizabeth C. Sprague (*Illinois Sta. Circ. 71, pp. 30*).—The influence of different shapes and sizes of pans, time of cooking, heat of the oven, and other factors upon the character of roasted meat (beef) was studied with the special purpose of securing data on the effects of cooking.

In a comparison of an oval concave pan with open and closed rectangular pans with flat bottoms, it was found that so far as total losses in weight were concerned, the shape and size of the pan did not seem to be of great importance. So far as color and consequently the flavor of the drippings were concerned, the area of the pan and its shape were important, the pan with the smaller area giving the lighter colored drippings in the experiments reported.

"If the whole amount of drippings was used for gravy, the darkening if not excessive might not be undesirable, but because of the number of uses for the excessive fat in drippings, it is desirable to avoid the darkening of them. Moreover, authority can be found for the idea that this darkening means that the fat was heated to such a temperature as to render it less digestible."

The results obtained with different sized pans were not definite as regards the losses in weight in cooking. In comparing open and closed pans it was found that the total losses in weight in roasting were greater in the open pan. However, when cooked in a closed pan the meat was inferior in flavor, and was not as attractive in appearance, since it did not brown well, nor was the color satisfactory if browned outside the pan and subsequently cooked. The meat cooked to a greater degree in the closed pan in 15 minutes than in the open pan. When cooked in a closed pan a larger percentage of the material lost was recovered in the drippings, owing to the fact that in the open pan the drippings are almost water free, while in the closed pan considerable water is retained.

As regards the effect of temperature, in the 14 experiments in which this factor was considered the heat of the oven ranged from 83 to 260° C., and the total loss in weight from 5.9 per cent to 20.6 per cent, which was less than one-sixteenth of the total weight of the beef roast used. In general, the higher the temperature the greater the loss in roasting. A temperature of not less than 249° C. was required for the development of the so-called osmazome and the flavors in the meat. When meat is baked for a short time at a very high temperature, 260° C., the outside layer is apt to be overdone and the center too rare for use. When baked very slowly in a special oven at a comparatively low temperature it was very evenly cooked throughout and the juices were well retained, but the savoriness and flavor produced by higher temperatures were lacking. Even if the meat was seared before cooking in this oven it did not retain this appearance, but came from the oven gray and unattractive. "If

browned at the end of the process the outside became tough and seemed to have the characteristics of over-cooked albumen emphasized."

The effect of basting was studied, and in the opinion of the authors the only definite conclusion which can be drawn regarding the differences between the basted and the unbasted meat was that when cooked under otherwise identical conditions the former was always the rarer. Evidently the temperature of the roast was lowered by basting it.

Summarizing the results of 21 tests, the total meat before roasting weighed 62 lbs. and after cooking 52.25 lbs., the loss being about one-sixth of the original weight. The average cost of the cooked meat was 19.2 cts. per pound, "an increase of 4 cts. a pound over the original cost." The possibility of using drippings, the loss of weight in boning, and some other problems were also considered.

Relative merit of butter or oil in cookery (*Dietet. and Hyg. Gaz., 19 (1903), No. 5, p. 303*).—A brief note quoting experiments with animals by P. Carnot and Miss Deflandre, in which the digestibility of fat is shown by the action of osmic acid on sections of liver substance. The quantity of fat thus obtained was greater after the ingestion of butter than after cod-liver oil or neat's-foot oil. Vegetable oils, such as olive oil, were not found to be as well assimilated by the liver as animal oils. On the basis of these experiments the superiority of animal to vegetable oils for culinary purposes is pointed out.

Further investigations among fruitarians at the California Agricultural Experiment Station, 1901-1902, M. E. JAFFA (*U. S. Dept. Agr., Office of Experiment Stations Bul. 132, pp. 81*).—Continuing earlier work (E. S. R., 13, p. 974), 9 dietary studies and 31 digestion experiments with subjects on a more or less strictly fruitarian diet were carried on at the University of California. Some of the subjects had for years confined their diet to vegetables and fruits; others were used to the ordinary fare.

While part of the dietaries make it plain that it is possible to obtain the requisite amount of protein and energy from a fruitarian diet, the majority of those studied fell below the tentative dietary standards, but, as the author notes, it is not just to ascribe this to the form of diet, since the same people might have consumed no larger quantities of nutrients on a mixed diet. In several cases small quantities of cereals and other common foods were eaten to render the rather unusual food combinations more palatable. The dietaries which contained cereals furnished more protein and energy in most cases than those which were limited strictly to fruits and nuts. The cost of the food per person per day ranged from 18 to 46 cts.

Considering the digestion experiments as a whole, the fruit and nut diets had the following coefficients of digestibility: Total organic matter 90.26 per cent, protein 75.30 per cent, fat 86.43 per cent, nitrogen-free extract 95.10 per cent, crude fiber 78.54 per cent, and ash 54.76 per cent, the available energy being 86.13 per cent.

"As shown by their composition and digestibility, both fruit and nuts can be favorably compared with other and more common foods. As sources of carbohydrates, fruits at ordinary prices are not expensive, and as sources of protein and fat, nuts at usual prices are reasonable.

"In the present investigations the question of the wholesomeness of a long-continued diet of fruit and nuts is not taken up. The agreement of one food or another with any person is frequently more or less a matter of personal idiosyncrasy, but it seems fair to say that those with whom nuts and fruits agree can, if they desire, readily secure a considerable part of their nutritive material from such sources."

Concerning the diet in public institutions, E. O. HULTGREN (*Versamml. Nord. Naturf. u. Aerzt., Verhandl. Sek. Anat., Physiol. u. Med. Chem., 1902, pp. 77-85*).—Studies of the diet in a number of hospitals in Stockholm are briefly reported.

Notes on the feeding of troops, VARGES (*Deut. Mil. Aerztl. Ztschr., [illegible], No. 5, p. 251; abs. in Hyg. Rundschau, 13 (1903), No. 15, pp. 785, 786*).—A tablet composed

of skim milk and egg yolk is described, which is proposed as a substitute for the canned meat in the ration of troops on the march. Skim-milk tablets containing sugar, cacao, and citric acid are also spoken of.

Cost of living (*U. S. Dept. Com. and Labor, Bureau of Labor Bul. 49, pp. 1137–1141*).—Data are given regarding the income and expenditures of 2,567 families in 33 States for the year 1901, the basis of selection being "that the head of the family must be a wage worker or a salaried man earning not over $1,200 during the year, and must be able to give information in regard to his expenditures in detail."

It appeared that the expenditure for food represented 42.54 per cent of the total family expenditure. This was an increase of 16.1 per cent over the corresponding expenditure for 1896, the year of lowest prices in the period covered by the data recorded by the Bureau, and an increase of 10.9 per cent as compared with the average of the period extending from 1890 to 1899. The article also includes data regarding the retail prices of food in the regions represented by the families studied.

Feeding adults with cows' milk and human milk, A. Schlossmann and E. Moro (*Ztschr. Biol., 45 (1903), No. 3, pp. 261–291*).—A comparative study of the nutritive value of cows' milk and human milk, one of the authors being the subject.

On the influence of diet, muscular exertion, and loss of sleep upon the formation of uric acid in man, H. C. Sherman (*Jour. Amer. Chem. Soc., 25 (1903), No. 11, pp. 1159–1166*).—The formation of uric acid was studied in connection with experiments with professional athletes of the effect of severe and prolonged muscular work on food consumption, digestion, and metabolism previously reported (E. S. R., 13, p. 575), and similar studies with a professional man on the effect of loss of sleep (E. S. R., 14, p. 788).

According to the author's summary "both with professional athletes and with the subject of sedentary habits, the elimination of uric acid was primarily dependent upon the food consumed.

"While very small changes, apparently, resulted from large variations in the amount of a bread-and-milk diet, the elimination of uric acid was mainly determined by the quantities of meat products consumed.

"In the case of well-trained professional athletes very severe and prolonged muscular exertion had little influence upon the formation and elimination of uric acid, except indirectly, by inducing an appetite for stimulating foods such as meat extracts.

"Marked loss of sleep had no apparent influence upon the amount of uric acid eliminated."

The effect of different foods on the water content of organs and the hemoglobin content of blood, J. Tsuboi (*Ztschr. Biol., 44 (1903), No. 3, pp. 376–406*).—Experiments with animals led to the conclusion that the hemoglobin content of the blood can be influenced by the food, being diminished in the experiments reported. When on an insufficient diet of bread and potatoes the carbohydrates were very abundant in comparison with protein. At the same time the insufficient food causes an increase in the water content of the blood and of the whole body.

The hemoglobin content of muscles, K. B. Lehmann et al. (*Ztschr. Biol., 45 (1903), No. 3, pp. 324–345*).—The author summarizes the results obtained by 5 of his students on the occurrence of hemoglobin in different sorts of muscular tissue. Some of the principal conclusions follow:

The muscles of young animals in general contain less hemoglobin than those of adults, apparently owing to the fact that they are less used. In young animals of the same kind marked differences were observed in the blood content of corresponding muscles, which could not be explained by a difference in age, but seemed to be due to heredity or other special cause. With adult animals the differences were often greater and were more difficult of explanation.

The effect of exercise on the color of the muscular tissue is spoken of in connection with the flesh of game, attention being directed to the high blood content of

venison and the dark-red color of squirrel flesh. In birds, the groups of muscles which are most used contain about 3.7 per cent blood and those least used 1 to 1.6 per cent. The flesh of chicken is characterized by a very low hemoglobin content.

The general conclusion is drawn that the blood content of striated muscle of warm-blooded animals often depends on the frequency and intensity of exercise. The hemoglobin content of the flesh of cold-blooded animals is discussed and other related topics, including the connection between hemoglobin content and the flavor of flesh foods. The author states that in general, though not always, other soluble bodies are present in abundance when the hemoglobin content is high. In other words, the red muscular tissues, generally speaking, have the most pronounced flavor.

On the time relations of proteid metabolism, P. B. HAWK (*Amer. Jour. Physiol., 10 (1903), No. 3, pp. 115–145, figs. 4*).—In experiments with 2 men the time relations of proteid metabolism were studied. After the ingestion of an extra quantity of proteid it was found that the nitrogen excretion began to rise rapidly, the point in maximum excretion being reached in 6 to 9 hours with one subject and in 9 to 12 hours with the other, this point of maximum excretion being followed at once by a very rapid fall which after a few hours gradually returned to the normal rate. The minimum rate of nitrogen excretion for each subject was observed during the night period.

In general, the excretion of sulphur was parallel to that of nitrogen, the maximum excretion occurring with each subject 6 to 9 hours after the ingestion of the proteid, and the normal rate being regained in 24 hours. In the case of one subject a tendency to 2 maxima daily was noted in the excretion of phosphorus. With the other subject a single maximum was generally observed, the normal level being regained with each subject in the first period of the day following the experimental day in which the extra proteid was taken at breakfast.

The ratio of the nitrogen content of the urine to the heat of combustion of its unoxidized material was somewhat lower on the day of extra proteid ingestion than on normal days.

Influence of rennin upon the digestion of the proteid constituents of milk, P. B. HAWK (*Amer. Jour. Physiol., 10 (1903), No. 1, pp. 37–46*).—Artificial digestion experiments led the author to conclude that rennin inhibits the digestion of milk proteids and that rennin ash does not possess this property. The inhibitory action of rennin upon the digestion of milk proteids was not modified by preliminary contact with pepsin solution at 40° C. for 30 minutes. Paracasein was found to be somewhat more difficult of digestion than casein. Rennin retarded the pancreatic digestion of milk proteids in alkaline or neutral solution, but had no inhibitory action upon the gastric digestion of fluid egg albumen.

Results of tests with man and animals of 50 coal-tar colors, G. W. CHLOPIN (*Hyg. Rundschau, 13 (1903), No. 15, pp. 753–756*).—The author summarizes briefly the results of an extended investigation of coal-tar colors from a hygienic standpoint, the results of which have not yet been published in detail. Experiments of 8 to 14 days' duration were made with dogs, in which 1 to 3 gm. of the different colors studied were introduced into the stomach daily.

The effect of the colors on human skin was also studied, subjects wearing on the hands or feet for 10 or 14 days woolen or cotton bandages colored with the dyes studied. Fifteen colors, or 30 per cent of the dyes studied, are regarded as poisonous, since they caused the death of the dogs or marked symptoms of poisoning. Seven of these 15 colors belong to a group whose constitution is not known, namely, the so-called Widal colors containing sulphur. Forty per cent of the dyes were regarded as harmful since they caused serious functional disturbances, as vomiting, diarrhea, or the excretion of albumin in the urine.

In the test of the effect of the colors upon the skin only 2 were found to be poisonous, namely, Ursol *d* and Auramin *o*, the effect of the former being much the more pronounced. In the author's opinion, with the data at present available no relation can be traced between the chemical classification of the coal-tar dyes and their physiological and toxicological properties. It should be noted, however, that he, as well as other investigators, did not find that any of the red dyes were poisonous.

Composition of East Indian foods according to analyses made in the laboratory of the Colonial Museum at Haarlem, M. Greshoff and J. Sack (*Bul. Koloniaal Mus. Haarlem, 1903, No. 28, Sup.*).—In continuation of earlier work [a] by the authors and J. J. van Eck, analyses of 100 samples of East Indian food materials are reported in tabular form, together with brief descriptions of the samples.

The composition of Indian food materials, M. Greshoff (*Chem. Ztg., 27 (1903), No. 42, pp. 499–501*).—Analyses are reported of 200 food materials from the Dutch East Indies, including cereals, legumes, flours, starches, bread, pastry, seeds and fruits, edible fungi, preserves and pickles; fresh, dried, and preserved fish and meat; oysters and other sea food; eggs of different sorts, edible birds' nests, and miscellaneous food products.

Some of the fruits, fresh and preserved, which were analyzed follow: Bananas, dates, box myrtle (*Myrica sapida*), durian (*Durio zibethinus*), Indian mulberry (*Morinda citrifolia*), *Gnetum gnemon, Averrhoa carambola, Bouea macrophylla,* and *Zalacca edulis.* These analyses were made under the author's direction by J. Sack and J. J. van Eck, and the present account, which includes only analytical data, is a summary of material which has been reported in publications of the Haarlem Koloniaal Museum (see above), later figures being given in a few instances.

Concerning plum jam, R. Woy (*Ztschr. Oeffentl. Chem., 8 (1902), pp. 270, 271; abs. in Hyg. Rundschau, 13 (1903), No. 15, p. 793*).—Three analyses of plum jam are reported.

Nut menu, A. S. Flowers (*Mount Joy, Pa.: Author, 1903, pp. 42, pls. 7*).—A large number of recipes are given for the preparation of various dishes from chestnuts and other nuts. The value of nuts as food is also briefly discussed.

Cocoa and chocolate, C. B. Cochran (*Pennsylvania State Dept. Agr. Rpt. 1902, pt. 1, pp. 662–679, pls. 4*).—Cacao beans, chocolate, and other cacao products are described, as well as their principal chemical constituents, the object being to present data useful for the detection of adulterants. The author also gives information concerning several adulterants of cocoa butter, "chocolate glazing," and the starches used as adulterants of chocolate.

Analyses of salt (*Connecticut State Sta. Rpt. 1902, pt. 4, p. 424*).—Analyses of 4 brands of salt are reported.

Some food products and food adulteration, E. F. Ladd (*North Dakota Sta. Bul. 57, pp. 249–315*).—In compliance with the State Pure Food Law, analyses were made of a number of samples of canned fruits and vegetables, vinegars, and flavoring extracts. The detection of sulphites and formic acid in canned goods when the manufacturers state positively that such materials had not been added leads the author to suggest that possibly these materials are added to fresh berries by producers and shippers. "Future investigations must determine whether this supposition is correct." The use of saccharin is briefly discussed.

Seventeenth annual report of the Ohio Dairy and Food Commissioner, J. E. Blackburn (*Ohio Dairy and Food Com. Rpt. 1902, pp. 100*).—In addition to the financial report of the State dairy and food commissioner, statistics are given of the number of foods and condiments examined, and the results of the examination.

German meat regulations (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 50,*

[a] Bul. Koloniaal Mus. Haarlem, 1900, Nos. 22, Sup.; 23, Sup.; 1901, No. 25, Sup.

pp. 51).—For the information of American packers and exporters, a translation of the German official regulations and proclamations which have a direct bearing upon the meat-inspection law have been published. The translation is accompanied by the original German text.

Encyclopedia of household enconomy, EMILY HOLT (*New York: McClure, Phillips & Co., 1903, pp. 381, pls. 11*).—This volume includes useful information on cooking, preservation of fruits, vegetables, etc., sanitation, water supply, and other topics connected with the household.

ANIMAL PRODUCTION.

The status of phosphorus in certain food materials and animal by-products, with special reference to the presence of inorganic forms, E. B. HART and W. H. ANDREWS (*New York State Sta. Bul. 238, pp. 181–196*).—It is apparently quite generally believed that phosphorus exists in vegetable products partly in organic compounds and partly as inorganic salts. With a view to determining the correctness of this belief the authors studied the character of the phosphorus bodies in a number of animal and vegetable products.

Different methods of separating and estimating organic and inorganic phosphorus were tested and compared, that finally adopted depending upon the solubility of phosphorus compounds in hydrochloric acid. Samples of suitable size are treated with this reagent, and the inorganic phosphorus and the total phosphorus removed by it are determined in aliquot portions of the extract, the total soluble phosphorus by the Neumann method, and the inorganic phosphorus as magnesium pyrophosphate, minimum amounts of nitric acid being added to insure quantitative separation of ammonium phospho-molybdate and to prevent the cleavage of the organic phosphorus compounds into organic and inorganic radicals. Any phosphorus in the original substance undissolved by the reagent used is assumed to exist in organic compounds as nucleo-proteids, nucleins, and lecithins, and its amount is directly determined, as is also the total phosphorus in the materials studied.

The following table shows the amounts of different kinds of phosphorus compounds in a number of materials as determined by the method outlined, and for comparison the results obtained by similar methods, water and dilute acetic acid being used as solvents:

Forms of phosphorus in a number of feeding stuffs and in feces.

Substance.	Total phosphorus.	In aqueous extract.		In acetic-acid extract.		In hydrochloric-acid extract.	
		Total soluble phosphorus.	Inorganic phosphorus.	Total soluble phosphorus.	Inorganic phosphorus.	Total soluble phosphorus.	Inorganic phosphorus.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Oats	0.355	0.180	....	0.114	....	0.096	....
Bran (wheat)	1.548	.356	0.143	1.100	0.055	.951	0.036
Malt sprouts	.677	.548	.391	.489	.279	.477	.017
Brewers' grains	.421	.142	.007	.039	.007	.040	.009
Distillers' grains	.307	.079	.012	.104	.005	.069	.007
Corn	.313	.276	.014	.203	....	.177	....
Alfalfa	.266	.196	.064	.182	.079	.180	.079
Linseed meal	.789	....	....	.327	.085	.195	.088
Oat straw	.135	....	....	.095	.028	.086	.009
Wheat	.390	.125	.028	.174	.040	.172	.008
Blood	.123	.029	.005	.028	.010	.054	....
Meat meal	4.073	....	....	....	....	1.387	.098
Liver-meat meal	1.034	....	....	....	....	.486	.005
Cow feces	.344	....	....	....	....	.148	.004

The experiments led to the conclusion that commercial feeding stuffs of vegetable origin do not contain appreciable quantities of phosphorus in inorganic compounds, and that feeding stuffs of animal origin, such as liver meal and dried blood, are also approximately free from such phosphorus compounds. Commercial meat meal, which contains varying quantities of bone, contains inorganic phosphorus due to the presence of more or less bone. The cow manure was also found to be free from inorganic phosphorus. It was evident that it was possible by different methods of manipulation to increase the amount of inorganic phosphorus found in different materials, owing to the cleavage of inorganic phosphorus compounds from bodies rich in phosphorus, such as nucleic acid.

The amount of different sorts of phosphorus compounds in germinated and ungerminated seeds was also studied, the period of germination extending over 2 weeks. "Our results bring us to the conclusion that during germination there is a proteolysis of nucleo-proteids with formation of more soluble mobile nucleins and nucleic acids, but not a transformation of the organic phosphorus into the inorganic."

In the comments by W. H. Jordan, which are appended to the report, the importance of the study of different phosphorus compounds from the standpoint of nutrition is discussed.

Commercial feeding stuffs, E. H. Jenkins et al. (*Connecticut State Sta. Rpt. 1902, pt. 4, pp. 359–423*).—Three hundred samples of commercial feeding stuffs were analyzed under the State law, including cotton-seed meal, old and new process linseed meal, wheat brans and middlings, mixed wheat feeds, gluten meal, gluten feed, corn meal, hominy feed, rye bran, rye feed, malt sprouts, brewers' grains, ground oats, oat feed, buckwheat middlings and hulls, peanut bran, broken peanuts, distillers' grains, white meal, proprietary feed, and cereal breakfast food by-products, and calf meal.

"The composition of most of the feeds which have guaranties is in substantial agreement with these guaranties. The only evidence of deliberate fraud in the feed market which is shown by the analyses is the mixing of finely-ground corncob or corn bran with mixed wheat feed, and selling this mixture in packages which do not bear the name of the manufacturers nor any statement giving the composition of the mixture. . . . The prices charged at present for commercial feeding stuffs often bear no relation to their chemical composition or feeding value. It therefore requires special care and intelligence to select feeds which shall be economical for the dairyman or feeder of other stock. The standard feeds sold by reputable dealers are, as a rule, much 'cheaper' and more satisfactory than the low-priced factory wastes."

Inspection of feeding stuffs, W. H. Jordan and F. D. Fuller (*New York State Sta. Bul. 240, pp. 213–250*).—From October, 1902, to February, 1903, 518 samples were analyzed under the State feeding-stuffs law, including cotton-seed meal, distillers' grains, brewers' grains, ground linseed cake, linseed-oil meal, gluten meal, gluten feed, hominy feed, malt sprouts, germ-oil meal, ground oats, corn meal, bran and corn meal, mixed feeds (bran and middlings), wheat offals (bran and middlings, unmixed), proprietary and mixed feeds (mostly corn and oat products), chicken feed, pigeon feed, duck feed, animal meals and similar products, rye flour, rye feed, buckwheat feed, and barley skimmings.

"No adulteration was observed among the cotton-seed and linseed meals, gluten products, and brewery and distillery residues, as shown by the official samples. Corncobs were shown to be present in 3 brands of licensed feeds, in 2 samples of unlicensed bran, and in 1 sample sold as pure corn meal. Several proprietary feeds were found, as usual, to be made up in part of oat hulls. Many samples of wheat offals, bran, middlings, and the same mixed, were found to be unadulterated and of good quality. The same can be said of numerous samples of corn and oats ground together.

"The markets are offering many inferior feeding stuffs. At the same time, the great bulk of commercial cattle foods available to buyers are unadulterated and of good quality."

Licensed concentrated feeding stuffs, F. W. WOLL and G. A. OLSEN (*Wisconsin Sta. Bul. 100, pp. 13–17, 20–22*).—This contains a list of 49 brands of commercial feeding stuffs licensed for sale in the State during 1903, suggestions as to the purchase of concentrated feeding stuffs, and the text of the Wisconsin feeding-stuff law.

Farm products and foods, F. T. SHUTT (*Ottawa: House of Commons, 1903, pp. 22*).—The comparative value of different cattle feeds, the feeding and management of chickens, and other topics are included, the matter being summarized from publications of the Canada experimental farms.

Concerning an animal meal, GLAGE (*Monatsh. Prakt. Thierh., 13 (1902), p. 550; abs. in Ztschr. Fleisch u. Milchhyg., 13 (1903), No. 11, p. 353*).—The possible value of sterilized animal meal made from the bodies of animals which have been destroyed is discussed.

Intensive feeding of animals with fenugreek, SCHLAGDENHAUFFEN and REEB (*Rec. Méd. Vét., 8. ser., 9 (1902), No. 5, pp. 161–165; abs. in Ztschr. Fleisch u. Milchhyg., 13 (1903), No. 5, p. 146*).—Noted from another publication (E. S. R., 14, p. 381).

Different applications of the results of recent investigations in animal production, M. FISCHER and O. KELLNER (*Fühling's Landw. Ztg., 52 (1903), Nos. 9, pp. 305–310; 10, pp. 346–351; 11, pp. 396–402; 13, pp. 475–482*).—A controversy between the authors regarding this point.

Sheep ranching in the Western States, E. V. WILCOX (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 79–98, pls. 12*).—The management and care of sheep on ranges is discussed on the basis of data gathered by the author on the sheep ranges of the western United States. It is pointed out that the natural conditions have necessarily resulted in the evolution of a different system of management from that followed in other regions, the system followed being tolerably uniform throughout the range States from Mexico to Canada.

As a general rule the sheep ranches are so located that they may be readily divided into summer and winter ranges, the summer range being located in the higher altitudes or in localities where a comparatively large amount of rainfall occurs, insuring an abundant growth of grasses and other forage crops. In some of the mountain ranges buffalo grass prevails, and in others bunch grass and various species of blue joint. Though some sheep seem to prefer grasses, there are hardly any other native plants which are not eaten to some extent, all such being classified under the local term "weeds." Some of the plants are poisonous, and as it has been found that the danger from poisoning is greatest in the early part of the season, it is a common custom to delay entering the mountain pastures until the time of greatest danger is past.

The importance of water in summer is pointed out. In winter it is less necessary, as snow takes its place. If the winter feeding ground is favorably situated, little feed is needed in addition to the self-cured grasses. With the increasing scarcity of suitable land for winter ranges the custom of supplementing the natural feed has increased, alfalfa being most commonly raised for this purpose. The number of sheep which can be maintained on an acre naturally depends upon the region. Under favorable conditions an acre will maintain 2 sheep during a whole season, while under others 2 or 3 acres will be required for a single sheep.

The cost of sheep raising naturally varies, 25 cts. per head per year being regarded as a fair estimate where the sheep raiser simply makes use of public lands, and if he be fortunate enough to find suitable grazing in localities where winter feeding is not necessary. On the other hand, sheep raisers who maintain extensive plants, feed their flocks in winter, and rent or own a considerable tract of land for grazing estimate the cost at from 75 cts. to $1.25 per head per year.

The author also discusses breeds, lambing, shearing, buildings, and other topics of importance in this connection.

Welsh mountain sheep, G. F. Thompson (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 99–102, pls. 2*).—A descriptive article.

The food requirements of pigs from birth to maturity, W. L. Carlyle (*Wisconsin Sta. Bul. 104, pp. 51, figs. 13*).—The object of this investigation was to determine the food consumed and the gains made by pigs of different breeds and types from birth until they were slaughtered, and also to secure data regarding the amount and composition of sow's milk.

The animals studied included 12 sows (Berkshires, Poland Chinas, Razorbacks and crosses) and their litters. The sows ranged in age from 1 to 5 years, and in weight from 206 lbs. in the case of the yearling Razorback to 532 lbs. in the case of a 4-year-old Berkshire, the average weight being 343 lbs. The average number of pigs in a litter ranged from 5.5 pigs with the small sized sows to 9.2 pigs with the large ones, the average weight of the litters ranging in the 2 cases from 14 to 27 lbs. The age of the sows also apparently influenced the number of pigs and the weight of the litters, fewer and lighter pigs being farrowed by the younger animals.

According to the author the older and larger sows are much better mothers than the younger and smaller ones, and he believes that the common practice of many farmers in disposing of their old brood sows each year and reserving young and immature animals for breeding purposes is not to be commended.

The pigs were separated from the sows and were allowed to suckle every 2 hours during the day and every 4 hours at night. On 2 days during the fourth and eighth week each litter was carefully weighed immediately before and after nursing, the difference in weight being assumed to represent the milk yield. "The time actually spent by the pigs in nursing varied from 1 to 2 minutes, with fully one-half of this time taken in getting the milk started."

On the basis of the recorded data, the average estimated daily milk yield for 12 weeks for Berkshire sows was 6.31 lbs. per head per day, for the Poland China sows 4.86 lbs., and for the Razorback sows 5.17 lbs., the average for all being 5.44 lbs. It was observed that "some sows yield almost double the quantity of milk given by others, hence it seems evident that there is as much variation in the amount of milk given by different sows as there is among dairy cows. A marked falling off is also apparent in the quantity of milk given by all the sows from the fourth to the eighth week. . . .

"A sow is very slow in giving down her milk under normal conditions, and although not generally known it is impossible to get any milk from the udder except while some of the pigs are nursing. . . . We also learned that the forward teats on the breast of the sow gave a larger quantity of milk and gave it more freely than the teats farther back, the hindermost teats apparently yielding least of all. . . . Each pig has its particular teat at every nursing period. After the milk had been started by the rooting and kneading process of the pigs with their noses on the udder of the sow, the herdsman and his assistant quickly drew into flasks what milk they could from the vacant teats." In nearly every case at least 2 oz. was thus obtained, samples of which were analyzed.

On an average the sow's milk had a specific gravity of 1.0412, and the following percentage composition: Total solids 19.49, casein and albumen, 6.06, fat 6.89, milk sugar, 5.64, and ash 0.98 per cent.

For the first few days after farrowing the sows were fed very sparingly of shorts, oil meal, and skim milk. Later corn meal was added to their ration, the feeds being supplied ad libitum until the pigs were weaned, which was done when they were 12 weeks old. After weaning the ration was continued for 8 weeks, but the quantity was limited to an amount calculated to be just sufficient for maintenance. The data recorded show that after weaning the litters the sows required for maintenance on an

average 1.19 lbs. of grain and 2.4 lbs. of skim milk per head daily, the cost of the ration being 0.013 ct. "The Razorback sows ate less feed on the average than any of the other breeds, while they ate much more in proportion to their live weight, though they made a slight gain in weight, while the sows of the other breeds lost slightly."

As regards the gains, each pig in the litters averaging 23.5 lbs. at birth made an average gain of 4 lbs. per week for the 12 weeks before weaning, those averaging 16 lbs. an average gain of 3.6 lbs. per pig per week, and those averaging less than 15 lbs. an average gain of 2.9 lbs. per pig per week. "Many prominent breeders seem positive that a small or medium-sized litter will make better gains in the aggregate than a large one, and it not unfrequently occurs that where a large litter is farrowed they kill some of the pigs at birth. From the data presented it would seem that owing to the vitality transmitted to the pigs from their prolific dam or from some other physiological cause, the pigs in large litters are more thrifty and better feeders than those in a small litter."

From the time they were 4 weeks old until weaned the pigs were given some grain. After weaning the feeding test was continued for 8 weeks, the sows and pigs being divided for convenience into 4 uniform groups. Lot 1 was fed corn meal and skim milk about 1:8, lot 2 corn meal and shorts 2:3, lot 3 corn meal and beef meal 2:1, and lot 4 concentrated feed and skim milk about 2:3, the concentrated feed consisting of corn meal, shorts, and beef meal 4:3:1. Before weaning the average daily gain per pig in the first month of the test was 0.4 lb., in the second 0.47 lb., and in the third month 0.69 lb.; in the first month after weaning it was 0.71 lb. and in the second month 0.81 lb.

The amount of feed required per pound of gain and its cost were calculated in every case, and "the amount eaten by the sow while she was suckling the pigs is always charged to the pigs, less the sow's feed of maintenance." On this assumption a pound of gain required from 1.7 lbs. grain and 6.1 lbs. skim milk in the first month of the whole period to 3.9 lbs. of grain and 6.2 lbs. of skim milk in the last month, the cost of a pound of gain ranging from 2.21 cts. to 3.96 cts.

With 2 pigs from each litter, the feeding test was continued on the same rations as before for 12 weeks, that is, until the pigs were ready for slaughter. The first 4 weeks of this period the average net gain per pig was 29.1 lbs. and for the last 4 weeks it was 32.4, the cost of a pound of gain being 3.19 cts. and 4.20 cts., respectively. The corresponding values for the first 4 weeks of the nursing period were 8.8 lbs. and 1.17 cts., and for the test as a whole 22.1 lbs. and 2.8 cts. per month. On the basis of these figures the author calculates that on an average it requires 2.77 lbs. of digestible nutrients, at a cost of 3.12 cts., to produce a pound of gain with pigs from birth to maturity, the nutritive ratio of the ration being 1:3.99.

At the close of the test the pigs were slaughtered and the live weight and dressed weight, weight of internal organs, and other similar data recorded. The breaking strength of the thigh bones was also tested and it was found that there was a marked difference depending upon the character of the rations fed, the bones of the pigs fed corn and beef meal having a breaking strength of 1,200 lbs., which was about 8 times the weight of the body. Those of the pigs fed corn and shorts had a breaking strength of 835 lbs. or 4.3 times the average weight of the body, and the bones of the pigs fed corn and skim milk 977 lbs. or 3.8 times the average weight of the body, and of the group fed the grain and beef meal ration it was 1,169 lbs. or 5.2 times the average weight of the body.

"From these data it would seem that the beef meal in the rations had a marked influence on the strength of the bones in the different pigs, while the rations containing a large proportion of corn seemed to have the effect of greatly weakening the bones of the pigs to which they were fed."

The results obtained in this test are discussed at considerable length in relation to breeds and rations fed.

Corn, wheat and soy-bean meal with skim milk for pork production, A. M. Soule and J. R. Fain (*Tennessee Sta. Bul. Vol. XVI, No. 3, pp. 35–48, figs. 5*).—Two tests, the first of 60 days' and the second of 77 days' duration, were undertaken for the purpose of studying the value of corn meal alone and fed with different amounts of skim milk, and also the effects of substituting wheat meal and soy-bean meal for part of the corn meal when combined with skim milk.

In the test made in 1892 each lot contained 3 grade Chester White pigs, while in the test made in 1893 each lot contained 4 grade Berkshires. The rations fed and the general experimental conditions were practically the same in the 2 tests, lots 1, 2, 3, 4, and 7 being fed corn meal and wheat meal, 2:1, with skim milk, the proportion of grain to milk ranging from 1:3 in the case of lot 1 to 1:12 in the case of lot 4. In each case lot 5 was fed corn meal only; lot 6 corn meal and skim milk, 1:8; and lot 8, corn meal and soy-bean meal, 2:1, with skim milk in the proportion of 1 part grain to 8 parts milk.

The gains on corn meal, wheat meal, and skim milk in 1892 were practically uniform, being about 1.5 lbs. per head per day. With lot 8 (corn meal, soy-bean meal, and skim milk) the average daily gain was 1.6 lbs. per head per day. With lot 5 (corn meal only) it was 0.9 lb., and with lot 6 (corn meal and skim milk) 1.7 lbs. In 1903 the gains on corn meal, wheat meal, and skim milk ranged from 1 lb. per head per day with lot 7 (grain and skim milk 1:8) to 1.3 lbs. with lot 3 (grain and skim milk 1:9). With lot 6 (corn meal and skim milk) and with lot 8 (corn meal, soy-bean meal and skim milk) the average daily gain in each case was 1 lb. per head per day, and with lot 5 (corn meal only) 0.24 lb.

Considering the averages for the 2 years, the smallest gain, 0.5 lb. per head per day, was made with lot 5 (corn meal only), and the greatest gain, 1.4 lbs., with lot 3 (grain and skim milk 1:9), and lot 4 (grain and skim milk 1:12). The largest amount of grain per pound of gain, 4.1 lbs., was required on corn meal alone. When grain was fed with skim milk the amount required per pound of gain ranged from 1.4 lbs. with lot 4 (grain and skim milk 1:12) to 2.2 lbs. with lot 1 (grain and skim milk 1:3). In the latter case the smallest quantity of skim milk, 6.5 lbs., was required, and in the former the greatest amount, 16.4 lbs. With lot 1 the gains were made most economically, costing 4.4 cts. per pound, while with lot 5 the gain was most expensive. The profit ranged from $3.38 per lot on soy beans to $7.63 per lot on grain and skim milk 1:3.

"The cost of soy beans in the case of the [former] group was probably responsible for the small profit shown, which indicates the importance of studying and utilizing those grains best adapted for the cheap production of pork."

At the conclusion of the test the pigs were slaughtered, the weight of the carcass and other data being recorded for lots 5 to 8 in the first test and for all the lots in the second test.

"The best slaughter tests were made by the hogs receiving corn meal, wheat meal, and skim milk, there being little choice between the 4 groups; while those receiving corn meal and soy-bean meal were somewhat lower. That these hogs were not so profitable as those of higher grade is shown by the fact that certain well-bred animals, reared and fed on the University farm, sold and slaughtered at the same time, dressed from 81 to 83 per cent, a difference of from 2 to 10 per cent in favor of the better-bred hogs."

Peptone feed tested with pigs, W. Müller (*Fühling's Landw. Ztg., 52 (1903), No. 17, pp. 597–604, dgm. 1*).—Using 4 lots of 4 pigs each, the value of a so-called peptone feed, with or without meal, was compared with meal alone and with bran and a molasses mixture, potatoes forming a part of the ration in all cases. The pep-

tone feed used is a slaughter house by-product made from the partly-digested contents of the paunches of cattle. The pigs given this feed made the largest percentage gains in the 66 days of the test and at the least cost.

The American saddle horse, J. B. CASTLEMAN (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 62–78, pls. 5*).—The origin and development of the American saddle horse, size, and other requirements are discussed.

Fattening horses for market, W. J. KENNEDY (*Wallaces' Farmer, 28 (1903), No. 42, p. 1363*).—The fact that increased profits may attend fattening horses before marketing them is pointed out, a full grain ration with an abundance of forage being recommended for the purpose. The author states that many find clover a satisfactory coarse fodder, and corn, oats, and bran a good grain mixture. Cooked or steamed grain twice a week is recommended with some oil meal or flaxseed added. Glauber salts once a week is also useful, especially as the horses are given little or no exercise. Feeding horses 4 or 5 times a day is recommended. "Horses on full feed should gain from 3 to 5 lbs. per head per day."

Distribution and magnitude of the poultry and egg industry, G. F. THOMPSON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 149–213*).—A statistical article based largely on reports of the last census. A part of this article has been noted from another publication (E. S. R., 15, p. 291).

DAIRY FARMING—DAIRYING.

Studies in milk production, W. L. CARLYLE and F. W. WOLL (*Wisconsin Sta. Bul. 102, pp. 88, figs. 10, dgm. 1*).—During the period from the fall of 1898 to May, 1903, complete records were obtained of 38 cows, comprising 8 grade and 4 pure-bred Jerseys; 9 grade Guernseys, 1 grade and 4 pure-bred Holsteins; 8 grade and 3 pure-bred Shorthorns; and 1 grade Red Polled cow. The records obtained during the first 2 years of this period were discussed in previous reports of the station (E. S. R., 12, p. 83; 13, p. 81). The main part of the data previously presented, however, is included in this bulletin, which contains illustrations and descriptions of the cows, detailed data for the food consumption and the production of each, and a discussion of the results from different standpoints. "The primary object of the investigation has been to ascertain the capacity of the various cows for a large and economical production of milk and butter, and to study the system of feeding which was required to reach this end, in case of the individual cows in the herd. The general plan of feeding adopted has been the one which we consider the fundamental requirement in the successful management of a modern dairy, viz. to feed each cow as much rough feed as she will eat up clean and, in addition, such amounts of the available common concentrated feeds as she will give returns for in production of milk without any material change in live weight, the character and amounts of grain feed being therefore adjusted according to the peculiar characteristics of each cow." The average annual production of the 38 cows for 4 years was 7,340 lbs. of milk, and 307 lbs. of butter fat, equivalent to 370 lbs. of butter per head. The main results of the work as summarized by the authors are as follows:

"(1) The average annual yield of milk for the various cows in the herd ranged from 10,960.3 to 4,033 lbs., the production of fat ranged from 474.73 to 183.64 lbs., and the net profit returned by the cows from $79.31 to $19.59. The highest average production per year for any cow in the herd was that of the Jersey cow, Gold, which is credited with a production of 7,621.6 lbs. of milk and 474.73 lbs. of butter fat, and a net profit (value of butter and skim milk minus cost of food) of $79.31. This cow also produced the maximum amount of butter fat of any cow in the herd during 365 consecutive days, viz, 502.12 lbs., and returned the highest net profit of any cow during this time, with $84.55. Twenty-two of the cows produced more than 300 lbs.

of butter fat per year, on the average, and 25 out of the total number of 38 cows yielded a profit of $40 or more, over the cost of the food eaten.

"(2) The average production of 10 cows during their year of maximum production was 376.51 lbs. of butter fat, and their average net profit $58.21. During the year following their maximum production the same cows yielded, on the average, 281.47 lbs. of butter fat and a net profit of $40.82. Cows making exceptionally high records for a single year are almost certain to require a portion of the succeeding year for recovery, and will therefore give a much smaller production and lower net profit for that year.

"(3) Cows belonging to the different breeds represented in the herd yielded, on the average, as follows: Red Polled (1 cow), 461.81 lbs. of butter fat per year; Holstein (5 cows), 351.62 lbs.; Guernsey (9 cows), 319.35 lbs.; Jersey (12 cows), 301.13 lbs., and Shorthorn (11 cows), 281.73 lbs. The average net profit returned by cows of these breeds decreased in the same order from $56.70 (Red Polled) to $36.09 (Shorthorn).

"(4) The cows in the university herd may be considered as representing three different types of cows, viz, extreme dairy type, large dairy type, and dual-purpose type. If the results for cows of the same type be averaged, we find that the large dairy cows lead in average annual production of fat with 325.23 lbs., the extreme dairy cows being next with 310.21 lbs., and the dual-purpose cows last with 292.99 lbs. The rank of the cows, according to net profit returned, decreased in the same order from $45.31 for the large dairy cows, to $37.82 for the dual-purpose cows. In the opinion of the authors, cows of the large dairy type of the particular breed suiting the fancy of the farmer and weighing, say 1,000 lbs. or more, will, everything considered, be found the most satisfactory for the dairy farmer; cows of the dual-purpose type, on the other hand, are to be recommended for farmers who wish to utilize more or less of the rough feed produced on their farms for raising beef for the market, in conjunction with keeping a number of cows for milk production. It is not, in our opinion, the part of wisdom for our dairymen to select small refined cows with a square habit of body in an extreme degree as the most desirable type of dairy cow.

"(5) Cows of exceptional merit as producers were found within all the different types or breeds represented in our herd; the main reliance in selecting cows for the dairy herd should therefore be placed, not on any particular type or breed, but on individual excellence for dairy purposes. The best indications of true merit in dairy cows are a large digestive capacity, as evidenced by great depth and length of body, and a general refinement in conformation, as shown by fineness of bone in the legs, a clean-cut feminine head, a long and fine neck, light shoulders, prominent backbone, a fine, elastic quality of udder, and a well-developed milk vein system. Minor points are fine, silky hair, thin unctuous and movable skin, large bright eyes, and a general sprightly appearance.

"(6) The milk produced by the cows decreased somewhat in quality as the cows advanced in age. The average per cent for the year with cows in our herd came as follows: 1st year, 4.49 per cent; 2d year, 4.40 per cent; 3d year, 4.29 per cent, and 4th year, 4.17 per cent.

"(7) The flow of milk decreased, on the average, for all cows in our herd and for 4 years, with 8 per cent for each month during the progress of the lactation period, and the production of butter fat decreased with 7.3 per cent for each month.

"(8) Our dual-purpose cows maintained their flow of milk during the progress of the lactation period, as well or better than cows of the dairy types; the shrinkage in the production of milk between the third and the fortieth weeks of the lactation period for the same cows was 44 per cent for the extreme dairy cows, 59 per cent for the large dairy cows, and 49 per cent for the dual-purpose cows, and in the production of fat for the same types of cows, 43, 60, and 46 per cent, respectively.

"(9) The rations fed to the best producers in the herd during the winter period contained, on the average, 25.28 lbs. of dry matter, 2.05 lbs. of digestible protein, 15.22 lbs. of digestible carbohydrates and fat, and had a nutritive ratio of 1 : 7.4. The low-producing cows received, on the average, 21.14 lbs. of dry matter, 1.56 lbs. of digestible protein, and 12.20 lbs of carbohydrates and fat (nutritive ratio, 1 : 7.8), while intermediate figures were obtained for the cows with a medium production.

"(10) Only 10 cows out of a total of 33 required more than 2 lbs. of digestible protein in their average daily winter rations under our system of feeding for a large and economical production. The case of the cow Ella, weighing about 1,000 lbs., is especially worthy of note, from the fact that she received only 1.48 lbs. of digestible protein per day in her winter ration, and 12.19 lbs. of digestible carbohydrates and fat (nutritive ratio, 1:8.2), and produced 343 lbs. of butter fat yearly, as the average for 4 years. According to our present knowledge, we believe that only cows of large capacity will give economical returns for a supply of more than 2 lbs. of digestible protein per day, under the conditions present in the Northwest; and in the majority of cases with good average dairy cows, a supply somewhat less than this may be found most economical."

Soiling crops for dairy cows in Wisconsin, W. L. Carlyle, J. R. Danks, and G. E. Morton (*Wisconsin Sta. Bul. 103, pp. 14, figs. 3*).—A comparison is made of the average monthly yield of milk for 4 years of 15 farmers' herds and the average monthly yield for the past 2 years of the university herd, which was fed in part on soiling crops. In the case of the farmers' herds a rapid falling off from the highest yield in June to almost the lowest yield for the year in August is shown. The milk production of the university herd reached its maximum in April, remained almost constant until June, after which it decreased gradually and reached its lowest point in October.

The results of culture tests with various soiling crops at the university farm from 1900 to 1903 are presented in the following table:

Average data obtained in culture tests with soiling crops.

Variety of crops.	Number of crops averaged.	Seed per acre.	Dates of sowing.	Period of growth.	Average yield per acre.		Digestible nutrients in 100 lbs. gross yield.	
					Forage.	Dry matter.	Protein.	Carbohydrates.
		Lbs.		*Days.*	*Tons.*	*Tons.*	*Lbs.*	*Lbs.*
Fall rye	2	140	Sept. 10	248	8.41	2.0	2.1	14.2

Rye and vetches	1	140	....	....	10.6	....	....	....
Flint corn	....	35	May 16	86	15.52	3.1	1.0	12.6

The discussion of the subject considers variety, culture, yield, value, feeding stage, and cost of production of the crops, and a succession of the same that would supply succulent feed at all times. Nearly all of the crops grown are most palatable and satisfactory when fed at or a little before full bloom. Thick seeding in general gave a much greater yield and a better quality of forage than thin seeding. In 1901, sowing 25 lbs. sorghum seed per acre with alternate spouts of the drill open, and 25 and 50 lbs. with all the spouts open yielded, after a period of 82 days, 17,552, 21,200, and

24,216 lbs. per acre, respectively. In 1902 an acre of sorghum sown May 26 and harvested September 4 yielded 40.4 tons. Early Amber sorghum from northern-grown seed is considered the most valuable soiling crop for Wisconsin. Evergreen sweet corn gave almost as good results as sorghum.

It was found that cows fed on soiling crops alone without pasture consumed from 75 to 100 lbs. of forage daily.

Experiments with gluten meal for milch cows, H. Isaachsen and H. Solvsberg (*Norsk Landmandsblad, 22 (1903), No. 12, pp. 153–157*).—This is an account of a feeding experiment with 20 milch cows conducted at the agricultural college of Norway, in which the effect of feeding 2 kg. of gluten meal per head daily, in place of corn and fish meal, was studied. The gluten meal ration produced 0.2 kg. less milk per head daily than the regular ration fed to the herd, but the fat content of the milk was increased 0.12 per cent. The authors conclude that 100 kg. of gluten meal was worth 48.2 cts. more than 97 kg. of equal parts of corn and fish meal.—F. W. WOLL.

On the production of milk, B. Boggild (*Mälkeritid., 16 (1903), Nos. 31, pp. 535–544; 32, pp. 551–559, figs. 3; 33, pp. 569–575, figs. 2; 34, pp. 585–593, figs. 7; 35, pp. 601–608*).—Notes on lectures on dairying delivered at the Royal Danish Agricultural and Veterinary College at Copenhagen.

Recent experimental inquiry upon milk secretion, C. D. Woods (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 234–253*).—This is a popular summary of the more important data and conclusions relating to the subject of milk secretion, and is reprinted from the report of the Connecticut State Board of Agriculture for 1900.

Variations in the proteids of cow's milk during lactation, A. Trunz (*Ztschr. Physiol. Chem., 39 (1903), No. 5, pp. 390–395*).—This investigation was begun by G. Simon,[a] who reported some of the data along with a discussion of methods of analysis. The present article completes this data and discusses briefly the results.

The milk of 2 cows was analyzed at frequent intervals during the course of lactation. Omitting the colostrum period, the protein content of the milk of one of the cows was about 3 per cent for the first 7 months, after which it gradually increased to 5.54 per cent. The albumin and casein bore a ratio averaging 1:3 for the entire period. The protein content of the milk of the other cow was about 3.5 per cent for the first 9 months, after which it increased to 6.29 per cent. The ratio of albumin to casein was 1:5.2.

Observations on several breeds showed no constant difference in the ratio of albumin to protein. This variation is pointed out as of practical importance inasmuch as milk with a relative and absolute high content of albumin is best suited for infant feeding, while the reverse is true for cheese making.

Ulander's milk strainer, L. F. Rosengren (*Nord. Mejeri Tidn., 18 (1903), No. 17, pp. 223–225, figs. 2*).—In a series of trials this strainer removed all but 3.52 mg. of the impurities in 20 liters of milk, as compared with 22.18 mg. left by a common strainer.—F. W. WOLL.

Comparative skimming trials with milk from old and new milch cows, L. F. Rosengren (*Nord. Mejeri Tidn., 18 (1903), No. 13, pp. 173–174*).—The trials reported in this paper were conducted at the Alnarp Dairy Institute, and were made with milk from either old or new milch cows, or mixtures of the two kinds of milk. The skimming was done with an Alpha Dairy separator, having a stated capacity of 200 kg. per hour, the crank being turned 52 times per minute. The skimming temperatures ranged from 30 to 50° C.

The skim milk from the milk produced by old milkers had uniformly a higher fat content than that from milk of fresh milch cows, although the difference was not great when the amount of milk run through the separator was reduced by one-fourth

[a] Ztschr. Physiol. Chem., 33 (1901), No. 5–6, pp. 466–541.

to one-third. By reducing the flow of milk to this extent the fat content of the skim milk from old milkers was reduced to about one-tenth, when the separation took place at 50° or above.—F. W. WOLL.

A hitherto unexplained cause of poor skimming, C. BARTHEL (*Landtmannen, 14 (1903), No. 20, pp. 311–315; Nord. Mejeri Tidn., 18 (1903), No. 18, pp. 235, 236*).—It was found that milk which was emptied out of a pasteurization apparatus by means of a steam injector gave a skim milk much richer in fat when separated than milk which was run through the pasteurization apparatus without pressure; the fat contents of the 2 kinds of skim milk, as determined by the Gottlieb method, being on an average 0.31 and 0.13 per cent, respectively.

In investigating the subject the author found that violent agitation of the milk at separating temperatures caused a division of the fat globules, the minute globules remaining in the skim milk in the process of separation. Milk churned for 5 minutes at 50° C. and afterwards pasteurized at 75°, gave skim milk containing 0.69 per cent of fat, against 0.12 per cent found in skim milk from milk not previously churned. When the milk was churned at a very low temperature (5.5°) for 5 minutes, a similar fat content was obtained as in the case of the skim milk from milk not previously churned. Similar results were obtained in a number of different trials.—F. W. WOLL.

Influence of pasteurizers on clean skimming, T. BERG (*Landtmannen, 14 (1903), No. 29, pp. 460–462*).—The results of the work by Barthel, noted above, have been corroborated by the author. In experiments with a steam turbine pasteurizer no increase in the fat content of the skim milk was observed when the stirrer was turned at a speed of 200 to 250 revolutions per minute; but with 300 to 500 revolutions an increasing amount of fat remained in the skim milk, the average percentages in the 2 cases being about 0.118 and 0.225 per cent. In trials with milk pumps no appreciable difference was obtained in the fat content of the skim milk, whether the milk passed through the pump at 50 or at 17°.—F. W. WOLL.

Influence of clean skimming on the yield of butter, T. BERG (*Nord. Mejeri Tidn., 18 (1903), No. 22, pp. 301–303*).—Experiments conducted by the author showed that a decrease in the fat content of the skim milk from 0.223 to 0.147 per cent increased the amount of butter obtained from 50 kg. of milk from 1.691 to 1.734 kg., or 0.043 kg., while a further decrease in the fat content of the skim milk from 0.147 to 0.092 per cent increased the yield of butter only 0.022 kg. In the former case the difference in the fat content of the buttermilk was 0.086 per cent, in the latter 0.039 per cent.

There is apparently a limit below which it does not pay to skim the milk; the nearer this is reached the more expensive the reduction in the fat content of the skim milk becomes. It is shown by the results published in the paper that 0.01 kg. of butter may be obtained per 100 kg. of milk for every 0.01 per cent of fat more or less in the skim milk.—F. W. WOLL.

Influence of clean skimming on the yield of butter, L. F. ROSENGREN (*Nord. Mejeri Tidn., 18 (1903), No. 23, pp. 307–309*).—The same conclusion was reached as in the work by Berg, noted above, that somewhat more fat is, as a rule, left in the buttermilk by close skimming; but that this is much less than the amount going over into the butter. Of the 88.3 gm. which the cream from 100 kg. of milk in one series of trials exceeded that in another series, 12 gm. remained in the buttermilk while 76.3 gm. went into the butter. The closer skimming reduced the fat content of the skim milk 0.0984 and increased the yield of butter 99.6 gm. Calculated per 100 kg. new milk, a decrease of 0.01 per cent in the fat content of the skim milk is equivalent to an increase of 10 gm. in the yield of butter, even if the milk is skimmed so as to leave only 0.05 per cent of fat in the skim milk.—F. W. WOLL.

Researches on the fermentation of milk, H. TISSIER and P. GASCHING (*Ann. Inst. Pasteur, 17 (1903), No. 8, pp. 540–563*).—In connection with a study of the bac-

terial flora of the alimentary tract the authors have investigated the organisms ordinarily concerned in the putrefaction of meat and milk. In the work reported in this article samples of milk were obtained from different sources and permitted to undergo spontaneous fermentation, examinations being made at frequent intervals for a period of about 10 months. Notes are given on the 13 species of bacteria and fungi quite constantly found, and *Bacillus lactopropylbutyricus nonliquefaciens* n. sp., is described in detail.

The bacteria constantly found were divided into 2 groups designated "simple" and "mixed" depending upon their action upon the proteids alone or upon the proteids and carbohydrates simultaneously. The mixed ferments included staphylococci, a streptococcus identified with the Enterococcus of Thiercelin, *Bacillus acidiparalactici*, *B. lactopropylbutyricus*, and *B. coli communis;* and the simple ferments, *B. mesentericus*, *B. subtilis*, *B. putrificus*, *B. fæcalis alcaligenes*, *Proteus vulgaris*, and *P. zenckeri*. In sterilized milk the mixed group gave rise to 2 principal fermentations, lactic, due to the Enterococcus, *B. coli communis*, and *B. acidiparalactici*, and butyric, due to *B. lactopropylbutyricus*. The simple ferments caused a destruction of the casein until their growth was arrested by the presence of acid.

The process of spontaneous putrefaction was found to be uniform in all samples examined. The Enterococcus was the predominant species at first which, with *B. coli communis*, produced an acidity of about 0.2 per cent, stopping proteolytic action and causing coagulation of the milk. *B. acidiparalactici* continued the destruction of the lactose, producing dextrolactic acid. *B. lactopropylbutyricus* then developed, producing inactive lactic acid, but especially propionic acid and butyric acid. All bacterial growth was stopped at this stage by the presence of 0.4 to 0.6 per cent of acid, when the development of *Oidium lactis* and *Rhizopus nigricans* caused a reduction in the amount of acid and also a decomposition of the remaining lactose and of the casein. Finally the simple ferments completed the breaking down of the casein and its products.

In the absence of predisposing causes the ordinary bacteria concerned in the putrefaction of milk and meat are not believed to cause digestive disturbances. This view is supported by the results of several experiments made by the authors with animals and men, and here reported.

Studies on the antagonism between the bacteria of the lactic-acid group and the Bacillus subtilis group, F. W. Bouska (*Landw. Jahrb. Schweiz, 17 (1903), No. 6, pp. 349–357; Rev. Gén. Lait, 3 (1903), No. 1, pp. 1–11*).—Bacteria of the 2 groups were grown together under different conditions. Both types developed rapidly during the first few hours, the lactic-acid bacteria, however, developing more rapidly. Later the development of *Bacillus subtilis* stopped, their number gradually decreasing until in old cultures only a few were found.

The growth of the lactic-acid bacteria on the contrary continued until about 0.8 per cent of lactic acid was formed, when their multiplication stopped. In a medium containing sugar the antagonistic power of the lactic-acid bacteria is believed to be due, for the most part, to the acid produced. In general, however, the rapidity of their growth gives them an advantage over the other forms. In the absence of sugar they are also capable of supplanting *B. subtilis* and preventing the growth of this species. It is believed to be very probable that the lactic-acid bacteria produce other products than acid inhibiting the growth of *B. subtilis*.

Hygiene and dairying, K. Gappikh (*Arch. Vet. Nauk, St. Petersburg, 33 (1903), No. 9, pp. 960–980*).—The author discusses in a general way the relation between the dairy industry and public hygiene, and concludes that the attention of dairymen should be called to the urgent necessity of observing greater precautions in the conduct of this business from a sanitary standpoint.

Effect of pasteurization temperatures on tubercle bacilli in milk, J. Svensson (*Landtmannen 14 (1903), No. 18, pp. 273–276*).—In an apparatus in which the

milk was heated rapidly by being in a thin layer, a temperature of 80° C. for 2 minutes was sufficient to destroy the tubercle bacilli. This was not true in experiments in which the temperature was 75° C.—F. W. WOLL.

On the water content of butter, L. F. ROSENGREN (*Landtmannen, 14 (1903), No. 33, pp. 520–527*).—A discussion of the various factors influencing the water content of butter, with the results of a number of experiments bearing upon this point.—F. W. WOLL.

Report of Swedish butter exhibits, 1902, N. ENGSTRÖM (*Meddel. K. Landtbr. Styr. [Sweden], 1903, No. 84, pp. 53*).—The report presents the usual annual summary of the butter exhibits in Sweden. The number of creameries which took part in the exhibits was 346. The total number of tubs of butter exhibited and scored was 1,491. The main results of the examination of the butter as to scores, water content, loss of brine on storage, etc., are given in the report; as well as the average results of examinations of skim milk, buttermilk, and butter made during the year.—F. W. WOLL.

The rôle of the lactic-acid bacteria in the manufacture and in the early stages of ripening of Cheddar cheese, H. A. HARDING (*New York State Sta. Bul. 237, pp. 165–180*).—In the introduction to this bulletin brief explanations are given concerning 3 theories of cheese ripening namely, (1) that ripening is due mainly, if not entirely, to lactic-acid bacteria, (2) that ripening is brought about by liquefying bacteria, and (3) that the breaking down of the casein is largely due to the enzyms naturally present in milk. The results of some experimental work are included, and other investigations at the New York State Station are referred to in support of the views which are expressed concerning the rôle of lactic-acid bacteria in the ripening of cheese.

In factory milk lactic-acid bacteria are always present, and at the time of souring commonly make up more than 95 per cent of the total number. The rapid development of the lactic-acid bacteria checks the growth of other species, due to the conversior of milk sugar into lactic acid. The action of this acid has been found in practice and shown experimentally to hasten the curdling action of rennet. Investigations have shown that the lactic acid combines with paracasein to form 2 salts, one the unsaturated paracasein monolactate, insoluble in water but soluble in dilute salt solutions, and the other the saturated paracasein dilactate, insoluble in both water and dilute salt solutions.

That paracasein monolactate is formed in cheese curd by lactic-acid bacteria was shown experimentally as follows: Fresh milk was curdled by rennet in the presence of ether to prevent bacterial growth, and the curd was washed with water to remove the greater part of the sugar. After sterilization portions of the curd were inoculated with lactic-acid bacteria, with and without the addition of sugar. Without the addition of sugar only very small quantities of paracasein monolactate were formed, while with the addition of sugar considerable amounts were produced.

In normal cheese during the first week after it is made it is stated that from one-half to three-fourths of the nitrogen is found in the form of paracasein monolactate. In forming the amount of monolactate ordinarily present the bacteria use up an amount of sugar equal to from 2 to 4 per cent of the weight of the cheese. The presence of the monolactate is considered essential to the digestive action of the rennet enzym. As the part played by the enzyms of the milk itself is not confined to the first stages of ripening, this subject is to be treated in a separate bulletin. The action of rennet enzym is not believed to extend much beyond the formation of peptones, leaving the formation of the simpler nitrogenous compounds characteristic of a ripened cheese to be explained in some other manner.

Some changes in a ripening cheese, F. H. HALL ET AL. (*New York State Sta. Buls. 214, 215, 219, 231, 233, 236, 237, popular ed., pp. 14*).—This bulletin summarizes the more important points brought out in recent investigations at the station, and

reported in bulletins already noted (E. S. R., 14, pp. 67, 545, 805, 1115; and 15, pp. 400, 508).

Shrinkage of cold-cured cheese during ripening, S. M. BABCOCK, H. L. RUSSELL, and U. S. BAER (*Wisconsin Sta. Bul. 101, pp. 30, figs. 11*).—This is essentially the same as that portion of the report of cooperative work previously noted (E. S. R., 15, p. 398), which deals with the effect of cold curing upon the loss in weight of cheese.

The duration of the life of the tubercle bacillus in cheese, F. C. HARRISON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 217–233*).—This is a translation of articles previously noted (E. S. R., 12, p. 985; 14, p. 292), with an introductory statement by H. E. Alvord.

Examination of Babcock test apparatus (*Connecticut State Sta. Rpt. 1902, pt. 4, p. 423*).—During the year 600 pieces of glassware were tested, of which 1 per cent was found inaccurate.

Statistics of oleomargarine, oleo oil, and filled cheese, 1900–1902, R. A. PEARSON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 274–292*).

Preparation of condensed milk by means of a centrifuge (*Chem. Ztg., 27 (1903), No. 78, p. 964*).—The milk in a thin layer is brought into contact with a cold surface, revolved at the right speed to freeze the water out of the milk, and at the same time to throw out the condensed product. The process is covered by German patents.

VETERINARY SCIENCE AND PRACTICE.

Cytotoxic sera, WANDA SZCZAWINSKA (*Arch. Parasit., 6 (1902), No. 3, pp. 321–358*).—The author presents a general discussion of cytotoxic sera, including the method of preparation, their properties and actions, and the various practical uses to which these sera have been put. It was found that specific toxic sera could be obtained either from isolated cells or from groups of cells in the form of a tissue, and that these sera owe their specific action to the presence of 2 substances, an intermediary body and complement. As a rule these sera exercise a toxic effect when given in large doses, a slightly injurious effect in medium doses, and a stimulating action in small doses.

Precipitating sera, H. VALLÉE (*Rev. Gén. Méd. Vét., 1 (1903), No. 1, pp. 9–18*).—If a given species of animal is repeatedly inoculated with albuminous matter of another species, the serum of the inoculated animal soon acquires the power of precipitating in vitro-albuminous solutions coming from the second species. Notes are given on the practical application of these facts in the examination of meat and milk and in the study of animal diseases.

The absorption of tetanus antitoxin in wounds and the immunizing action of dry antitetanus serum employed in the treatment of wounds affected with tetanus, A. CALMETTE (*Compt. Rend. Acad. Sci. Paris, 136 (1903), No. 19, pp. 1150–1152*).—During experiments carried out by the author it was found that guinea pigs could easily be immunized against tetanus by causing absorption of small quantities of antitetanus serum in wounds involving the whole thickness of the skin. Good results, however, are usually not obtained from rubbing the wound with a brush dipped in the liquid serum. Positive results, on the other hand, were almost always obtained when a small quantity of finely-pulverized dry serum was sprinkled into the wound.

Experiments were also conducted for the purpose of testing the action of dry antitetanus serum when placed in the wound simultaneously with living tetanus bacilli. In a test during which 10 guinea pigs were inoculated and not treated and 10 others inoculated and treated as just indicated, with dry antitetanus serum, the latter 10 animals all failed to develop tetanus while the former 10 died after the usual course of the disease.

Intracerebral injections of various kinds of virus, K. BREIDERT (*Fortschr. Vet. Hyg., 1 (1903), No. 5, pp. 160–167*).—Extensive experiments were made, principally on rabbits, for the purpose of determining the comparative advantages of making intracerebral injections in the diagnosis of infectious diseases. The organisms employed in these experiments included anthrax bacilli, *Staphylococcus pyogenes aureus*, *Bacterium avicidum*, swine-plague bacteria, and the bacilli of swine erysipelas. The author concludes as a result of these experiments that for the majority of pathogenic organisms which he has studied the brain substance is a very favorable nutrient medium and intracerebral injection brings about a fatal development of the disease within a shorter time than can be accomplished by subcutaneous injection. In the use of the intracerebral method of injection very minute quantities are sufficient to produce results. Cultures may be diluted so as to employ one-millionth or even one-billionth cubic centimeter with positive results. The method is therefore recommended in cases where it is necessary to obtain a diagnosis within a very short time. All of the organisms upon which the author experimented were found to develop readily in the brain substance, with the exception of that of swine erysipelas.

The pyogenic bacteria of cattle, O. KÜNNEMANN (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 1–2, pp. 128–157, fig. 1*).—The author made elaborate comparative studies for the purpose of determining the relative frequency of various organisms in suppurative processes in cattle. The literature of the subject is critically reviewed. The green-colored multiple abscesses frequently found in the liver of cattle are due to the action of the necrosis bacillus, and this organism can always be found, but sometimes in small numbers. Suppurative pyelonephritis of cattle is characterized by the constant presence of *Bacillus renalis bovis* and *B. pyelonephritidis boum* in the purulent products and diseased kidney tissue.

In the pus of the abscesses in cattle, in 90 per cent of cases, the author found a bacillus not hitherto mentioned, which he names *B. pyogenes*. It is not identical with a similar bacillus described by Lucet. In 35 per cent of the cases observed by the author this bacillus was found alone in the pus, and in 55 per cent it was associated with other bacteria.

The bacterial flora of the intestinal canal of pigs, E. HEINICK (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 5, pp. 476–525*).—The author presents in a systematic manner lists of micro-organisms found in the small intestines, cecum, colon, and rectum of pigs. A number of known and unknown species of bacteria were found. Tables are given showing the results of inoculation of mice with various organisms found in different parts of the alimentary tract.

A number of tuberculous hogs were carefully examined for the purpose of determining whether tubercle bacilli were present in the intestines of such animals. No tubercle bacilli could be found, either as a result of microscopic examination or from inoculation of guinea pigs. As a result of the author's investigations, which were made upon 23 pigs, it was found that *Bacillus coli communis* and *B. lactis aërogenes* were the only organisms commonly found in the intestines of pigs. The bacillus of swine erysipelas was not found in a single instance.

Some experiments on the intravascular use of antiseptics, W. V. SHAW (*Jour. Hyg. [Cambridge], 3 (1903), No. 2, pp. 159–165*).—The author briefly reviews the literature relating to intravascular injection of antiseptics in the treatment of infectious diseases. The antiseptics employed were formalin, guaiacol, and chinosol, and the experimental animals were rabbits.

Preliminary experiments were made for the purpose of determining the maximum doses of these antiseptics which could be given without causing serious consequences in the experimental animals. The organism with which the rabbits were infected was *Bacillus pyocyaneus*. Additional experiments were also made with the tubercle bacillus. The experiments showed conclusively that the course of septicemia produced by *B. pyocyaneus* was not checked, but on the contrary was somewhat accelerated by the intravenous injection of the antiseptics already mentioned.

The formalin appeared to be absorbed rapidly by the tissues, otherwise it is believed that some antiseptic action would have been manifested, since the quantity of formalin injected stood in the ratio of 1 : 1,500 to the blood. Rabbits were inoculated with tuberculosis and subsequently treated with formalin in intravenous injections. The rabbits were given formalin in doses of 5 to 10 cc. The injection of formalin appeared to exercise no action whatever upon the development of the disease. The author concludes, therefore, that no advantages are derived from the intravenous use of antiseptics.

Transplantation of tumors, L. LOEB (*Arch. Path. Anat. u. Physiol.* [*Virchow*], *172* (*1903*), *No. 3, pp. 345–368*).—In the author's investigations rats were used as experimental animals, and numerous experiments were made in transplanting tumors from one animal to another. These tumors were placed in pure glycerin for a period of 17 to 24 hours and were then transplanted upon normal animals. In one set of experiments tumors developed upon 7 out of 13 inoculated rats.

The author concludes from his experiments that a micro-organism found just outside of the tumor cells, and small enough to pass through a Berkefeld filter, was probably not the cause of the sarcomata. A similar conclusion is drawn regarding another organism which closely resembles the tubercle bacillus. Detailed notes are given on the constancy and variability of the structure of sarcomata, the growth of these tumors, and the phagocyte action of sarcomatous cells.

During these experiments it was shown that sarcomatous cells may be removed from an infected animal and propagated for many generations on other animals by the process of transplantation.

The eye and its diseases, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 23* (*1903*), *No. 4, pp. 405–415, pls. 2*).—The author discusses the anatomy of the eye, with special reference to certain diseases to which it is subject in South Africa. These include conjunctivitis, recurrent ophthalmia, keratitis, trichiasis, bleeding fungus tumor, amaurosis, and a disease due to the presence of *Filaria lachrymalis* in the inner angle of the eye. In the author's experience keratitis has been most successfully treated by the use of nitrate of silver or by a mixture containing boracic acid, sulphate of zinc, fluid extract of belladonna, and water.

The poisoning of stock, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 23* (*1903*), *No. 4, pp. 390–399, pl. 1*).—In Cape Colony losses of cattle are sometimes suffered as the result of feeding on *Moræa polystachya.* The poisonous effects are rapidly manifested, and consist in acute gastro-enteritis accompanied with nervous prostration and collapse. Experiments were made in feeding *M. tenuis* and *M. polystachya* to steers; fatal results were produced with either plant when fed in quantities of 1½ lbs. Notes are also given on the poisonous effects of *Cestrum nocturnum*, oleander, *Nicotiana glauca*, stramonium, and other plants.

Report of State veterinarian, T. BUTLER (*Rpt. Comr. Agr. North Carolina, 1902, pp. 40–47*).—The author briefly relates the progress in animal industry in North Carolina during the past year, and gives an account of cattle quarantine, losses from Texas fever, methods of exterminating the cattle tick, staggers, tuberculosis, glanders, hog cholera, and blackleg.

Contagious diseases of animals in foreign countries, G. F. THOMPSON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 417–425*).—A statistical account showing the prevalence of the more important animal diseases, such as hog cholera, foot-and-mouth disease, glanders, anthrax, and sheep scab in Great Britain, Switzerland, France, German Empire, Belgium, Italy, Denmark, Netherlands, Norway, Sweden, and New Zealand.

Note on the correlation of several diseases occurring among animals in South Africa, A. EDINGTON (*Jour. Hyg.* [*Cambridge*], *3* (*1903*), *No. 2, pp. 138–154*).—In various parts of South Africa goats and sheep are extremely susceptible to the attack of a disease known as heartwater, and a high mortality in horses and mules is brought about by horse sickness.

The author studied the conditions under which this disease occurred for the purpose of determining if possible the means of infection. Some observations were made on a disease of cattle known by a number of different names, but usually by the term veld sickness. Experiments were made to determine the relation between horse sickness and veld sickness. Cattle were inoculated with the blood of horses affected with horse sickness, and as a result of these experiments it was found that cattle are somewhat susceptible to horse sickness. The disease produced in cattle by inoculation was indistinguishable from the form which occurs spontaneously among cattle. Detailed notes are given on the pathological anatomy of this disease.

The author succeeded also in transmitting heartwater from goats to cattle and horse sickness from horses to goats. The author concludes as a result of these studies that the contagion which causes horse sickness is responsible under certain conditions for the infection of various other species of domestic animals in South Africa.

Bovine tuberculosis and other animal diseases affecting the public health, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 332–353*).—This paper was read at the American Public Health Association at New Orleans, and deals with the inter-relationship between human and bovine tuberculosis. The literature of the subject is critically reviewed, and the conclusions are reached that great differences of virulence are observed in tubercle bacilli obtained from different human patients, and that some of these bacilli may be virulent for cattle and others not.

The author believes that tuberculosis may be transmitted from animals to man or from man to animals. An account is also presented of rabies, glanders, and anthrax, with special reference to the methods of control of these diseases and the prevention of the infection of man.

A discussion of the tuberculosis question, M. SCHOTTELIUS (*Beitr. Path. Anat. u. Allg. Path., 33 (1903), No. 1–2, pp. 32–50*).—A critical review of the recent controversy concerning the problem of the unity or duality of tuberculosis. The author outlines the positions of various authors on the subject. A number of experiments were made in testing the possibility of transmitting tuberculosis from man to animals. In these experiments 3 cows and 2 calves were used, the cows being 2 years old and the calves 4 to 5 weeks old at the beginning of the experiments. Each animal received from 50 to 60 gm. of human sputum in the milk or upon green fodder.

No alteration of temperature was observed in any of the animals during the course of the experiments. After a period of 4 months the 3 animals which had received virulent sputum were killed and examined. In all cases infection had taken place and was apparent in the various abdominal organs; the origin of the infection appeared to have been in all cases the lymphatic glands in the region of the pharynx. Positive results were obtained from the examination of diseased glands for the presence of tubercle bacilli.

The author believes that the sputum of tuberculous human patients is one of the important sources of tuberculosis in cattle.

The tuberculin test of cattle in Great Britain, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 550–553*).—Before March 1, 1900, cattle shipped to this country from Great Britain were inspected after arrival in the United States. Since disease frequently developed on shipboard in animals which did not appear to be affected at the time of shipment, great losses were suffered by cattle dealers.

In order to avoid inflicting these losses upon the individuals concerned, arrangements were made for the application of the tuberculin test in Great Britain to cattle about to be shipped to this country. The test is applied to all cattle over 6 months old, and has been made in Great Britain for the past 2 years. The inspector of the Canadian government and the inspector of the United States have made arrangements by which each government accepts certificates of the other's inspector.

During the years 1901 and 1902, 1,655 cattle were tested and 13.9 per cent were found to be tuberculous. The tests show the great prevalence of tuberculosis among pure-bred herds in Great Britain, but the cattle on the islands of Guernsey and Jersey were found to be practically free from tuberculosis.

Mammary tuberculosis in cattle, A. CONTE (*Rev. Gén. Méd. Vét., 1 (1903), No. 10, pp. 553–566*).—Statistics are presented showing the prevalence of mammary tuberculosis in cattle with special reference to the ratio which this form of the disease bears to general infection from tuberculosis. Notes are also given on the legal regulations which prevail in various countries regarding the sanitary control of milk from tuberculous cows.

Mammary tuberculosis in a mare, C. PARASCANDOLO and V. DE MEIS (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 1–2, pp. 198–208*).—The author presents a detailed description of a case of mammary tuberculosis in a mare, with notes on the symptoms, course, and history of the disease. From pus obtained from the diseased tissue tubercle bacilli were isolated of sufficient virulence to cause the death of guinea pigs within a period of 2 weeks. The tubercle bacilli were found in small numbers inside of the tubercles in immediate connection with the giant cells.

Foot-and-mouth disease, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 391–410, pls. 13, map 1*).—This is a general account of the recent outbreak of foot-and-mouth disease in New England, with notes on the measures undertaken by the Bureau of Animal Industry and the affected States for its repression. Quarantine regulations were made prohibiting the shipment of cattle and sheep, other ruminants, or swine from one affected State to another, or out of any affected State into other States or foreign countries.

The measures for eradication adopted by the Bureau of Animal Industry were stringent, and involved the destruction of infected animals and disposal of the carcasses by deep burying or burning. Notes are given on the occurrence of the disease in Europe and the measures adopted in various countries for its control. In order to avoid imposing too great hardships upon cattle owners indemnities were paid for the animals which were destroyed.

Serum therapy for foot-and-mouth disease, E. NOCARD (*Rev. Gén. Méd. Vét., 1 (1903), No. 7, pp. 369–375*).—A general account is given of the various methods which have been used in combating this disease. It has been found that a serum can be produced which will confer an immediate beneficial effect upon treated animals, but the immunity produced by this treatment is only of short duration.

New systems of treatment for parturient paresis, E. LECLAINCHE (*Rev. Gén. Méd. Vét., 1 (1903), No. 2, pp. 65–71*).—A general review of the results obtained from the application of Schmidt's method and also from the use of the hot water, air, and oxygen methods in the treatment of parturient paresis. All of these methods bring about the same condition in the udder, viz, a dilatation of the sinus and the large milk ducts. The possibility of an undue diminution of pressure within the udder is thus avoided. In addition to infusions of iodid of potash or water, or the injection of air or oxygen, the author recommends in cases of cardiac weakness intrarectal injections of salt water in the proportion of 9 : 1,000 parts.

The etiology of so-called parturient blackleg, S. CARL (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 3–4, pp. 225–285*).—The author undertook a comparative study of cases of true blackleg and so-called parturient blackleg. The latter disease was studied with special regard to the symptoms and the pathological anatomy. Parturient blackleg is observed quite frequently in the Grand Duchy of Baden in regions where true blackleg is also apt to be prevalent.

As a rule the disease appears within from 2 to 5 days after calving, or in some cases not until a lapse of 2 to 3 weeks. The course of the disease is from 1 to 3 days and fatal results are observed in almost all cases. A bloody exudation is found in the thoracic cavity and also in the paricardial cavity. The symptoms and patho-

logical findings differ quite decidedly from those observed in cases of true blackleg, and a bacteriological study combined with inoculation experiments with white rats demonstrated that in all cases the organism of malignant edema was present, and that consequently the disease called parturient blackleg is nothing more nor less than malignant edema. Infection apparently comes about as the result of the penetration of the spores of this organism through the walls of the reproductive organs at the time of parturition.

Passive immunity in various forms of hemorrhagic septicemia, K. Z. Kleptzov (*Arch. Vet. Nauk, St. Petersburg, 33 (1902), Nos. 6, pp. 553–581; 7, pp. 685–700; 8, pp. 781–815*).—The literature relating to swine plague, hemorrhagic septicemia in cattle, and other related diseases is critically discussed, in connection with a bibliography including 67 titles. The author conducted an elaborate series of experiments for the purpose of obtaining immunizing sera and determining their preventive action. These sera were obtained from experimental animals according to the various methods generally employed in such work.

As a result of these experiments it is concluded that it is possible, by means of inoculation with the organisms of hemorrhagic septicemia, to obtain sera which exercise a preventive action even in comparatively small doses. A blood serum obtained from animals strongly immunized against a single species of bacteria from this general group exhibits immunizing power, not only against different races of this organism, but also against other organisms of the same group.

Hemorrhagic septicemia, M. H. Reynolds (*Minnesota Sta. Bul. 82, pp. 249–280, pls. 10*).—Hemorrhagic septicemia has been known in Minnesota for more than 2 years and during this time has occurred in 80 outbreaks on 52 farms, and with a loss of 551 cattle. Thus far it has been impossible to trace any connection between one outbreak and another, or to determine the method of infection.

The specific cause of the disease is considered to be *Bacillus bovisepticus*. This organism is not distinguished in cultural and morphological characteristics from the bacillus of swine plague. The disease appears suddenly and in acute cases results fatally within a short period. Some chronic cases recover. It has been frequently mistaken for anthrax, blackleg, cerebro-spinal meningitis, cornstalk disease, and parturient paresis. The disease is known to occur in many parts of the United States. It appears not to depend upon seasonal or climatic conditions.

During the author's investigations 17 cases were studied in detail. As a rule the temperature remains normal or subnormal. The prominent symptoms were those of cerebro-spinal meningitis. The symptoms, however, are not characteristic. Postmortem findings give more definite information. Subcutaneous hemorrhages are almost always present and are readily recognized from their sharply defined borders.

Detailed notes are given on a number of outbreaks which occurred at the experiment station or in various parts of the State. A description is also given of 1 case in a sheep, and of a supposed case of milk fever which was probably hemorrhagic septicemia. A number of outbreaks of cattle disease have occurred in various parts of the State, believed to have been hemorrhagic septicemia. No treatment has been discovered for this disease.

Hemorrhagic septicemia, J. Black (*Amer. Vet. Rev., 27 (1903), No. 3, pp. 202–205*).—The cases first observed by the author had been diagnosed as cornstalk disease. They occurred near St. Clair, Mich. Notes are given on the symptoms as seen in 5 affected cattle. Later other cases were observed in this neighborhood and the author believes that the disease was hemorrhagic septicemia. In 1 case recovery took place rapidly after the administration of potassium iodid. Hemorrhagic patches were observed under the skin in these cases.

The cornstalk disease, A. T. Peters and S. Avery (*Nebraska Sta. Rpt. [illegible], pp. 63–94*).—A special appropriation made by the Nebraska legislature in 1901 enabled the station officers to undertake an elaborate study of the cornstalk disease.

Various theories regarding the cause of cornstalk disease have been suggested, including impaction, insufficient salt and water, poisonous plants, corn smut, chinch bugs, bacteria, saltpeter, and other substances which have been assumed to be present in the cornstalks. The theory of impaction was found to be untenable, as was also the theory that disease was caused by a lack of salt and water. An examination of 434 reports concerning losses from this disease shows that the animals died in the field under quite different conditions.

The literature relating to the effect of corn smut on cattle is critically discussed, and the conclusion is reached that this can not be considered as the cause of the trouble in cattle. The Burrill disease of corn is also shown to have no connection with cornstalk disease. The symptoms of cornstalk disease closely resemble those of sorghum poisoning, and it is believed that some poison may yet be found in the cornstalks to account for the disease.

In the seasons of 1902 and 1903 the losses from the disease were not severe, but losses occurred only where corn was somewhat checked in its growth. Detailed reports are given of the conditions surrounding several outbreaks of the disease. It occurs most frequently in yearlings and 2-year-olds. The disease appears suddenly without premonitory symptoms and runs a course of from 24 to 36 hours. Postmortem examinations showed that the organs are usually in a normal condition. No satisfactory treatment can be recommended.

While moldy corn may have no injurious effects upon cattle, it is believed to cause disease and death in horses. This fact has been proved by feeding experiments and by other evidence obtained from natural outbreaks of the disease among horses.

An examination was made of 23 samples of stomach contents from cattle which had died of cornstalk disease. The presence of coniin, which is the active principle of water hemlock, was demonstrated in 1 case, and appeared to be present in 2 others. It was not considered, however, as being the cause of the disease. Tests were also made for the presence of minerals which might be connected with the disease. Various mineral elements were found, especially potassium in the form of potassium chlorid. Potassium in some form or other was found in all of the 16 stomachs which were examined for mineral salts. The amount of potassium found in the stomach, however, was in no case sufficient to produce fatal results.

Samples of cornstalks from various fields were analyzed, and potassium nitrate was found in such material in all of the 14 samples examined. These analyses were made in 1901. In 1902, however, an analysis of cornstalks received from fields where stock had died failed to show more than mere traces. It was concluded, therefore, that the disease was not due to vegetable alkaloids, and that the cause can not be determined without further investigation.

Report on an enzootic among cattle caused by a bacillus of the entiritidis group, J. R. Mohler and J. S. Buckley (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 297–331, pls. 5*).—A peculiar, highly infectious disease appeared among cows on a dairy farm near Washington, D. C. A motile micro-organism was obtained from the infected animals and cultivated on various nutrient media. The sanitary conditions of the stable were satisfactory except for the fact that the manure was allowed to accumulate in the basement to a great extent.

The symptoms of the disease were excessive salivation, drooping of the ears, purulent lachrymal discharges, occasional convulsions, and a temperature of 102.7 to 104.1°. Affected animals died within from 48 hours to 5 days. Petechial hemorrhages were found under the endocardium in all cases, the lungs were uniformly in a normal condition, while hemorrhagic extravasations were found in the small intestines. In 1 case which ran a chronic course the liver showed punctiform hemorrhages and areas of necrosis.

The bacillus isolated from these cases is aerobic or facultatively anaerobic, does not form spores, and is pathogenic for rats, guinea pigs, rabbits, pigeons, dogs, sheep,

hogs, and calves, but not for chickens. Notes are given on the behavior of the organism on various culture media. This organism was destroyed by exposure for 12 minutes to a temperature of 58° C. or for 3 minutes to a temperature of 70° C. Desiccation and exposure to diffuse light for a period of 3 days also produced sterility. The organism was killed by treatment for 30 seconds in a 1:10,000 solution of bichlorid of mercury, and growth was prevented by subjection to a 1:500 solution of permanganate of potash for 1 minute. Limewater in a 0.08 per cent solution killed the organism within 3½ hours.

A comparison was made between the organism isolated in this disease and the hog-cholera bacillus, in which it was found that the organism of the cattle disease was more virulent than the bacillus of hog cholera. It appears that a mutual agglutinative reaction exists between these 2 organisms. The literature of the subject is critically discussed in connection with a brief bibliography.

Hemoglobinuria of cattle in Germany, H. KOSSEL ET AL. (*Arb. K. Gesundheitsamte, 20 (1903), No. 1, pp. 1–77, pls. 3*).—Hemoglobinuria has long been recognized in cattle in Germany, and has been referred to under a large number of common names. The author made an extensive investigation of this subject, including a study of the symptoms, pathological anatomy, treatment, and prevention of the disease. It was found that as a rule the period of incubation was about 14 days.

A large number of inoculation experiments were made with the blood of diseased animals for the purpose of determining more accurately the symptoms and pathological lesions of the disease. Detailed notes are given on post-mortem examinations made on these cases. The blood parasite is identical with that found in Texas fever, and the disease may therefore be considered as Texas fever. It may be transferred to susceptible cattle by inoculation with virulent blood.

During the authors' experiments it was found possible to maintain the blood parasites outside the body in serum containing hemoglobin for a long period. In some instances the blood parasites were virulent after being preserved in this manner for a period of 42 days. Inoculation experiments with muscle serum showed that the blood parasites in animals affected with Texas fever remained alive only a short time in the muscles. The tick which is responsible for carrying hemoglobinuria in Germany from one animal to another is *Ixodes reduvius*. Detailed notes are given on this tick in its various stages. Experiments showed that it was possible to transmit the disease by placing infected ticks upon susceptible cattle. A large number of inoculation experiments have been made in order to determine practical methods of immunization against the disease.

As a result of the authors' investigations it is recommended that the material used in vaccination be obtained in a sterile condition, defibrinated, and preserved in an ice chest, and that it should be taken from animals only after 50 days following recovery from the disease. It is also recommended that preventive inoculation be made from 4 to 6 weeks before the animals are turned upon pasture and by the subcutaneous method in doses of 5 cc. The animals should then be kept in good hygienic conditions during the progress of the inoculation disease.

Diagnosis, prognosis, and treatment of actinomycosis, H. VALLÉE (*Rev. Gén. Méd. Vét., 1 (1903), No. 6, pp. 313–325, figs. 8*).—The author presents a detailed description of the organisms of actinomycosis and actinobacillosis. The symptoms of the disease are described with special reference to those which may serve for differential diagnosis. Notes are also given on the beneficial effects of treatment with iodid of potash.

The disinfection of the skins of animals affected with anthrax, J. LIGNIÈRES and J. ZABALA (*Rev. Gén. Méd. Vét., 1 (1903), No. 5, pp. 249–255*).—The antiseptic substances with which experiments were made included crude carbolic acid, lysol, coal-tar products, such as cresol, creolin, acaroin, etc. Notes are given on the conditions under which sporulation of the anthrax bacillus takes place. Solutions of crude

carbolic acid and 5 per cent solutions of the coal-tar derivatives were sufficient to destroy the anthrax bacillus but not the spores, when the skins were dipped in these solutions for a period of 15 minutes.

According to the observations of the author, sporulation does not take place under ordinary conditions within a period of 2 hours after removal from the animal. It is recommended therefore that the skins of animals affected or suspected of being affected with anthrax be dipped in an antiseptic solution immediately after being removed. This treatment will destroy all of the bacilli present and will thus effectively prevent the formation of spores.

Anthrax regulations (*Jour. Agr. and Ind. South Australia, 7 (1903), No. 2, pp. 85–87*).—A copy is given of regulations concerning the importation of stock, feed, bones, bone dust, and other material, and the quarantine regulations regarding disinfection of suspected or infected material for the purpose of preventing the introduction and spread of anthrax.

Garotilha, E. MARCHOUX and A. SALIMBENI (*Ann. Inst. Pasteur, 17 (1903), No. 8, pp. 564–568*).—A fatal disease known under this name has long prevailed among cattle in Brazil. The disease is most destructive in herds of cattle which have been shipped from various parts of the country and are held temporarily in yards or pasture grounds near abattoirs. The disease was investigated by the authors, with the result that the anthrax bacillus was found in all cases. It was therefore concluded that this is nothing more nor less than anthrax. Under the conditions which prevail in Brazil it is believed that vultures play the most important rôle in distributing infection.

Some puzzling cases in cattle, possibly epizootic cerebro-spinal meningitis, J. N. GOULD (*Amer. Vet. Rev., 27 (1903), No. 6, pp. 512–514*).—A description of a number of cases of disease which occurred in parts of Minnesota and Iowa. Cattle were affected with a dullness, difficulty in locomotion, and later with cerebral disturbances. A large percentage of cases terminated fatally. The author believes that the trouble may have been due to the presence of ergot in the feed. Treatment with belladonna and magnesium sulphate gave good results.

Bursal enlargements upon the carpus of cattle and their treatment, A. ZEHL (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 5, pp. 445–475, pl. 1, fig. 1*).—The literature of this subject is critically discussed in connection with a bibliography of 81 titles. The author secured a large amount of material and investigated the growth and microscopical anatomy of the affected parts. Notes are given on the symptoms, differential diagnosis, prognosis, and treatment of this disease. The best results were obtained from the application of thorough drainage to the bursal enlargement and irrigation with antiseptic solutions.

The formation of callosities, chronic catarrh, and traumatic constriction of the teats of the bovine udder, E. KUHN (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 6, pp. 626–645, figs. 8*).—Detailed notes are given on the gross and microscopic anatomy, situation, and cause of callosities in the teats of cows. The symptoms and treatment of chronic catarrh of these structures is also discussed, together with notes on constriction of the lumen as the result of various injuries.

White scour in calves (*Norsk Vet. Tidsskr., 15 (1903), No. 3, pp. 92–97*).—Notes on the symptoms, etiology, and treatment of this disease. Antiseptic applications to the navel are recommended for controlling the disease. For this purpose a 2 per cent solution of lysol or a mixture of iodin and potassium iodid may be used.

Splenic leukemia in a calf five weeks old, D. A. DE JONG (*Arch. Path. Anat. u. Physiol. [Virchow], 173 (1903), No. 3, pp. 511–519*).—Notes are given on the symptoms and pathological anatomy of this disease, with special reference to a case recently observed by the author. In this case the carcass was rather fat, but showed a pronounced degree of icterus in the muscle and connective tissue. The spleen was much enlarged.

The number of red and white blood corpuscles was 400,000 and 30,000 per cubic millimeter, respectively. The number of leucocytes in proportion to that of the red blood corpuscles was therefore far greater than normal, and this proportion was chiefly due to the multiplication of large uninuclear leucocytes. The chromocytes were for the most part much smaller than under normal conditions. A critical examination in this case led the author to believe that it was of congenital origin.

The work against sheep scab in 1902, E. B. JONES (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 33–44*).—The effectiveness of dipping experiments in 1902 was greater than that obtained during the previous year. In 1902, 15,327,766 sheep were inspected, 1,840,308 dipped once, and 275,921 given a second dipping.

The number of scabby sheep received at stock yards where regular inspection stations are located was considerably decreased. The effectiveness of dipping was 92 per cent, as compared with 91.8 per cent of the previous year. Many more sheep were dipped by the owners the second time than during the previous year. Of the total number inspected, 1,366,007 were reported as infected. This number amounts to 8.9 per cent of the whole number. Detailed statistics are presented in a tabular form showing the number of sheep received at various stations and the results of dipping.

A comparison of the 3 dips used in 1902 showed the effectiveness of tobacco extract and sulphur to be 100 per cent, of lime and sulphur 89 per cent, and of nicotin and sulphur 21.3 per cent. At Kansas City nicotin and sulphur showed an effectiveness of 100 per cent, and lime and sulphur 99 per cent. The great effectiveness of these remedies from a single application is sufficiently indicated by these data. The author believes, however, that too much confidence should not be placed in a single dipping; a few scab mites may escape, and sheep are also subjected to subsequent infection.

Serum therapy for sheep pox, H. MARTEL (*Rev. Gén. Méd. Vét., 1 (1903), No. 11, pp. 609–617*).—The literature of this subject is briefly reviewed and statistics are given showing the success which has been had from vaccination for sheep pox. The results obtained are encouraging. It has been found that 10 cc. of the serum for adults and 5 cc. for young lambs is sufficient to produce quite substantial immunity, while encouraging curative properties were manifested when the serum was used in doses of 40 cc.

Epizootic abortion in mares, J. GUILLEREY (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 1–2, pp. 37–68, figs. 4*).—The literature of this subject is critically discussed in connection with a brief bibliography. Detailed notes are given on a number of cases observed by the author and statistics are presented showing the period of incubation, age of the mother, age of the fetus, and complications which followed the act of abortion.

As a rule the period of incubation ranged from 10 to 18 days, and in certain cases the disease assumed a very acute form. In some cases the spread of the disease was exceedingly rapid, and in others quite slow. The most usual complications following abortion were retention of the afterbirth, metritis, infectious arthritis, hemoglobinuria, laminitis, and inflammation of the udder. In the prophylaxis of this disease the author recommends isolation of affected animals, thorough disinfection of the premises where the disease has prevailed, and destruction of the fetus. In treating the disease the author considers antiseptic applications in the uterus and vagina to be indispensable, especially in cases complicated with metritis.

Voges's description of mal de caderas, C. W. STILES (*U. S. Dept. Agr., Bureau of Animal Industry Rpt. 1902, pp. 411–416*).—A brief summary of Voges's account of this disease, as presented in an article already noted (E. S. R., 14, p. 400).

Hyphomycosis destruens equi, J. DE HAAN and L. J. HOOGKAMER (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 3–4, pp. 395–410, figs. 5*).—A number of cases of this disease was observed by the authors. The chief symptoms are swelling and redness

of the gums in affected horses. The treatment tested by the authors consisted in removing the diseased tissue, painting the wounded part with iodin, and the administration of potassium iodid internally. This treatment appeared at first to give encouraging results, but later the pathological symptoms recurred in a more acute form.

The authors conclude as a result of the study that the disease appears most frequently on the skin and mucous membranes, especially on the lips and in the mouth and nasal cavities. In treating the disease it is recommended that affected tissue should be completely removed as soon as a diagnosis is possible. Microscopic examination of diseased tissue revealed the fact that mycelia of a fungus nature were present in the affected tissue. These pathogenic fungus mycelia were accompanied with spores, and are believed to be the cause of the disease. Brief notes are given by way of comparison of this disease with bursattee.

A larval form of Oxyuris equi, A. RAILLIET and A. HENRY (*Arch. Parasit., 7 (1903), No. 1, pp. 133–137, figs. 4*).—A detailed description is given of a larval form of this worm found in the esophagus and other portions of the alimentary tract of horses.

A parasitic Anguillula of the horse, JERKE (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 1–2, pp. 113–127, pl. 1*).—Notes are given on *Oxyuris curvula*, *O. mastigodes*, and *O. vivipara*. In the author's opinion the last-named species should be referred to the genus Anguillula. Detailed notes are given on the gross and microscopic anatomy of this species and on its economic importance. The author believes that the pathogenic action of this worm is very slight.

Ascaris megalocephala, SCHIMMELPFENNIG (*Arch. Wiss. u. Prakt. Thierh., 29 (1903), No. 3–4, pp. 332–376*).—A study was made of the chemistry of fluids found in the body of this worm, of the physiological action of these fluids, the chemical composition of the body of the worm, and the toxic effect of the presence of these worms. During these investigations it was found that there is a diastatic enzym in *A. megalocephala* with an action similar to the pancreatic juice, and also a number of proteolytic enzyms especially active in alkaline solutions.

Notes are given on the anatomy of the male and female worms of these species. As a result of infestation by these worms it is believed that sufficient nutriment may be removed from the alimentary tract to produce emaciation and anemia. Analyses of the worm showed the presence of 1.3 to 2.1 per cent glycogen.

A new filarial parasite of the blood, J. CAROUGEAU and G. MAROTEL (*Rev. Gén. Méd. Vét., 1 (1903), No. 8, pp. 447–454, figs. 6*).—A new species of Filaria, for which the name *F. blini* is proposed, was discovered in the aorta of the Asiatic buffalo (*Buffelus indicus*). The parasite is partly embedded in the tubercle produced by its presence on the inside of the aorta. The remainder of the parasite hangs free in the circulating blood. This parasite has thus far not been found in cattle.
